#### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers may always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

## EDITOR BIOGRAPHIES

---

### EDITORS IN CHIEF

**Laurence Melton**

Professor Laurence Melton was the Inaugural Professor of Food Chemistry at the University of Auckland, New Zealand, where he set up degrees in Food Science and Wine Science. He has been a Principal Investigator for the Riddet Centre of Research Excellence for Food Research. Formerly he was Professor of Food Science at the University of Otago, at Dunedin, N.Z. and earlier a scientist at Unilever's Colworth House in Bedfordshire, UK. His major research interest is how food macromolecules interact to give foods their structure (e.g. the complex mixture of polysaccharides that comprise plant cell walls (dietary fibres) and the interaction of proteins and polysaccharides such  $\beta$ -lactoglobulin and pectins). He has published over 300 scientific papers and reports. Currently he is an Editor for Food Chemistry and Emeritus Professor at the University of Auckland. He wrote "As a teenager I was training to be an electrician but I thought it would be more exciting to be a chemist because there could be fires and explosions. And there were some. However, what kept me motivated over 50 years was the excitement of discovering stuff by doing research."

**Fereidoon Shahidi**

Professor Fereidoon Shahidi is a University Research Professor at the Memorial University of Newfoundland, Canada. He is highly respected for his research in such areas as marine products and functional foods.

**Peter Varelis**

Dr Peter Varelis is an applications chemist with Shimadzu Scientific Australia where he manages a team of chemists. Prior to joining Shimadzu he was a principal scientist and team leader at Food Standards Australia New Zealand. He trained as an organic chemist and has more than 20 years of research experience in both government and industry. His research interest is the application of mass spectrometry to the analysis of organic compounds that have implications for human health and nutrition. Peter obtained his PhD from the University of Western Australia. He was research professor at the Illinois Institute of Technology and principal research scientist with the Commonwealth Scientific and Industrial Research Organization in Australia. From 2007 through to 2011, Peter was a theme leader with the National Centre for Food Protection and Defense.

## SECTION EDITORS

**Rotimi Aluko**

Dr Rotimi Aluko, a Certified Food Scientist is a Professor in the Department of Food and Human Nutritional Sciences at the University of Manitoba, Winnipeg, Canada. He also serves as the Assistant Director of the Richardson Centre for Functional Foods and Nutraceuticals, Winnipeg. He obtained a PhD (Food Science) degree in 1996 from the University of Guelph, Ontario, Canada. His work focuses on the structure-function properties of bioactive proteins and peptides with special focus on oilseeds and pulses. In addition to over 170 journal article publications, Dr Aluko holds two patents on the antihypertensive properties of plant seed protein-derived peptides. Dr Aluko has trained over 70 people in various areas of food chemistry and human nutrition. He is a 2017 “Highly Cited Researcher” in the Agricultural Sciences category, which is recognition given to researchers with peer-reviewed journal citations in the top 1% in the world. Dr Aluko is a Fellow of the Canadian Institute of Food Science & Technology, the Institute of Food Technologists and the American Oil Chemists’ Society. He currently serves as the Editor-in-Chief for the *Journal of Food Biochemistry* and an Associate Editor for *Current Topics in Nutraceutical Research*.

**John Birch**

John teaches Food Science undergraduate and postgraduate courses specializing in food chemistry, food processing and food quality management and safety.

His research area is on physicochemical composition and properties of food components, increasing value of secondary food processing products and their contribution to consumer health and wellness. Students research on value-added oilseed products, transesterification of oils with phenolic acids (to produce antioxidants), bioactive peptides, alternative protein sources to traditional farming practices, fish oil composition, stabilization and analysis of oxidative products, biofuel production from primary wastes, nanoencapsulation of bioactives, frying oil stability and lipid derived flavour in meat. Analytical instruments: HPLC, GC, GCO, PTRMS, GC-MS, NMR, DSC, TGA and access to specialized University instruments.

**Danae Larsen**

Danae Larsen, PhD, is a Food Science Consultant in Zurich, Switzerland. She has worked in various sectors of the food industry and academia, having held research positions in the School of Chemical Sciences and the Department of Chemical and Materials Engineering at the University of Auckland, New Zealand and at the Centre for Organismal Studies, Heidelberg University, Germany. Her research interests include, food structure, oral processing pathways, molecular biology, sensory perception, product development and the role of textural complexity in satiation and satiety.

**Michael Rogers**

Dr Rogers operates one of only three TIM-1 simulated GI tracks in Canada and the only one where physical properties of foods can be measured directly in the system. His research area focuses on lipid digestion kinetics of processed foods, with particular interest in developing infant formula that have similar digestion kinetics to human breast milk. Dr Rogers' joined the University of Guelph after holding faculty positions at Rutgers University and University of Saskatchewan, he was also the Director of the Gastrointestinal physiology laboratory at the New Jersey of Food, Nutrition & Health. He currently holds a Tier II Canadian Research Chair in Food Nanotechnology studying how to make high fat foods healthier. For his work on lipid structure and food nanostructures he has recently been awarded The Young Scientist Research Award from the American Oil Chemists' Society and has been appointed as a Fellow of the Early Career Scientists' Section of the International Academy of Food Science and Technology. He holds two patents, 70 peer reviewed manuscripts and more than 40 technical presentations.

**Richard Stadler**

Richard Stadler is Head of the Nestlé Institute for Food Safety and Analytical Sciences, based in Lausanne, Switzerland. His current research interests include food process contaminants, new analytical approaches in food safety, exploring digital solutions to identify and mitigate food chain risks. He is a member of several editorial boards of scientific journals, as well as Editor of the Journal "Food Additives & Contaminants". He is chairman of two expert groups in FoodDrinkEurope, and permanent guest in the "Senate Commission on Food Safety" of the German Research Foundation (DFG). He has published more than 120 scientific papers/book chapters in international journals, and is lecturer at the ETH Zürich.

**Dongxiao Sun-Waterhouse**

Dr Dongxiao Sun-Waterhouse is a Fellow of the New Zealand Institute of Food Science & Technology, a Chief Expert of the Guangdong Institute of Food Science and Technology, and Chair of the “Functional/Wellness Foods & Nutrition Working Group” of the International Commission of Agricultural and Biosystems Engineering. She also holds Chair Professorships at the South China University of Technology and Shandong Agricultural University. She has a wealth of experience working in the food industry, academia, research institutes and a food safety authority. Her R&D expertise encompasses food chemistry and biomaterials, food processing/manufacturing and food safety, industrial biotechnology, functional foods and nutrition. Her particular research strength is the smart use of food component interactions in food systems, as well as formulation and processing synergies, for wellness/functional food development and bioactive delivery. She has been actively involved in applied research and industrial consulting nationally and internationally to improve commercialisation outcomes. Dongxiao is a Section Editor of Elsevier's *Encyclopedia of Food Chemistry* and an Editorial Board member of the journal *Food Chemistry*. She has also acted as a conference convenor, conference chair, scientific advisory board member or organizing committee member for a number of international conferences.

# CONTENTS OF VOLUME 1

---

<i>Contributors to Volume 1</i>	<i>xv</i>
<i>Contents of all Volumes</i>	<i>xxi</i>
<i>Preface</i>	<i>xxxv</i>
 Acids and Bases in Food	 1
<i>Iris J Joye</i>	
 Anthocyanins	 10
<i>Celestino Santos-Buelga and Ana M González-Paramás</i>	
 Aromas	 22
<i>Keith R Cadwallader</i>	
 Artificial Sweeteners	 30
<i>Runu Chakraborty and Arpita Das</i>	
 Betalains	 35
<i>Delia B Rodriguez-Amaya</i>	
 Carotenoids	 40
<i>Luxsika Ngamwonglumlert and Sakamon Devahastin</i>	
 Clarifying Agents	 53
<i>Harsh P Sharma, Aditya Madan, and D C Joshi</i>	
 Dietary Fiber (Psyllium, $\beta$ -Glucan)	 61
<i>Lilian E Figueroa and Marina Dello Staffolo</i>	
 Diglycerides	 70
<i>Reed A Nicholson and Alejandro G Marangoni</i>	
 Egg Proteins	 74
<i>Snigdha Guha, Kaustav Majumder, and Yoshinori Mine</i>	
 Enzyme Applications in Food Processing: Traditional Uses to New Developments	 85
<i>Takuji Tanaka</i>	
 Encyclopedia of Food Chemistry: Fat replacers	 96
<i>Michael A Rogers</i>	
 Flavor Enhancers and Modifiers	 101
<i>Nicole J Gaudette</i>	

Flavors (Bittering Agents, Astringent Flavors, Pungency, Menthol) <i>Paul Hughes</i>	104
Galactomannans (Guar, Locust Bean, Fenugreek, Tara) <i>Vassilis Kontogiorgos</i>	109
Gases and Vapors Used in Food <i>Loong-Tak Lim</i>	114
Gelatin <i>Soottawat Benjakul and Phanat Kittiphattanabawon</i>	121
Hardstock Triglycerides <i>Dongming Tang</i>	128
Medium Chain Triacylglycerides <i>Fernanda Peyronel</i>	132
Milk Proteins <i>Ryan Hazlett, Christiane Schmidmeier, and James A O'Mahony</i>	138
Bioavailability of Minerals (Ca, Mg, Zn, K, Mn, Se) in Food Products <i>Mitra Nosratpour and Seid Mahdi Jafari</i>	148
Monoglycerides: Categories, Structures, Properties, Preparations, and Applications in the Food Industry <i>Song Miao and Duanquan Lin</i>	155
Muscle Proteins <i>Mike Boland, Lovedeep Kaur, Feng Ming Chian, and Thierry Astruc</i>	164
Natural Antioxidants in Foods <i>Bingcan Chen and Minwei Xu</i>	180
Natural Sweeteners <i>Jean-Baptiste Chéron, Axel Marchal, and Sébastien Fiorucci</i>	189
Nitrates <i>Gayatri Suresh, Weihui Xiong, Tarek Rouissi, and Satinder Kaur Brar</i>	196
Oligosaccharides: Structure, Function and Application <i>Yan Wang, Qingbin Guo, H Douglas Goff, and Gisèle LaPointe</i>	202
Pectin in Foods <i>Randall G Cameron</i>	208
Phospholipids <i>Meizhen Xie</i>	214
Phosphates <i>Gary A Dykes, Ranil Coorey, Joshua T Ravensdale, and Amreeta Sarjit</i>	218
Phytosterols <i>Arjen Bot</i>	225
Plant Protein Ingredients <i>Andrea K Stone, Yun Wang, Mehmet Tulbek, and Michael T Nickerson</i>	229
Salts and Salt Replacers <i>Elena S Inguglia, Joseph P Kerry, Catherine M Burgess, and Brijesh K Tiwari</i>	235

Seaweed Polysaccharides (Agar, Alginate Carrageenan) <i>Katerina Alba and Vassilis Kontogiorgos</i>	240
Sequestrants as a Food Ingredient <i>Benjamin M Bohrer</i>	251
Starch <i>Iris J Joye</i>	256
Sugar Alcohols <i>Małgorzata Grembecka</i>	265
Surfactants <i>Natalie Ng and Michael A Rogers</i>	276
Artificial Antioxidants <i>João C M Barreira and Isabel C F R Ferreira</i>	283
Synthetic Food Colors <i>Maria G Corradini</i>	291
Encyclopedia of Food Chemistry: Water <i>Peter Chen and Michael A Rogers</i>	297
Water-Soluble Vitamins <i>Hannah Pinchen and Paul Finglas</i>	305
Waxes <i>Yaqi Lan</i>	312
Introduction to the Volume: Food Adulteration & Contamination <i>Richard H Stadler</i>	317
New Breeding Techniques: Detection and Identification of the Techniques and Derived Products <i>Yves Bertheau</i>	320
Biogenic Amines in Food: A Review of Factors Affecting Their Formation <i>G Tabanelli, C Montanari, and F Gardini</i>	337
Plant Alkaloids <i>Birgit Dusemund, Bernd Schaefer, and Alfonso Lampen</i>	344
Pyrrolizidine Alkaloids: Analytical Challenges <i>Oliver Keuth, Hans-Ulrich Humpf, and Peter Fürst</i>	348
Big Data Applications in Food Safety and Quality <i>Stephanie Pollard, Hossein Namazi, and Ramin Khaksar</i>	356
Omics Methods For the Detection of Foodborne Pathogens <i>David I Ellis, Howbeer Muhamadali, Malama Chisanga, and Royston Goodacre</i>	364
New Analytical Frontiers in Mycotoxin Research <i>Laura Righetti and Chiara Dall'Asta</i>	371
Next-Generation Sequencing <i>Martin Wiedmann and Laura M Carroll</i>	376
Dioxins and Dioxin-like PCBs in Feed and Food <i>Peter Fürst</i>	384

Modified Mycotoxins: A New Challenge?	393
<i>H -U Humpf, Michael Rychlik, and Benedikt Cramer</i>	
Mycotoxins in Food and Feed: An Overview	401
<i>Joerg Stroka and Carlos Gonçalves</i>	
Occurrence & Risk of OTA in Food and Feed	420
<i>Vita Di Stefano</i>	
Occurrence & Risk of Aflatoxins in Food and Feed	424
<i>Martien C Spanjer</i>	
Pesticide MRLs and Impact on Global Trade	428
<i>Marina Rusch, Gordon Cameron, and Karsten Hohgardt</i>	
Pesticides: An Update on Mass Spectrometry Approaches	433
<i>Jon W Wong, Jian Wang, Kai Zhang, Douglas G Hayward, Paul Yang, and James B Wittenberg</i>	
Pesticides: Evaluation Process in the EU	449
<i>Claudia Heppner</i>	
Polycyclic Aromatic Hydrocarbons in Food and Feed	455
<i>Thomas Wenzl and Zuzana Zelinkova</i>	
Veterinary Drugs: Progress in Multiresidue Technique	470
<i>Patricia Regal, Alexandre Lamas, Carlos M. Franco, and Alberto Cepeda</i>	
Endocrine Disrupters: A Review	481
<i>Alberto Mantovani</i>	
Acrylamide: US FDA Guidance to Industry	487
<i>Lauren Posnick Robin and Eileen Abt</i>	
Acrylamide: An Overview of the Chemistry and Occurrence in Foods	492
<i>Aytil Hamzahoglu, Burçe Ataç Mogol, and Vural Gökmen</i>	
Dietary Acrylamide: An Update on the Chronic Risks	500
<i>Janneke Hogervorst</i>	
Advanced Glycation End Products (AGEs): Occurrence and Risk Assessment	525
<i>Michael Hellwig and Thomas Henle</i>	
Furan and Alkylfurans: Occurrence and Risk Assessment	532
<i>Gabriele Scholz and Richard H Stadler</i>	
Processing Contaminants: Furfuryl Alcohol	543
<i>Alex O Okaru and Dirk W Lachenmeier</i>	
Heterocyclic Aromatic Amines: An Update on the Science	550
<i>Medjda Bellamri and Robert J Turesky</i>	
Managing Acrylamide at the Agricultural Stage: Variety Selection, Crop Management, and the Prospects for Solving the Acrylamide Problem Through Plant Breeding and Biotechnology	559
<i>Nigel G Halford</i>	
MCPD Esters and Glycidyl Esters: A Review of Analytical Methods	569
<i>Shaun MacMahon</i>	

MCPDE and GE: An Update on Mitigation Measures	578
<i>Zsolt Kemeny, Krish Bhaggan, Falk Brüse, Adina Creanga, Rob Diks, Luisa Gambelli, Yves Le Bail-Collet, and Daniel Ribera</i>	
Mineral Oils in Food: An Update	588
<i>Koni Grob and Maurus Biedermann</i>	
N-Nitroso Compounds in Foods	593
<i>Michael Habermeyer and Gerhard Eisenbrand</i>	
Migration From Food Contact Materials	603
<i>Gregor McCombie and Maurus Biedermann</i>	
Process Contaminants: A Review	609
<i>Michael Murkovic, Franco Pedreschi, and Zuzana Ciesarová</i>	
Food Allergens: A Regulatory/Labelling Overview Including the VITAL Approach	615
<i>Carmen Diaz-Amigo and Bert Popping</i>	
Food Allergens: An Update on Analytical Methods	622
<i>Michael J Walker</i>	
Food Allergens: Seafood, Tree Nuts, Peanuts	640
<i>Marie-Claude Robert</i>	
Food Counterfeiting: A Growing Concern	648
<i>John Spink</i>	
Food Defense	652
<i>Andrew G Huff</i>	
Food Fraud and Adulteration: Where We Stand Today	657
<i>John Spink</i>	
Food Fraud and Vulnerability Assessments	663
<i>Saskia M van Ruth</i>	
Food Fraud Vulnerabilities in the Supply Chain: An Industry Perspective	670
<i>Christophe Cavin, Geoffrey Cottenet, Christophe Fuerer, Lien-Anh Tran, and Pascal Zbinden</i>	
Food Chemistry and Analysis for the Purpose of Kosher and Halal	679
<i>Joe M Regenstein</i>	
Modern Concepts in Chemical Risk Assessment	685
<i>Dieter Schrenk</i>	
Emerging Food Safety Risks	690
<i>Farai Maphosa</i>	
Managing Chemical Hazards in HACCP	699
<i>Jantra Daolert</i>	
The Legislative Landscape in the EU: Challenges Faced by the Food Industry	709
<i>Andrew Curtis</i>	
Biocides: A Critical Review of Current and Proposed EU Legislation	715
<i>Heiko Faubel</i>

# CONTENTS OF ALL VOLUMES

---

## VOLUME 1

Acids and Bases in Food <i>Iris J Joye</i>	1
Anthocyanins <i>Celestino Santos-Buelga and Ana M González-Paramás</i>	10
Aromas <i>Keith R Cadwallader</i>	22
Artificial Sweeteners <i>Runu Chakraborty and Arpita Das</i>	30
Betalains <i>Delia B Rodriguez-Amaya</i>	35
Carotenoids <i>Luxsika Ngamwonglumlert and Sakamon Devahastin</i>	40
Clarifying Agents <i>Harsh P Sharma, Aditya Madan, and D C Joshi</i>	53
Dietary Fiber (Psyllium, $\beta$ -Glucan) <i>Lilian E Figueroa and Marina Dello Staffolo</i>	61
Diglycerides <i>Reed A Nicholson and Alejandro G Marangoni</i>	70
Egg Proteins <i>Snigdha Guha, Kaustav Majumder, and Yoshinori Mine</i>	74
Enzyme Applications in Food Processing: Traditional Uses to New Developments <i>Takuji Tanaka</i>	85
Encyclopedia of Food Chemistry: Fat replacers <i>Michael A Rogers</i>	96
Flavor Enhancers and Modifiers <i>Nicole J Gaudette</i>	101

Flavors (Bittering Agents, Astringent Flavors, Pungency, Menthol) <i>Paul Hughes</i>	104
Galactomannans (Guar, Locust Bean, Fenugreek, Tara) <i>Vassilis Kontogiorgos</i>	109
Gases and Vapors Used in Food <i>Loong-Tak Lim</i>	114
Gelatin <i>Soottawat Benjakul and Phanat Kittiphattanabawon</i>	121
Hardstock Triglycerides <i>Dongming Tang</i>	128
Medium Chain Triacylglycerides <i>Fernanda Peyronel</i>	132
Milk Proteins <i>Ryan Hazlett, Christiane Schmidmeier, and James A O'Mahony</i>	138
Bioavailability of Minerals (Ca, Mg, Zn, K, Mn, Se) in Food Products <i>Mitra Nosratpour and Seid Mahdi Jafari</i>	148
Monoglycerides: Categories, Structures, Properties, Preparations, and Applications in the Food Industry <i>Song Miao and Duanquan Lin</i>	155
Muscle Proteins <i>Mike Boland, Lovedeep Kaur, Feng Ming Chian, and Thierry Astruc</i>	164
Natural Antioxidants in Foods <i>Bingcan Chen and Minwei Xu</i>	180
Natural Sweeteners <i>Jean-Baptiste Chéron, Axel Marchal, and Sébastien Fiorucci</i>	189
Nitrates <i>Gayatri Suresh, Weihui Xiong, Tarek Rouissi, and Satinder Kaur Brar</i>	196
Oligosaccharides: Structure, Function and Application <i>Yan Wang, Qingbin Guo, H Douglas Goff, and Gisèle LaPointe</i>	202
Pectin in Foods <i>Randall G Cameron</i>	208
Phospholipids <i>Meizhen Xie</i>	214
Phosphates <i>Gary A Dykes, Ranil Coorey, Joshua T Ravensdale, and Amreeta Sarjit</i>	218
Phytosterols <i>Arjen Bot</i>	225
Plant Protein Ingredients <i>Andrea K Stone, Yun Wang, Mehmet Tulbek, and Michael T Nickerson</i>	229
Salts and Salt Replacers <i>Elena S Inguglia, Joseph P Kerry, Catherine M Burgess, and Brijesh K Tiwari</i>	235

Seaweed Polysaccharides (Agar, Alginate Carrageenan) <i>Katerina Alba and Vassilis Kontogiorgos</i>	240
Sequestrants as a Food Ingredient <i>Benjamin M Bohrer</i>	251
Starch <i>Iris J Joye</i>	256
Sugar Alcohols <i>Małgorzata Grembecka</i>	265
Surfactants <i>Natalie Ng and Michael A Rogers</i>	276
Artificial Antioxidants <i>João C M Barreira and Isabel C F R Ferreira</i>	283
Synthetic Food Colors <i>Maria G Corradini</i>	291
Encyclopedia of Food Chemistry: Water <i>Peter Chen and Michael A Rogers</i>	297
Water-Soluble Vitamins <i>Hannah Pinchen and Paul Finglas</i>	305
Waxes <i>Yaqi Lan</i>	312
Introduction to the Volume: Food Adulteration & Contamination <i>Richard H Stadler</i>	317
New Breeding Techniques: Detection and Identification of the Techniques and Derived Products <i>Yves Bertheau</i>	320
Biogenic Amines in Food: A Review of Factors Affecting Their Formation <i>G Tabanelli, C Montanari, and F Gardini</i>	337
Plant Alkaloids <i>Birgit Dusemund, Bernd Schaefer, and Alfonso Lampen</i>	344
Pyrrolizidine Alkaloids: Analytical Challenges <i>Oliver Keuth, Hans-Ulrich Humpf, and Peter Fürst</i>	348
Big Data Applications in Food Safety and Quality <i>Stephanie Pollard, Hossein Namazi, and Ramin Khaksar</i>	356
Omics Methods For the Detection of Foodborne Pathogens <i>David I Ellis, Howbeer Muhamadali, Malama Chisanga, and Royston Goodacre</i>	364
New Analytical Frontiers in Mycotoxin Research <i>Laura Righetti and Chiara Dall'Asta</i>	371
Next-Generation Sequencing <i>Martin Wiedmann and Laura M Carroll</i>	376
Dioxins and Dioxin-like PCBs in Feed and Food <i>Peter Fürst</i>	384

Modified Mycotoxins: A New Challenge? <i>H -U Humpf, Michael Rychlik, and Benedikt Cramer</i>	393
Mycotoxins in Food and Feed: An Overview <i>Joerg Stroka and Carlos Gonçalves</i>	401
Occurrence & Risk of OTA in Food and Feed <i>Vita Di Stefano</i>	420
Occurrence & Risk of Aflatoxins in Food and Feed <i>Martien C Spanjer</i>	424
Pesticide MRLs and Impact on Global Trade <i>Marina Rusch, Gordon Cameron, and Karsten Hohgardt</i>	428
Pesticides: An Update on Mass Spectrometry Approaches <i>Jon W Wong, Jian Wang, Kai Zhang, Douglas G Hayward, Paul Yang, and James B Wittenberg</i>	433
Pesticides: Evaluation Process in the EU <i>Claudia Heppner</i>	449
Polycyclic Aromatic Hydrocarbons in Food and Feed <i>Thomas Wenzl and Zuzana Zelinkova</i>	455
Veterinary Drugs: Progress in Multiresidue Technique <i>Patricia Regal, Alexandre Lamas, Carlos M. Franco, and Alberto Cepeda</i>	470
Endocrine Disrupters: A Review <i>Alberto Mantovani</i>	481
Acrylamide: US FDA Guidance to Industry <i>Lauren Posnick Robin and Eileen Abt</i>	487
Acrylamide: An Overview of the Chemistry and Occurrence in Foods <i>Aytül Hamzahoğlu, Burçe Ataç Mogol, and Vural Gökmen</i>	492
Dietary Acrylamide: An Update on the Chronic Risks <i>Janneke Hogervorst</i>	500
Advanced Glycation End Products (AGEs): Occurrence and Risk Assessment <i>Michael Hellwig and Thomas Henle</i>	525
Furan and Alkylfurans: Occurrence and Risk Assessment <i>Gabriele Scholz and Richard H Stadler</i>	532
Processing Contaminants: Furfuryl Alcohol <i>Alex O Okaru and Dirk W Lachenmeier</i>	543
Heterocyclic Aromatic Amines: An Update on the Science <i>Medjda Bellamri and Robert J Turesky</i>	550
Managing Acrylamide at the Agricultural Stage: Variety Selection, Crop Management, and the Prospects for Solving the Acrylamide Problem Through Plant Breeding and Biotechnology <i>Nigel G Halford</i>	559
MCPD Esters and Glycidyl Esters: A Review of Analytical Methods <i>Shaun MacMahon</i>	569
MCPDE and GE: An Update on Mitigation Measures <i>Zsolt Kemeny, Krish Bhaggan, Falk Brüse, Adina Creanga, Rob Diks, Luisa Gambelli, Yves Le Bail-Collet, and Daniel Ribera</i>	578

Mineral Oils in Food: An Update <i>Koni Grob and Maurus Biedermann</i>	588
N-Nitroso Compounds in Foods <i>Michael Habermeyer and Gerhard Eisenbrand</i>	593
Migration From Food Contact Materials <i>Gregor McCombie and Maurus Biedermann</i>	603
Process Contaminants: A Review <i>Michael Murkovic, Franco Pedreschi, and Zuzana Ciesarová</i>	609
Food Allergens: A Regulatory/Labelling Overview Including the VITAL Approach <i>Carmen Diaz-Amigo and Bert Popping</i>	615
Food Allergens: An Update on Analytical Methods <i>Michael J Walker</i>	622
Food Allergens: Seafood, Tree Nuts, Peanuts <i>Marie-Claude Robert</i>	640
Food Counterfeiting: A Growing Concern <i>John Spink</i>	648
Food Defense <i>Andrew G Huff</i>	652
Food Fraud and Adulteration: Where We Stand Today <i>John Spink</i>	657
Food Fraud and Vulnerability Assessments <i>Saskia M van Ruth</i>	663
Food Fraud Vulnerabilities in the Supply Chain: An Industry Perspective <i>Christophe Cavin, Geoffrey Cottenet, Christophe Fuerer, Lien-Anh Tran, and Pascal Zbinden</i>	670
Food Chemistry and Analysis for the Purpose of Kosher and Halal <i>Joe M Regenstein</i>	679
Modern Concepts in Chemical Risk Assessment <i>Dieter Schrenk</i>	685
Emerging Food Safety Risks <i>Farai Maphosa</i>	690
Managing Chemical Hazards in HACCP <i>Jantra Daolert</i>	699
The Legislative Landscape in the EU: Challenges Faced by the Food Industry <i>Andrew Curtis</i>	709
Biocides: A Critical Review of Current and Proposed EU Legislation <i>Heiko Faubel</i>	715

## VOLUME 2

Antioxidant and Flavor in Spices Used in the Preparation of Chinese Dishes <i>Yan Ping Chen and Hau Yin Chung</i>	1
--	---

Anthocyanins in Food	10
<i>Xiaonan Sui, Yan Zhang, Lianzhou Jiang, and Weibiao Zhou</i>	
Caramelization in Foods: A Food Quality and Safety Perspective	18
<i>Tolgahan Kocadağlı and Vural Gökmen</i>	
Carbohydrate Active Enzymes Applied in the Production of Functional Oligosaccharides	30
<i>Fabiano Jares Contesini, Evandro A de Lima, Fernanda Mandelli, Gustavo P Borin, Rafael F Alves, and César Rafael F Terrasan</i>	
Chemically Reducing Properties of Maillard Reaction Intermediates	35
<i>George P Rizzi</i>	
Protein Oxidation	41
<i>Leticia Mora, Marta Gallego, M-Concepción Aristoy, and Fidel Toldrá</i>	
Coffee Flavor	48
<i>Adane Tilahun Getachew and Byung-Soo Chun</i>	
Configuring Phenolic Antioxidants for Frying Applications	54
<i>Felix Aladedunye and Eliza Gruczynska</i>	
Milk Protein Interactions	63
<i>Anant Chandrakant Dave and Harjinder Singh</i>	
Effect of Heat on Food Properties	70
<i>Rana Muhammad Aadil, Ume Roobab, Abid Aslam Maan, and Ghulam Muhammad Madni</i>	
Effect of Emerging Processing Technologies on Maillard Reactions	76
<i>Mohamed Koubaa, Shahin Roohinejad, Tanyaradzwa E Mungure, Bekhit Alaa El-Din, Ralf Greiner, and Kumar Mallikarjunan</i>	
Effect of Storage on Fruit Bioactives	83
<i>Rana Muhammad Aadil, Ume Roobab, Muhammad Kashif Iqbal Khan, and Ubaid Ur Rahman</i>	
Enzymatic Production of Antioxidants and Their Applications	92
<i>Taiwo O Akanbi and Colin J Barrow</i>	
Factors Influencing Red Wine Color From the Grape to the Glass	97
<i>Jacqui M McRae, Bo Teng, and Keren Bindon</i>	
Fermentation of Grains	107
<i>Isam A Mohamed Ahmed, Fahad Y Al-Juhaimi, and Alaa El-Din Ahmed Bekhit</i>	
Fruit Pigment Changes During Ripening	117
<i>Wee Sim Choo</i>	
$\alpha$ -Galactosidase and Its Applications in Food Processing	124
<i>Lu-Kwang Ju, Abdullah A Loman, and S M Mahfuzul Islam</i>	
Influence of Food Processing Operations on Vitamins	129
<i>Merve Tomas and Seid Mahdi Jafari</i>	
Microbial Xylanases in Bread Making	140
<i>Seema Dahiya and Bijender Singh</i>	
Lipases for Biofuel Production	150
<i>Oseweuba Valentine Okoro, Zhifa Sun, and John Birch</i>	
Lipase/Esterase: Properties and Industrial Applications	158
<i>Oi-Ming Lai, Yee-Ying Lee, Eng-Tong Phuah, and Casimir C Akoh</i>	

Holistic Control of Fats and Oils by NMR Spectroscopy <i>Elina Zailer</i>	168
Lipid-Derived Flavours and Off-Flavours in Food <i>Fereidoon Shahidi and Abreham Abad</i>	182
Lipophilized Antioxidants <i>Maria Cruz Figueroa-Espinoza, Claire Bourlieu, Erwann Durand, Jérôme Lecomte, and Pierre Villeneuve</i>	193
Meat Color: Factors Affecting Color Stability <i>Alaa El-Din Ahmed Bekhit, James D Morton, Zuhaib Fayaz Bhat, and Lingming Kong</i>	202
Meat Colour: Chemistry and Measurement Systems <i>Alaa El-Din Ahmed Bekhit, James David Morton, Zuhaib Fayaz Bhat, and Xu Zequan</i>	211
Homeostasis of Plasmalogens in Mammals <i>Masanori Honsho and Yukio Fujiki</i>	218
Biochemical Reactions During Fresh Meat Storage <i>José A Beltrán, Pedro Roncalés, and Marc Bellés</i>	224
Nonenzymatic Browning Reactions: Overview <i>Yuliya Hrynets, Abhishek Bhattacharjee, and Mirko Betti</i>	233
Pulsed Electric Fields Processing of Plant-Based Foods: An Overview <i>Sze Ying Leong and Indrawati Oey</i>	245
Oleogels in Food <i>Kristin D Mattice and Alejandro G Marangoni</i>	255
Oxidative Rancidity <i>Charlotte Jacobsen</i>	261
Pectic Enzymes <i>Jin-lan Xia and Pei-jun Li</i>	270
Phospholipases <i>Angeliki Bourtsala and Dia Galanopoulou</i>	277
Polyphenoloxidase in Fruit and Vegetables: Inactivation by Thermal and Non-thermal Processes <i>Filipa Vinagre Marques Silva and Alifdalino Sulaiman</i>	287
Processing Effects on Meat Flavor <i>Siripong Kanokruangrong, John Birch, and Alaa El-Din Ahmed Bekhit</i>	302
Proteases and Meat Tenderization <i>James David Morton, Zuhaib Fayaz Bhat, and Alaa El-Din Ahmed Bekhit</i>	309
Proteases as Digestive Aids <i>Utpal Bose, Crispin A Howitt, and Michelle L Colgrave</i>	314
Protection of Enzymes Against Thermal Degradation <i>Rosalía García-Torres, José I Reyes-De-Corcuera, and Daoyuan Yang</i>	322
Stabilization of Carotenoids in Foods <i>Amna Sahar, Ubaid Ur Rahman, Rana Muhammad Aadil, and Anum Ishaq</i>	330
The Role of Bioinformatics in the Discovery of Bioactive Peptides <i>Dominic Agyei, Erandi Bambarandage, and Chibuike C Udenigwe</i>	337

Thermal Analysis for Lipid Decomposition by DSC and TGA <i>Tengku Mohamad Tengku-Rozaina and Edward John Birch</i>	345
Pyrazines in Thermally Treated Foods <i>Javier García-Lomillo and Maria L González-SanJosé</i>	353
Formation of Selected Heterocyclic Flavor Chemicals in Beverages <i>Takayuki Shibamoto</i>	363
Xanthine Oxidase in Dairy Foods <i>Ali Rashidinejad and John Birch</i>	374
Bioactive Peptides <i>Leticia Mora, M-Concepción Aristoy, and Fidel Toldrá</i>	381
Resistant Starch Preparation Methods <i>Amir Amini Khoozani, John Birch, and Alaa El-Din Ahmed Bekhit</i>	390
Interactions of Milk Proteins With Minerals <i>Keegan Burrow, Wayne Young, Alan Carne, Michelle McConnell, and Alaa El-Din Bekhit</i>	395
Protein-Stabilised Emulsions <i>Chia Chun Loi, Graham T Eyres, and E John Birch</i>	404
Application of HPLC in characterisation of Triacylglycerols and Detection of Adulteration in Cold Pressed Seed Oils <i>Tanyaradzwa E Mungure, Alaa El-Din Bekhit, Alan Carne, Shahin Roohinejad, Kumar Mallikarjunan, and John Birch</i>	410
Enzyme Immobilization for Oligosaccharide Production <i>César R F Terrasan, Wilson G de Moraes Junior, and Fabiano J Contesini</i>	415
Interactions of Macromolecules: $\beta$ -Lactoglobulin Interaction With Pectins <i>Laurence D Melton, Amy Y Xu, Martin A K Williams, and Duncan J McGillivray</i>	424
Milk Protein–Polysaccharide Interactions in Food Systems <i>Natasha Nayak and Harjinder Singh</i>	431
Interaction Between the Polysaccharides and Proteins in Semisolid Food Systems <i>Min Zhang, Chanchan Sun, and Qian Li</i>	439
Protein-Starch Interactions in Cereal Grains and Pulses <i>Jitendra Paliwal, Sandeep Thakur, and Chyngyz Erkinbaev</i>	446
The Use of Spin-Label ESR Spectroscopy to Study Protein-Lipid Interactions <i>Musti J Swamy</i>	453
Lipoprotein Lipase and Its Interactions With Phospholipids <i>Yonghua Wang and Dongxiao Sun-Waterhouse</i>	462
Reactivity of Lipid Oxidation Products in Foods – Is Malondialdehyde a Reliable Marker? <i>Angelique Vandemoortele and Bruno De Meulenaer</i>	468
Protein-Lipid Interactions and the Formation of Edible Films and Coatings <i>Victor N Enujiughu and Ajibola M Oyinloye</i>	478
Protein Ingredients in Low- and Intermediate-Moisture Systems <i>Thom Huppertz</i>	483

Interactions Between Starch, Proteins and Lipids and the Formation of Ternary Complexes With Distinct Properties	487
<i>Shujun Wang, Mengge Zheng, and Chen Chao</i>	
O/W Emulsions Stabilized by Interactions Between Proteins and Polysaccharides	494
<i>Vânia Regina Nicoletti Telis</i>	
Changes in the Interactions Between Proteins and Other Macromolecules Induced by HPP	499
<i>Bian-Sheng Li and Biao-Shi Wang</i>	
Different Catalytic Activities of Microbial L-Glutaminases Against Bitter Amino Acid Phenylalanine in the Production of Kokumi $\gamma$ -Glutamyl Peptides	505
<i>Juan Yang, Dongxiao-Sun Waterhouse, and Chun Cui</i>	
Effect of the Structure of Tannins on Their Binding Site on a Human Salivary Proline-Rich Protein	510
<i>Francis Canon</i>	
Interactions Between Polyphenols and Macromolecules: Effect of Tannin Structure	515
<i>Carine Le Bourvellec and Catherine M G C Renard</i>	
A Molecular Thermodynamics Approach to Capture Non-specific Flavour–Macromolecule Interactions	522
<i>Seishi Shimizu, Steven Abbott, and Nobuyuki Matubayasi</i>	
Flavor Enhancement Induced by Taste–Odor Interactions	528
<i>Guowan Su, Dongxiao Sun-Waterhouse, Yaqi Zhao, Weiwei He, and Mouming Zhao</i>	
Encyclopedia of Food Chemistry: Protein–Phenol Interactions	532
<i>Fereidoon Shahidi and Ruchira Senadheera</i>	
Analysis of Flavonoid-Protein Interactions by Advanced Techniques	539
<i>JuDong Yeo and Fereidoon Shahidi</i>	
Covalent Interactions Between Proteins and Phenolic Compounds	544
<i>Sascha Rohn</i>	
Interactions Between Proteins and Polyphenols in Beer	550
<i>Haifeng Zhao and Dongxiao Sun-Waterhouse</i>	
Interactions Between Milk Proteins and Polyphenols in Model Systems or Complex Dairy Matrices	554
<i>Seda Yildirim-Elikoglu</i>	
Interactions of $\beta$ -Lactoglobulin With Small Molecules	560
<i>Lei-Wen Xiang, Laurence D Melton, and Ivanhoe K H Leung</i>	
Polyphenol-Protein Interactions and Changes in Functional Properties and Digestibility	566
<i>Tugba Ozdal, İpek Ekin Yalcinkaya, Gamze Toydemir, and Esra Capanoglu</i>	
The Potential Role of Polyphenol–Enzyme Interactions on Human Health	578
<i>Gordon J McDougall</i>	
Thermal Stability of Carotenoids– $\alpha$ -Lactalbumin Complex	583
<i>Iuliana Aprodu, Loredana Dumitraşcu, and Nicoleta Stănciuc</i>	
Component Segregation During Spray Drying of Milk Powder	589
<i>M Foerster, M W Woo, and C Selomulya</i>	
Impact of Antioxidants on Oxidized Proteins and Lipids in Processed Meat	600
<i>M Estévez and J M Lorenzo</i>	

Plant Antioxidant Extracts: Effect on Lipid or Protein Oxidation in Seafood Products <i>K H Sabeena Farvin and A Surendraraj</i>	609
Protein–Lipid–Phenolic Interactions During Soybean and Flaxseed Protein Isolation <i>Muhammad H Alu'datt, Taha Rababah, Mohammad N Alhamad, Majdi A Al-Mahasneh, Sana Gammoh, Mohammed Al-Duais, Carole C Tranchant, Stan Kubow, and Inteaz Alli</i>	621
Interactions Between Dietary Antioxidants and Plant Cell Walls <i>Catherine M G C Renard</i>	633
Interactions of Some Common Flavonoid Antioxidants <i>Dapeng Li, Dongxiao Sun-Waterhouse, Yongli Wang, Xuguang Qiao, Yilun Chen, and Feng Li</i>	644
Polyphenol Interactions and Food Organoleptic Properties <i>Susana Soares, Nuno Mateus, and Victor de Freitas</i>	650
Effects of Interactions Between Antioxidant Phytochemicals and Coexisting Food Components on Their Digestibility <i>Sukanya Thuengtung and Yukiharu Ogawa</i>	656
Bioactive Delivery Systems Based on Stimuli-Sensitive Biopolymer Stacks: Chitosan-Alginate Systems <i>Geoffrey I N Waterhouse and Dongxiao Sun-Waterhouse</i>	661
Interactions Between Food Ingredients and Nanocomponents Used for Composite Packaging <i>Adam Ekielski</i>	669
Use of Pectin to Formulate Antimicrobial Packaging <i>M M Gutierrez-Pacheco, L A Ortega-Ramirez, and J F Ayala-Zavala</i>	675
Effect of Three-Component Interactions Among Starch, Lipids and Proteins on the Glycemic Response <i>Javier Parada and Jose L Santos</i>	681
Encapsulation Systems Containing Multi-Nutrients/Bioactives: From Molecular Scale to Industrial Scale <i>Geoffrey I N Waterhouse and Dongxiao Sun-Waterhouse</i>	687
Nanoparticle-Based Encapsulation of Green Tea Polyphenols: An Approach to Enhance Their Bioavailability and Therapeutic Efficacy <i>Feng Li, Yongli Wang, Dapeng Li, Dongxiao Sun-Waterhouse, Yilun Chen, and Xuguang Qiao</i>	695
Food Soft Nano-Dispersions for Bioactive Delivery: General Concepts and Applications <i>Maria D Chatzidaki and Aristotelis Xenakis</i>	701
New Insights on Bio-Based Micro- and Nanosystems in Food <i>Daniel A Madalena, Ricardo N Pereira, António A Vicente, and Óscar L Ramos</i>	708
Oleogelation for Food Structuring Based on Synergistic Interactions Among Food Components <i>Ashok R Patel</i>	715
Protein-Based Nanodelivery Systems for Food Applications <i>Ogadimma D Okagu, Bo Wang, Caleb Acquah, and Chibuike C Udenigwe</i>	719
Edible Delivery Systems Based on Favorable Interactions for Encapsulation of Phytochemicals <i>Jie Xiao, Wenbo Wang, Qingrong Huang, and Yunqi Li</i>	727
Fabrication of Electrospun and Electrosprayed Carriers for the Delivery of Bioactive Food Ingredients <i>Alex López-Córdoba, Jose Maria Lagarón, and Silvia Goyanes</i>	733

**VOLUME 3**

Fruit and Vegetable Texture: Role of Their Cell Walls <i>José A Mercado, Antonio J Matas, and Sara Posé</i>	1
Atomic Force Microscopy (AFM) and X-Ray Micro-Computed Tomography (Micro-CT): Applications in Cell Wall Imaging of Softening Fruit <i>Jovyn K T Frost and Roswitha Schröder</i>	8
Legume Microstructure <i>Duc Toan Do and Jaspreet Singh</i>	15
Meat Structure During Processing <i>Hanne Christine Bertram</i>	22
The Structure and Properties of Eggs <i>Danaé S Larsen</i>	27
Crustacean By-products <i>Fatih Özogul, Imen Hamed, Yesim Özogul, and Joe M Regenstein</i>	33
Microstructure of Dairy Fat Products <i>P R Ramel and A G Marangoni</i>	39
The Structure and Properties of Ice Cream and Frozen Desserts <i>H Douglas Goff</i>	47
The Structure and Rehydration Properties of Dairy Powders <i>Irina Boiarkina and Brent Young</i>	55
Structure and Properties of Chocolate <i>Monica H Caparosa and Richard W Hartel</i>	61
Traditional African Bread and the Physicochemical Properties of Unfermented Flatbreads <i>Geremew Bultosa</i>	66
Traditional African Bread: Physicochemical and Sensory Properties of Fermented Breads <i>Geremew Bultosa</i>	81
Indian Flatbreads: How Structure Influences Properties <i>Shabir Ahmad Mir and Manzoor Ahmad Shah</i>	90
Tofu and Soy Products: The Effect of Structure on Their Physicochemical Properties <i>Qing Zhang and Wen Qin</i>	96
The Structure of Meat Analogs <i>Pavan Kumar, Nitin Mehta, Om Prakash Malav, Akhilesh Kumar Verma, Pramila Umraw, and Matli Krishna kanth</i>	105
Nanomaterials in Food: An Overview <i>Stéphane Dubascoux and Yves Wyser</i>	110
Delivery of Epigallocatechin-3-Gallate by Bovine Alpha-Lactalbumin Based on Their Non-covalent Interactions <i>Tanja Cirkovic Velickovic, Dragana Stanic-Vucinic, Ayah Al-Hanish, Jelena Mihailovic, Ivana Prodic, Simeon Minic, Marija Stojadinovic, Milica Radibratovic, and Milos Milcic</i>	118
Food Structure, Rheology, and Texture <i>L Day and M Golding</i>	125

Applications of Microrheology to Food Systems <i>Susav Pradhan, Catherine P Whitby, and Martin A K Williams</i>	130
Intrinsically Disordered Proteins: Polymers Without Structure but With Great Potential for Applications in Food Science <i>Davide Mercadante</i>	134
Structured Lipid Functionality and Application <i>Xun Ang, Siew-Young Quek, and Hong Chen</i>	141
Application of Electrospinning as Bioactive Delivery System <i>Siew Young Quek, Joshua Hadi, and Hartono Tanambell</i>	145
Food Texture, Oral Processing and Satiation: Examining Their Relationship <i>Danaé S Larsen</i>	150
Food Sensory Perception Influenced by Structure and/or Food–Saliva Interactions <i>Xinmiao Wang and Jianshe Chen</i>	154
How Food Structure and Processing Affect the Bioavailability of Nutrients and Antioxidants <i>Sui Kiat Chang</i>	158
Locusts as a Source of Lipids and Proteins and Consumer Acceptance <i>Claudia Clarkson, John Birch, and Miranda Miroso</i>	167
Edible Packaging <i>Miguel Ângelo Parente Ribeiro Cerqueira</i>	173

## PREFACE

---

This is an exciting time for all who wish to understand the nature of food and how it changes during storage, processing, cooking and digestion. This is because science has turned its focus onto soft matter and food is very largely soft matter. Earlier scientific effort was preoccupied with simple molecules in solution and solids (preferably pure crystalline proteins). When you think about it, knowing the total protein, carbohydrate, lipid and vitamin contents of a food doesn't tell you much about the nature of the food and how it will provide nutrients for us. Now we are seeing a huge effort to understand soft matter, which is directly applicable to food. Meaning we are increasing our knowledge of how food components (both macromolecules such as proteins and polysaccharides as well as smaller molecules) interact chemically with each other; leading ultimately to understanding the complex chemical structure of foods (everything from apples and ice cream to vegetable protein meat-substitutes and food for a visit to Mars).

A golden age for food research has begun, with so many new techniques available such as CRISPR, isothermal calorimetry (ITC), analytical ultracentrifugation (AUC), small angle neutron and X-ray scattering (SANS, SAXS), surface plasmon resonance, electronic tweezers, and computer modelling (for example molecular dynamics simulations for understanding the interactions of proteins and polysaccharides, enzymes and substrates, bioactives and encapsulating agents). This is in addition to the tried and tested techniques of nuclear magnetic resonance (NMR), mass spectroscopy, electron and confocal microscopy, high performance liquid chromatography (HPLC), and gas chromatography. Biosensors publications are huge and nanotechnology is a hot topic for research.

The *Encyclopedia of Food Chemistry* is for people who have a basic knowledge of food chemistry and wish to expand their understanding of a topic based on information from a reliable source. No fake news here! We welcome you to enjoy the excitement captured here by experts from across the planet.

# Acids and Bases in Food

Iris J Joye, University of Guelph, Guelph, ON, Canada

## General Definition and Theory

According to the theory of Brønsted-Lowry, an acid is a chemical substance that can donate protons ( $H^+$ ), *i.e.* a proton donor, while a base is a chemical substance that has a tendency to accept those protons, *i.e.* a proton acceptor:

A global acid–base reaction can, hence, be written as:

Water can both act as base and acid:

It has been shown that in pure water, the concentration of both these ions ( $H_3O^+$  and  $OH^-$ ) is  $10^{-7}$  M. In the presence of an acid, a proton donor, the concentration of protons in solution will increase and surpass the ‘neutral’ concentration of  $10^{-7}$  M, while a base, a proton acceptor, will deplete the protons in solution and the proton concentration will decrease below the ‘neutral’ concentration of  $10^{-7}$  M. A logarithmic scale has been introduced to make the concept ‘proton concentration in solutions’ more tangible, *i.e.* the pH scale:

$$pH = -\log[H_3O^+]$$

In neutral solutions, the  $H_3O^+$  (or  $H^+$ ) concentration is  $10^{-7}$  M and the pH would, hence, be 7.0. In acid solutions the pH will be lower than 7.0 while in alkaline solutions the pH will be higher. It is important to keep in mind that the pH scale is a logarithmic scale, which implies that when the pH decreases with one unit, the proton concentration actually multiplies by a factor 10.

With every acid and base a certain ‘strength’ is associated. This strength is an indication of the tendency of an acid or base to donate or accept protons, respectively. Strong acids/bases are usually completely deprotonated/protonated in water, while weak acids/bases will only be partially deprotonated/protonated in water. This is quantitatively expressed by the dissociation constants that are associated with these acids/bases. An in-depth explanation on how to use these dissociation constants can be found in most chemistry handbooks, but falls outside the scope of this chapter.

## Acid and Bases in the Food Sector

Food products are often classified according to their acidity (**Table 1**). Fruits are widely perceived as acid foods. The pH in a lime for example can be as low as pH 2.0, apples and grapes have pH values around 4.0, while bananas have a pH around 5.0. The pH of avocados is close to neutrality. Most vegetables have slightly acid pH values. Examples of neutral pH food products are milk and water. Tea, tofu and some cheeses are alkaline food products (**Table 1**) ([US. Food and Drug Administration/Center for Food Safety and Applied Nutrition, 2003](#)).

In addition to the naturally present acids and bases in food products, acids and bases are often also included in the product recipe as food additive or processing aid, or are generated during processing. Fermentation of food *e.g.* is an example of the *in situ* production of acid during processing.

Besides the targeted functionality, the selection of the acid or base which is most suitable for a specific food product depends on the flavor profile, the solubility and the hygroscopicity of the acid/base, and the food pH. Hygroscopicity, *i.e.* the tendency to absorb moisture, is especially important for those applications focusing on dry mixes or powders ([Igoe, 2011](#)). Besides the physical form of the food product, the cost, legal requirements, availability and storage and handling properties of the acids/bases are also considered when selecting the appropriate acid.

## Acids in the Food Sector

Current consumer trends towards clean label food products boost the use of so-called ‘natural’ acids (such as lime juice) or acid producing processes during food production. Biopreservation is one of the technologies that has recently gained a lot of attention and uses beneficial microbes such as lactic acid bacteria and their products (usually acids) to ensure food safety and shelf-life ([Akbar et al., 2016](#)). The most common acids for food use are organic acids such as acetic, lactic and citric acid. Phosphoric acid is an example of a mineral acid present in food. In **Fig. 1**, the structure of the different organic acids that will be discussed in this section are listed. Acids approved for use in food have been given an E-number by the European Food Safety Authority (EFSA). Their E-numbers classify most of them either in the preservative list (E200–E299) or as antioxidants and acidity regulators (E300–399). E-numbers are also increasingly found on products in North-America and largely follow the numbering of the

**Table 1** pH of some common foods or food ingredients (U.S. Food and Drug Administration/Center for Food Safety and Applied Nutrition, 2003)

<i>Food product/ingredient</i>	<i>pH value</i>
Apple juice	3.4–4.0
Apple sauce	3.1–3.6
Artichokes	5.5–6.0
Avocados	6.3–6.6
Bananas	4.5–5.2
Broccoli	6.3–6.9
Butter	6.1–6.4
Cabbage	5.2–6.8
Carrots	5.9–6.4
Cheese	4.1 (cream cheese) 7.4 (camembert cheese)
Coconut	5.5–7.8
Corn	5.9–7.5
Corn starch	4.0–7.0
Cucumber	5.1–5.8
Flour	6.0–6.3
Garlic	5.8
Grapes	2.8–3.8
Grapefruit	3.0–3.8
Honey	3.9
Fruit jam	3.5–4.5
Ketchup	3.9
Lettuce	5.7–6.1
Maple syrup	5.2
Milk	6.4–6.8
Molasses	5.0–5.5
Mushrooms	6.0–6.7
Pineapple	3.2–4.0
Potatoes	5.4–5.9
Pumpkin	4.9–5.5
Rhubarb	3.1–3.4
Rice (cooked)	6.0–6.8 (range includes brown, white and wild rice)
Spinach	5.5–6.8
Strawberries	3.0–3.9
Sugar	5.0–6.0
Tea	7.2
Tofu	7.2
Tomatoes	4.3–4.9
Vinegar	2.4–3.4

International Numbering System for Food Additives (INS) that is defined in the Codex Alimentarius (Food and Agriculture Organization of the United Nations and World Health Organization, 2017).

Functionalities that are targeted by adding acids to processed foods range from enhancing or altering flavor (*e.g.* in beverages, fruit drinks and desserts), improving food preservation (*e.g.* in mayonnaise, tomato sauce, delaying/inhibiting fruit discoloration), chelating metals (*e.g.* preventing oxidation of fatty and oily foods and delaying/inhibiting canned shrimp discoloration), buffering of food products (*e.g.* in prepared desserts), gelling (*e.g.* in desserts and jams) and/or coagulation (*e.g.* cheese and milk-based desserts) (Igoe, 2011). The perception of sour taste or flavor is a very complex phenomenon and falls outside the scope of this chapter. The interested reader is referred to the excellent review of Ramos Da Conceicao Neta *et al.* (2007).

In what follows, a few examples of acids important in the food sector are listed. It needs to be emphasized, however, that this list is not complete and other food additives exist which also have an effect on the pH of the food system.

### Acetic Acid

Acetic acid (E260 or INS 260), sometimes even called ethanoic acid (Fig. 1, Table 2), is a colorless organic acid with a very strong smell. According to the Codex Alimentarius (Food and Agriculture Organization of the United Nations and World Health Organization, 2017) it is classified as an acidity regulator and preservative. Acetic acid is the main acid in vinegar, in which it is often

**Figure 1** Chemical structure of a selection of acids important in food.

**Table 2** Overview of a selection of common acids used as additives in the food sector (Igoe, 2011; Ramos Da Conceicao Neta et al., 2007)

Acid	Appearance	pH of 1.0% solution	Sensory properties	Acid dissociation constants	Water solubility	Examples of use
Acetic acid	Liquid	2.8	Astringent, tart and sour, vinegary	4.75	High miscibility and solubility	Salad dressings, pickles, cured meat
Citric acid	Crystalline powder	2.2	Sharp, tart, delivers a 'burst' of tartness, fresh citrus flavor	3.08/4.74/5.40	Rapid and high solubility	Beverages
Fumaric acid	Crystalline powder	2.1	Sharp, tart and sour, metallic	3.03/4.44	Low solubility	Bakery applications, controlling leavening, beverages
Lactic acid	Powder or liquid	2.3	Bland or mildly acid	3.86	High solubility	Dairy foods
Malic acid	Powder	2.3	Mildly tart, green, smooth	3.40/5.11	High solubility	Sour confectionary
Phosphoric acid	Liquid	1.6	Sour, tangy	2.12/7.21/12.32	Miscible with and very soluble in water	Beverage syrups
Succinic acid	Crystalline powder	2.7	Tart and slightly bitter, salty, savory and brothy notes	4.19/5.50	Moderate solubility in water	Soup, broth, powdered drinks
Tartaric acid	Crystalline powder	2.3	Sharp, sour, very tart, slightly bitter, augments fruit flavor	2.98/4.34	Low solubility	Bakery applications, candy

present as 3% to 9% of the product volume. As a constituent of vinegar it is a very popular acid in food as e.g. a flavoring agent for salads (Table 2).

It is also used as a sanitizing agent, especially for salad vegetables which are eaten raw. The effect of acetic acid on microorganisms which are related to food spoilage has been of interest for a long time and seems to go beyond the pH effect alone. The undissociated acid is readily taken up by the cells and dissociates in the cell interior, causing a pH drop and metabolic disturbance by the acetate anion (Trcek et al., 2015). Although some bacterial food spoilage strains show a high tolerance towards acetic acid (Trcek et al., 2015), it has been proven to be very effective and toxic against *Salmonella aertrycke*, *Saccharomyces cerevisiae* and *Aspergillus niger* (Levine and Fellers, 1940). The inhibitory activity of acetic acid on *Aspergillus flavus* growth was also proven in terms of food preservation (Pelaez et al., 2012). In combination with sodium benzoate, acetic acid is used to preserve food products such as cucumbers without subjecting them to a thermal treatment (Perez-Diaz and McFeeters, 2008). Next to the above applications, acetic acid can also be used as a processing aid in the extraction of certain protein fractions from cereals. Indeed, acetic acid is a good solvent to extract the prolamin fraction of certain cereals and pseudocereals, a fact that may be of interest to food ingredient producers which are focusing on protein isolates (Taylor et al., 2005).

Acetic acid bacteria are commonly used in the food industry and *in situ* produce acetic acid in the food product or during processing (Sengun and Karabiyikli, 2011). Through the oxidation of sugars and alcohol to organic acid during food fermentation processes these bacteria have a distinct effect on the food appearance, flavor and shelf life. However, the action of these bacteria is not always wanted as they also cause wine spoilage through oxidation of ethanol into acetic acid. Next to the production of vinegar, these acetic acid producing bacteria can also be important to fermentation of cocoa beans and coffee processing (Sengun and Karabiyikli, 2011).

### Citric Acid

Citric acid (E330 or INS330) is a weak organic tricarboxylic acid (Fig. 1, Table 2) that naturally occurs in citrus fruits. Next to its role as flavoring agent, citric acid is widely used as an acidity regulator, antioxidant, color retention agent and sequestrant (Food and Agriculture Organization of the United Nations and World Health Organization, 2017). Sequestrants bind to metal ions, hence, slowing down oxidation reactions and prolonging the shelf life of food products. At the same time, it can also be considered as a nutrient enhancer. Its wide applicability and 'clean and natural' image, made it into probably the most widely used and popular acid in the food industry.

Originally, citric acid was extracted from citrus fruits. However, nowadays, it is produced through fermentation of molasses and other sugar sources. More than half of all citric acid is used in beverages. Over the years, some questions were raised on the innocence of citric acid as a food additive, especially with regard to the formation of reactive radicals (Gautier-Luneau et al., 2007).

### Fumaric Acid

Fumaric acid (E297 or INS297) is a four-carbon dicarboxylic acid (Fig. 1, Table 2) and used as acidity regulator in food (Food and Agriculture Organization of the United Nations and World Health Organization, 2017). Its low cost and non-toxicity are at the basis of its popularity as a food additive since 1946. Fumaric acid is claimed to be 1.5 times more acid than citric acid. Microbial inactivation studies have shown that fumaric acid can inactivate food-borne pathogens and extend the shelf life of products such as fresh

beef (Tango et al., 2014). It is often used as a beverage ingredient, but also finds application in bakery products, powdery dessert mixes and confectionary (Santini et al., 2012). Next to food applications, fumaric acid is used in feed as antibacterial agent and is a well-known chemical that is used in the production of polymers and as intermediate in the production of L-malic and L-aspartic acid. Fumaric acid is predominantly produced by petroleum-based chemical synthesis, but research focusing on microbial fumaric acid production (e.g. using *Rhizopus oryzae*) from starchy materials is in the process of optimizing and commercializing this 'green' technique (Xu et al., 2012; Yang et al., 2011; Alonso et al., 2014).

### Lactic Acid

Lactic acid (E270 or INS 270, Fig. 1, Table 2) is an acidity regulator and was one of the earliest food additives. It is very commonly found in sour milk products such as yoghurt and often used to regulate the acidity of processed food products. It has also been described to act as an antioxidant and preservative. Lactic acid was tested for its inhibitory effect on the growth of *A. flavus*. Its efficacy was lower than that reported for acetic acid. The combination of acetic and lactic acid, however, showed a synergistic effect (Pelaez et al., 2012).

Lactic acid is also produced by bacteria in a lot of (fermented) food products (Torino et al., 2015; de souza motta and da silva mesquita gomes, 2015, Ganzle, 2015). These bacteria are believed to have probiotic effects and, hence, caught the interest of consumers and the food industry. In the dairy industry e.g. lactic acid bacteria have been extensively researched with regard to their potential to design natural biofunctional health-promoting food (Linares et al., 2017). Through the production of products such as lactic acid, these bacteria influence the product's sensory properties and microbiological stability (De Souza Motta and Da Silva Mesquita Gomes, 2015).

### Malic Acid

Malic acid (E296 or INS 296, Fig. 1, Table 2) is a four-carbon dicarboxylic acid that is used as acidity regulator and flavor enhancer in food. It is often found in unripe fruit and is also present in wine. Malic acid levels in soft drinks, fruit juices and wine need to be strictly controlled as too low or high levels may result in product deterioration (Antonelli et al., 2008). Together with tartaric acid, malic acid makes up about 90% of the total acidity of wine. Malic acid is also used as flavoring agent in the sour confectionary sector. Similar as the other organic acids, malic acid has been found to be an effective agent for inactivating common food pathogens on fresh vegetables (Kim et al., 2016).

Malic acid is often synthesized chemically starting from fumaric acid (Chi et al., 2014). However, the increasing cost of fumaric acid production and the quest for more eco-friendly techniques has triggered more research efforts into producing malic acid from sugars using microorganisms (Chi et al., 2014).

### Succinic Acid

Succinic acid (E363, Fig. 1, Table 2) and its sodium salt are used as flavor enhancers in food products such as desserts, soups/broths and powders that can be used to prepare drinks at home (Chimirri et al., 2010). Succinic acid production through fermentation (e.g. using *Yarrowia lipolytica*) of agricultural and food waste streams is one of the strategies that is currently explored to reduce the less ecological chemical synthesis of succinic acid (Yang et al., 2017).

### Phosphoric Acid

Phosphoric or orthophosphoric acid ( $\text{H}_3\text{PO}_4$ , E338 or INS338, Fig. 1, Table 2) is used as an acidity regulator, antioxidant and sequestrant in food (Food and Agriculture Organization of the United Nations and World Health Organization, 2017). It is a widely used flavoring agent for carbonated soft drinks and lies at the basis of the tangy flavor of cola, root beers and other soft drinks. Although it is also a synthetic chemical, phosphoric acid derivatives are widely found in nature and are, hence, already naturally present in food. Phosphoric acid is the only inorganic acid that is widely used as food acid and, at the same time, is one of the least expensive food-grade acid additives. It is also, of all the acids described here, the strongest acid, which can give the lowest attainable pH values (Table 2). Next to its use in the soft drinks industry, phosphoric acid is also used in cheese manufacturing and brewing practices. It has also been shown to stimulate yeast growth (important to foods which involve fermentation by yeast) and is used in the production of gelatin.

### Tartaric Acid

Tartaric acid (E334 or INS 334) is a dicarboxylic acid (Fig. 1) that finds application as acidity regulator, antioxidant, flavor enhancer and sequestrant in the food sector. Tartaric acid is highly water soluble and has a very strong tart taste (Table 2). Tartaric acid is naturally found in grapes and bananas and has been reported to enhance the flavor of grape- and lime-flavored beverages. Together with malic acid it contributes 90% of the acidity in wine and its levels need to be tightly controlled in order to ensure product quality (Sprenger et al., 2015). Similar to malic acid, it is used as flavoring agent in sour-tasting confectionary. Its antioxidant activity stems from its function as sequestrant. Tartaric acid is commercially obtained in either a natural way (extraction from grapes or wine by-products) or by chemical synthesis starting from petroleum by-products (Serra et al., 2005).

### Benzoic Acid

Benzoic acid (E210 or INS210, Table 2), a colorless aromatic carboxylic acid (Fig. 1), is naturally present in plant (fruits, nuts, spices and vegetable), fungal and animal tissues, but it can also be produced by microorganisms during food processing and/or be added

as a food additive. Rich natural sources of benzoic acid are strawberries (up to 29 mg/kg), cayenne pepper and mustard seeds (up to 10 mg/kg), cloves, salvia, thyme and nutmeg (up to 50 mg/kg) and cinnamon (up to 335 mg/kg) (del Olmo et al., 2017). Benzoic acid levels in milk were also found to very sharply increase during fermentation, presumably due to the activity of lactic acid bacteria, *Pseudomonas* and/or *Escherichia coli*. Levels of up to 24 mg/L have been reported in fermented cow's milk. The benzoic acid levels in raw cow's milk cheese ripened for 6 months can be as high as 250 mg/kg (Del Olmo et al., 2017).

Next to its natural occurrence in food, benzoic acid and its derivatives are also commonly supplemented as antibacterial and -fungal preservatives or flavoring agents (Del Olmo et al., 2017). Benzoic acid has a low taste threshold and low volatility and wide antimicrobial spectrum (Ashurst, 1991). Although the undissociated form of benzoic acid is proven to be more effective as antimicrobial agent, the salt, due to its better water solubility, is more often used in food applications. The maximal antimicrobial activity of benzoic acid has been described between pH 2.5 and 4.5. It is clear that benzoic acid and its derivatives are, hence, most often used as preservatives in acid food products. However, when using benzoic acid as food additive, care needs to be taken that the food product's taste is not altered in such way that it becomes unacceptable. Benzoic acid is known to cause oral prickling, to increase the perception of sweetness, to reduce sourness and saltiness perception and to strongly suppress the perception of bitterness (Otero-Losada, 2003).

Notwithstanding its approval for food use and GRAS status, the toxicology of benzoic acid and its derivatives has always been controversial (Del Olmo et al., 2017). Information on maximum allowed limits of benzoic acid and its salt as food additives can be found in the Codex Alimentarius (Food and Agriculture Organization of the United Nations and World Health Organization, 2017).

### Other Acids

Examples of other non-organic acids in food are *hydrochloric acid* (HCl, E507 or INS 507), *boric acid* (E284) and *sulfuric acid* (H<sub>2</sub>SO<sub>4</sub>, E513). Hydrochloric and sulfuric acid act as acidity regulators, while boric acid can be used as a preservative. However, these acids are usually formed in the food rather than being added as a food additive. Hydrochloric acid has been described as having a faintly bitter taste (Ramos Da Conceicao Neta et al., 2007).

*Sorbic acid* (E200 or INS200, Fig. 1), analogous to benzoic acid, is used in beverages as preservative (Food and Agriculture Organization of the United Nations and World Health Organization, 2017) due to its non-volatile nature and effectiveness against yeasts (Otero-Losada, 2003). However, sorbic acid has a lower taste threshold and some consumers are very sensitive to its particular flavor in citrus flavored food products.

*Ascorbic acid* (E300 or INS300, Fig. 1) functions as acidity regulator, antioxidant, flour treatment agent and sequestrant in food applications. Ascorbic acid is highly water soluble and is often used as an antioxidant in beverages, wine and meat products (Sadecka and Polonsky, 2001).

*Chlorogenic acid* (Fig. 1) is a phenolic compound that is widely distributed in plants such as apples, artichokes, carrots, eggplants, kiwi fruits, pears, potatoes and tomatoes (Santana-Galvez et al., 2017). To this acid, a lot of health-promoting properties have been ascribed and it is, hence, often used as a food additive and nutraceutical. As a food additive, it fulfills the role of a broad spectrum antimicrobial agent effective against bacteria, yeasts, molds, viruses and amoebas. Furthermore, chlorogenic acid has also antioxidant activity and may be useful in reducing the degree of lipid oxidation or for protecting bioactive molecules (Santana-Galvez et al., 2017). Due to its properties, chlorogenic acid is certainly gaining more interest and importance for the formulation of dietary supplements or functional foods (Santana-Galvez et al., 2017). The health-improving effects ascribed to chlorogenic acid are anti-oxidant, anti-inflammatory, anti-obesity, anti-diabetic and anti-hypersensitive properties. Till date, however, the isolation of chlorogenic acid to be used as food additive is rather expensive, and, hence, not yet competitive relative to other well-known acids that are used as traditional preservatives (Santana-Galvez et al., 2017).

*Adipic acid* (E355 or INS355, Fig. 1) and its salts are used as acidity regulators, acidifiers, flavor enhancers, gelling aids and slow raising agents (Chimirri et al., 2010, Food and Agriculture Organization of the United Nations and World Health Organization, 2017). Adipic acid is used in filling and topping for bakery products, dry powdered dessert mixes, gel-like desserts, fruit-flavored desserts and beverage powders (Chimirri et al., 2010). It is also used to adjust the viscosity and melting behavior of food products such as cheese spread and as leavening acidulant in baking powder. Adipic acid's taste is sometimes described as chalky (Ramos Da Conceicao Neta et al., 2007).

*Propionic acid* (E280 or INS280, Fig. 1) is used in food as a preservative. One of its main applications is as antimicrobial additive in bread (Basler et al., 1987) (Table 1).

### Bases in the Food Sector

Next to acids, bases are also important in food. One of the most alkaline food products in the human diet is bird's nest soup, with a pH that varies between 7.2 and 7.6 (U.S. Food and Drug Administration/Center for Food Safety and Applied Nutrition, 2003). The (in the Western world) more commonly consumed Camembert cheese has a pH around 7.4 (Table 1). Acids in water will donate a proton to water and its conjugate base will be formed. Hence, for all the above acids conjugated bases also exist. For a lot of the above mentioned commonly used acids, the salt-form of the conjugated base is also an approved and commonly used food additive.

Examples of food products that require the use of bases during production are wheat noodles and pretzels (Rombouts et al., 2012b, 2014). During noodle production alkaline salts (such as sodium and potassium carbonate) are used. Pretzels, on the other

**Table 3** Overview of less common food acid additives and their properties (Food and Agriculture Organization of the United Nations and World Health Organization, 2017)

Name	E/INS-number	Type of additive	Notes	References
Carminic acid	E/INS120	Food dye	Red or purple color, obtained from an insect that lives on cacti	Muller-Maatsch and Gras (2016) (Fig. 1)
Formic acid	E236	Preservative	Produced by lactic acid bacteria, but level highly dependent on growth medium and bacterial strain	Ozcelik et al. (2016) and Ostling and Lindgren (1993) (Fig. 1)
Dehydroacetic acid	E265	Preservative	Used in <i>e.g.</i> butter, cheese and margarine	Ohtsuki et al. (2013) and Wolf (1950)
Erythorbic acid	E/INS315	Antioxidant	Stereoisomer of ascorbic acid with similar physicochemical properties, enhances the bioavailability of iron, does not have antiscorbutic activity	Fidler et al. (2004) and Kadin and Osadca (1959)
Metatartaric acid	E353	Emulsifier	Used in the wine industry to prevent the precipitation of tartrate salt	Sprenger et al. (2015)
Thiodipropionic acid	E/INS388	Antioxidant	Used in fatty foods to prevent rancidity	Stokes et al. (1975)
Phytic acid	E391	Antioxidant	Considered an antinutritional factor, tightly interacts with metals (antioxidant for lipid containing food systems and stabilization of colors) and buffers food systems	Graf (1983) (Fig. 1)
Alginic acid	E/INS400	Emulsifier, thickening and gelling agent	Used in <i>e.g.</i> soup, processed cheese, dairy spreads, pudding, mustard, jam	Usov and Zelinsky (2013)
Gluconic acid	E574	Acidity regulator	Also has raising, sequestering, hardening and flavor enhancing properties – bitter but refreshing flavor, used in fruit juices, pickled foods	Canete-Rodriguez et al. (2016) (Fig. 1)
Glutamic acid	E/INS620	Flavor enhancer	Its salt, monosodium glutamate (MSG) is an important food additive, imparts umami taste to food product	Populin et al. (2007)
Guanylic acid	E/INS626	Flavor enhancer	Enhances umami taste in food, used in soup, noodles, potato chips, savory rice, canned vegetables	
Inosinic acid	E/INS630	Flavor enhancer	Used in meat sector for intensification of meat flavor in soups, sauces and seasonings	Portela et al. (1994)
Cyclamic acid	E/INS952	Sweetener	Used in low calorie food and drinks	
Cholic acid	E1000	Emulsifier		(Fig. 1)

hand, are dipped in a hot alkaline solution (1.0 w/v NaOH at 80–90 °C) prior to baking. This causes gelatinization of starch at the dough surface, leads to dissociation of amylose–lipid complexes, promotes crosslinking of wheat gluten and induces Maillard and caramelization reactions (Rombouts et al., 2012a, 2012b). The alkaline treatment leads to the unique taste and the hard shiny surface of the pretzels (Rombouts et al., 2012a). However, in general, food consumed in a regular human diet has a more acid pH (Table 1).

In what follows, a few bases which have been approved for use as food additive in Europe and/or North America are listed. Again, this list is by no means not complete.

### Carbonates

Carbonates include sodium carbonate (E500 or INS500), calcium carbonate (E170 or INS170) potassium carbonate (E501 or INS501), ammonium carbonate (E503 or INS503), magnesium carbonate (E504 or INS504) and ferrous carbonate (E505). Besides the functionality as acidity regulators in food products, additional functionalities have been ascribed to each of these carbonates (Table 4). Carbonates are often also used as neutralizer for products which have undergone an acid treatment such as in the production of non-fermented soybean sauce (Food and Agriculture Organization of the United Nations and World Health Organization, 2017).

*Sodium bicarbonate* is commercially known under the name ‘baking soda’. Baking soda is used in the baking industry as raising agent. Upon exposure to water, sodium bicarbonate generates carbon dioxide, which leads to (chemical) leavening of bakery products.

*Calcium carbonate* is technically ground limestone or can be obtained by precipitation of calcium ions using carbonate ions. It is a white, odorless and tasteless powder that is insoluble in water and alcohol. In contact with an acid, it creates bubbles. Its traditional use was for adulteration of flour. Although it is also listed as a food coloring agent, this application is not widespread (Scotter, 2011).

### Hydroxides

*Sodium hydroxide* (E524 or INS524) and *potassium hydroxide* (E525 or INS525) are sometimes used during processing to sustain specific alkaline conditions in order to promote certain reactions in the food matrix (Rombouts et al., 2012a, 2012b).

**Table 4** Overview of food bases and their properties (Food and Agriculture Organization of the United Nations and World Health Organization, 2017)

Name	E/INS-number	Type of additive	Properties	References
Sodium carbonate	E/INS500	Acidity regulator, anticaking agent, emulsifying salt, raising agent, stabilizer, thickener	Used in cereal products, dairy products and fish products Studied as preservative in food coating, inhibiting growth of fungi	Karaca et al. (2014)
Calcium carbonate/chalk	E/INS170	Acidity regulator, anticaking agent, color, firming agent, flour treatment agent, stabilizer	Used in cereal products, dairy products, meat and fish products Use as food color is limited	Scotter (2011)
Potassium carbonate	E/INS501	Acidity regulator, stabilizer	Used in dairy products, pasta and noodles, studied as preservative in food coating, inhibiting growth of fungi	Palou et al. (2009)
Ammonium carbonate	E/INS503	Acidity regulator, raising agent	Used in frozen fish products, studied as preservative in food coating, inhibiting growth of fungi	Karaca et al. (2014)
Magnesium carbonate	E/INS504	Acidity regulator, anticaking agent, color retention agent	Used in dairy products, fish products, salt and salt substitutes	
Ferrous carbonate	E505	Acidity regulator		
Sodium hydroxide	E/INS524	Acidity regulator	Used in pretzel making, dried whey and whey products and infant formulae	Rombouts et al. (2012b), Rombouts et al. (2012a)
Potassium hydroxide	E/INS525	Acidity regulator	Used in dried whey and whey product and infant formulae	
Calcium hydroxide	E/INS526	Acidity regulator, firming agent	Improves textural properties of buckwheat noodles, used in infant formulae	Han et al. (2012)
Ammonium hydroxide	E/INS 527	Acidity regulator	Used in fermented milk	
Magnesium hydroxide	E/INS528	Acidity regulator, color retention agent	Used in fermented milk, salt substitutes, fish and coffee products	
Calcium oxide	E/INS529	Acidity regulator, flour treatment agent	Used in fermented milk	
Magnesium oxide	E/INS530	Acidity regulator, anticaking agent	Used in salt, dried whey and whey products	

Also the *hydroxides of calcium* (E526 or INS526), *ammonium* (E527 or INS527), and *magnesium* (E528 or INS528) are used in the food sector for the regulation of the acidity. Calcium hydroxide is also used as firming agent and has been proven useful for improving the texture of cereal products (Han et al., 2012).

## Conclusion

Acids and bases are omnipresent in food products. They are either naturally present in the main food ingredients, are generated during food processing and/or storage or are deliberately added to improve the quality and shelf life of food. Besides contributing to product taste and flavor, acids and bases also have roles as colorants, structure building or stabilizing agents and shelf life extenders.

## Introduction

Anthocyanins are the largest group of water-soluble pigments in the Plant Kingdom, displaying a diversity of colors that range from pink-orange through red to purple and blue hues. They are present in all types of vascular plants and can be found in any plant tissue, although most commonly in flowers and fruits, being widely distributed in the human diet through plant-based foods. Their chemical nature was established at the beginning of the 20th century through the pioneer works of Richard Willstätter (Nobel Laureate in Chemistry in 1915) and Muriel Wheldale Onslow, with initial studies mostly focused in understanding their role in flower coloration (e.g. Willstätter and Everest, 1913; Wheldale, 1914). Studies on color changes dependent on pH variation were developed by Shibata et al. (1919), whereas Sir Robert Robinson (Nobel Prize in 1947) made significant contributions to anthocyanin synthesis (Robertson and Robinson, 1926) and the copigmentation process (Robinson and Robinson, 1931). Equilibria among anthocyanin structures (Brouillard and Dubois, 1977; Brouillard and Delaporte, 1977) and the copigmentation mechanisms (Goto and Kondo, 1991) were mostly elucidated in the 1970s–1980s. Over the last thirty years, favored by the advances in the analytical techniques, a large number of novel structures have been identified and new families of anthocyanin-related pigments, like pyrananthocyanins, described (Andersen, 2008). Currently the complete structures of more than 700 anthocyanins present in natural sources have been described and above 200 have been tentatively identified (Andersen and Jordheim, 2013), although the number of reported compounds is continually increasing. The interest in anthocyanin research has renovated in recent times as evidences about their potential benefits in human health have accumulated, and novel applications of anthocyanin pigments as colorants or putative bioactives to be exploited by food, pharmaceutical and cosmetic industries have arisen (He and Giusti, 2010; Pina et al., 2012).

## Structural Features

Anthocyanins belong to the family of flavonoids and their basic structure consists of an aglycone (known as anthocyanidin) derived from the 2-phenylbenzopyrylium (flavylium) skeleton diversely hydroxylated/methoxylated. Anthocyanins are generally represented as positively charged flavylium cations (Fig. 1), which are the dominant equilibrium forms in strongly acidic aqueous solutions (see below).

About 30 anthocyanidins have been identified in nature (Table 1), although only six are widespread, with more than 90% of the naturally occurring anthocyanins based on them; these are: cyanidin (around 31%), delphinidin (22%), pelargonidin (18%), petunidin, peonidin, and malvidin (21% together) (Andersen, 2008). They share the same hydroxylation pattern in 3, 5, 7 and 4' positions, and differ in the number of hydroxyl and methoxyl groups at 3' and 5' in the B-ring. Less common anthocyanidins include those additionally hydroxylated at C6 or methoxylated at 5 or 7 positions on the A-ring, and the 3-deoxyanthocyanidins that lack the hydroxyl group at position 3.

The anthocyanin aglycones are quite unstable and seldom found as such in plant tissues and food, although the natural presence of free anthocyanidins, especially cyanidin, delphinidin and pelargonidin, has been reported in dried beans (*Phaseolus* spp) (Macz-Pop et al., 2006b).

Most anthocyanins are glycosylated on the hydroxyl at position 3; additional glycosylation may exist at 5, 7, 3', or 5', and more rarely at 4' (Brouillard, 1988). Unusual anthocyanins bearing sugar functional groups only in 3' position have also been reported (Fossen and Andersen, 1999), as well as C-glycosyl anthocyanins (Saito et al., 2003). The most common substituting sugar is glucose (90%), followed by rhamnose, galactose, xylose and arabinose; glucuronic acid is the rarest monosaccharide found (Andersen and Jordheim, 2006). Several di- and trisaccharides, such as rutinose (6-O- $\alpha$ -L-rhamnosyl-D-glucose), neohesperidose (2-O- $\alpha$ -L-rhamnosyl-D-glucose), sophorose (2-O- $\beta$ -D-glucosyl-D-glucose), sambubiose (2-O- $\beta$ -D-xylosyl- $\beta$ -D-glucose), xylosylrutinose or glucosylrutinose are also found as sugar moieties (Andersen and Jordheim, 2006).

Sugars may be substituted by aliphatic, hydroxybenzoic or hydroxycinnamic acids; the most usual are malonic, acetic, *p*-coumaric, and caffeic acids, although acylation with oxalic, succinic, malic, *p*-hydroxybenzoic, gallic, vanillic, syringic, protocatechuic, ferulic and sinapic acids can also occur. Polyacylated anthocyanins that contain chains consisting of multiple glycosyl and acyl groups have been described, being particularly reported in flowers from different plant species (Goto and Kondo, 1991). It has been estimated that more than 65% of naturally occurring anthocyanins are acylated (Andersen and Jordheim, 2006), being malonic acid the most frequent acyl moiety.

Un-like usual anthocyanins, 3-deoxyanthocyanidins are commonly found as free aglycones in plants. Nevertheless, these compounds have much restricted distribution, being present in mosses and ferns, as well as in certain members of the Poaceae, Gesneriaceae, Sterculiaceae or Bignoniaceae families among higher plants (Harborne, 1966; Iacobucci and Sweeny, 1983). Sorghum is the known major edible source of these compounds, especially apigeninidin and luteolinidin (Dykes and Rooney, 2006), whereas tricetinidin is formed in black tea from the enzymatic oxidation of epigallocatechin-3-O-gallate (Coggon et al., 1973). The leaves of

*Arrabidaea chica* (syn. *Bignonia chica*), traditionally used by the indigenous populations of the Amazonia for body painting and cloth dyeing, are rich sources of carajurin, arrabidin and carajurone (Devia et al., 2002).

## Anthocyanin-Related Pigments

Pyranoanthocyanins are an important group of anthocyanin-derived pigments that possess an additional pyranic ring in the anthocyanin structure (Fig. 2). They were identified over twenty years ago in red wines (Fulcrand et al., 1996; Bakker and Timberlake, 1997), where they are formed during winemaking and ageing from the cycloaddition onto the carbon 4 and the hydroxyl at position 5 of anthocyanins of different products from the yeast metabolism (e.g., acetaldehyde, pyruvic acid, diacetyl, acetone or acetoacetic acid) or coming from the grape (e.g., flavan-3-ols, hydroxycinnamic acids). All these pigments possess the same basic structure, as presented in Fig. 2, and differ in the type of substituents linked at position C-10 on ring D. A second generation of more complex pyranoanthocyanins that are not derived from anthocyanins but from other previously formed pyranoanthocyanins was further described in Port red wines, such as the so-called portisins, oxovitisins or pyranoanthocyanin dimers (de-Freitas and Mateus,

**Figure 2** Basic structure of pyranoanthocyanins. Positions 3' and 5' may be hydroxylated or methoxylated depending on the parent anthocyanin. Substituent R10 varies as a function of the precursor and defines the different classes of pyranoanthocyanins (see **Table 2**).

2011; Oliveira et al., 2014). A summary of the different types of pyranoanthocyanins that have been described in red wines is collected in **Table 2** together with their precursors. Some pyranoanthocyanins have also been found as naturally-occurring in plants or other foodstuffs like blackcurrant seeds (Lu et al., 2002), red onion (Fossen and Andersen, 2003), strawberries (Andersen et al., 2004), or blood orange (Hillebrand et al., 2004), black carrot (Schwarz et al., 2004) and berry juices (Rein et al., 2005).

Rosacyanins are a particular type of pyranoanthocyanidins that were isolated from petals of *Rosa hybrida* (Fukui et al., 2002; Fukui et al., 2006), namely the violet pigment rosacyanin B (**Fig. 3**) and their blue analogues rosacyanins A1 and A2 that contain ellagitannin moieties linked to the anthocyanidin nuclei. These pigments are present in the plant in the form of aglycones. A non-glycosylated pyrano-3-deoxyanthocyanidin derived from apigeninidin was also identified in red *Sorghum bicolor* (Khalil et al., 2010). Similar pigments were further synthesized by Sousa et al. (2013) that give them the name of deoxyvitisins (**Fig. 3**).

Other anthocyanin-related pigments that have been found in natural sources in non-glycosylated form are sphagnorubins (**Fig. 4**), a type of red pigments described in mosses from some *Sphagnum* species (Mentlein and Vowinkel, 1983), and riccionidins (**Fig. 4**) found in liverworts (Kunz and Burkhardt, 1994) and root cultures of *Rhus javanica* (Taniguchi et al., 2000).

Oligomeric pigments where anthocyanins are covalently linked to other flavonoids have also been described in some natural sources. Anthocyanin-flavonol conjugates were identified in flowers of different plants such as orchids (Strack et al., 1989), chive (Fossen et al., 2000) or *Agapanthus* spp (Bloor and Falshaw, 2000), whilst similar anthocyanin-flavone derivatives have been isolated from *Eichhornia* flowers (Toki et al., 2004). Pigments from the direct condensation between anthocyanins and flavan-3-ols (**Fig. 5A**) have been long indicated to be formed in red wines during winemaking and ageing (Jurd, 1969) and their presence further confirmed

**Table 2** Classes of pyranoanthocyanins identified in red wines

Type	Structure	Precursors
Non-substituted pyranoanthocyanins (B-type vitisins)		Anthocyanins + ethanal
Carboxypyrananthocyanins (A-type vitisins)		Anthocyanins + pyruvic acid
Methylpyrananthocyanins		Anthocyanins + acetone or acetoacetic acid

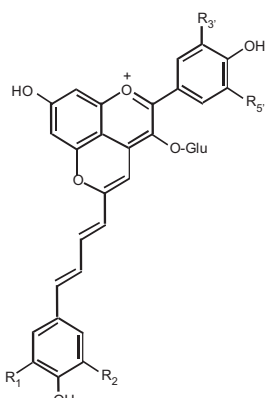

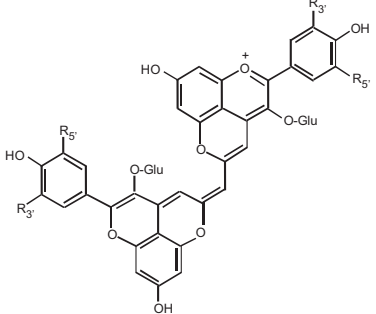

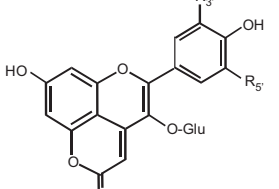

**Table 2** Classes of pyranoanthocyanins identified in red wines—cont'd

Type	Structure	Precursors
Acetylpyranoanthocyanins		Anthocyanins + diacetyl
Phenyl-pyranoanthocyanins (pinotins)		Anthocyanins + hydroxycinnamic acids or vinylphenols
Flavanol-pyranoanthocyanins		Anthocyanins + vinylflavanols or flavan-3-ols and acetaldehyde
Vinylflavanol-pyranoanthocyanins (A-type portisins)		Carboxypyrananthocyanins + vinylflavanols or flavan-3-ols and acetaldehyde
Vinylphenyl-pyranoanthocyanins (B-type portisins)		Carboxypyrananthocyanins + hydroxycinnamic acids or vinylphenols

(Continued)

**Table 2** Classes of pyranoanthocyanins identified in red wines—cont'd

Type	Structure	Precursors
Phenyl-butadienylidene-pyranoanthocyanins		Methylpyranoanthocyanins + hydroxycinnamaldehydes
Pyranoanthocyanin dimers		Carboxypyrananthocyanins + methylpyranoanthocyanins
Pyranone-anthocyanins (oxovitisins)		Carboxypyrananthocyanins + water

**Figure 3** Structures of particular non-glycosylated pyranoanthocyanidins. (A) Rosacyanin B (Fukui et al., 2002), (B) pyrano-apigeninidin 4-vinylphenol (Khalil et al., 2010), and (C) malvidin-derived type-A deoxyvitisin (Sousa et al., 2013).

**Figure 4** Structures of sphagnorubins (left) and riccionidins (right).

**Figure 5** Structures of different anthocyanin-related pigments. (A) Flavanol-anthocyanin condensed pigments; (B) pigments from the anthocyanin-flavanol condensation mediated by acetaldehyde, and (C) an oaklin (guaiacylcatechinpyrylium).

(Remy et al., 2000; Salas et al., 2004). Similar pigments have been found in extracts of different fruits and grains, such as strawberries (Fossen et al., 2004), black currant concentrates (McDougall et al., 2005), purple corn and red grape skin (González-Paramás et al., 2006), fig (*Ficus carica*) (Duenas et al., 2007) or dried beans (Macz-Pop et al., 2006a). Nevertheless, it is not totally clear whether these pigments actually occur in the plant or they are artefacts produced during extracts preparation or storage. Pigments from the condensation between anthocyanins and flavan-3-ols mediated by acetaldehyde (Fig. 5B) are another type of oligomeric anthocyanins that have also been described in red wines and assigned a crucial role in wine color evolution (Timberlake and Bridle, 1976). The presence of anthocyanin dimers has also been reported in grapes and red wines (Vidal et al., 2004; Alcalde-Eon et al., 2007), as well as that of oaklins (Fig. 5C), a type of anthocyanin-like brick-red pigments that are formed in red wines aged in oak barrels from the reaction between catechins and wood cinnamic aldehydes, such as sinapaldehyde or coniferaldehyde (Sousa et al., 2005).

## Anthocyanins Equilibria

In aqueous solutions anthocyanins exist in various equilibrium forms following different reactions (proton transfer, hydration, tautomerization) of the flavylium cation determined by the pH value. The basic mechanisms of these transformations were established by Brouillard and coworkers in the 1970s (Brouillard and Dubois, 1977; Brouillard and Delaporte, 1977; Brouillard et al., 1978) and are summarized in Fig. 6.

The flavylium cation ( $AH^+$ ), which shows a red color in common anthocyanins, is the predominant form in strongly acidic solutions ( $pH < 2$ ). The positive charge is delocalized through all the pyrylium moiety, although carbons 2 and 4 are the more positively charged atoms (Brouillard et al., 2010). In slightly acidic to neutral solutions, as the pH increases, competition occurs between two reactions: (a) deprotonation of the acidic hydroxyl groups to yield purple/blue quinonoidal bases (A), and (b) hydration of the flavylium cation to give colorless hemiketal forms also referred to as carbinol pseudo-bases (B). Although both positions 2 and 4 of the flavylium cation are charge-defective and susceptible to nucleophilic attack, the hydration reaction mainly takes place at C-2, since the formation of the 4-hydroxy adduct is thermodynamically less favored. The hemiketal form can eventually undergo a ring opening with the formation of the also almost colorless *cis*-chalcone ( $C_E$ ) by a tautomeric process, followed by further isomerization to the *trans*-chalcone ( $C_Z$ ) form (Pina et al., 2012; Brouillard et al., 2010). From the flavylium

**Figure 6** Scheme of the pH-dependent equilibria between main anthocyanin forms.

cation forward, the reactions in anthocyanins equilibria are endothermic, so that chalcone formation is favored by the increase in the temperature. Acidification reverts the equilibria to the flavylium cation; nevertheless, while there is a quick reversion from the hemiketal, the reconversion of the chalcone to  $AH^+$  is very slow and more than 1 h may be required to re-establish equilibrium (Iacobucci and Sweeny, 1983).

By their part, at pH values close to neutrality, the quinonoidal bases undergo a second deprotonation leading to more bluish resonance-stabilized quinonoidal anions ( $A^-$ ). The proton transfer is faster than the hydration reaction, lasting from microseconds to several seconds, respectively (Brouillard and Dubois, 1977). However, the hemiketal ( $B$ ) and chalcone species ( $C_E$ ,  $C_Z$ ) are more stable than the quinonoidal forms ( $A$ ), so that while these latter are rapidly formed as a kinetic product, later they totally or partially disappear in favor of the colorless species as the thermodynamic equilibrium is reached (Pina et al., 2012). However, in planta, the colorless forms ( $B$ ,  $C_E$ ,  $C_Z$ ) are rare, indicating the existence of vacuolar mechanisms that stabilize the colored species, such as copigmentation and metal complexation, which are described below.

In contrast to the 3-substituted flavylium derivatives, quinonoidal bases of 3-deoxyanthocyanins are quite stable and predominate over the colorless hemiketal (Devia, 2003). Actually, carajurin, the first isolated deoxyanthocyanin, was obtained in the form of the quinonoidal base (Chapman et al., 1927).

## Anthocyanin Color and Stability

The stability of the anthocyanins is affected by several factors like their structure, pH, temperature, concentration, oxygen, light and presence of other coexisting components, such as nucleophiles, copigments, metal ions or antioxidants, factors that also have a strong impact on their color. For the six most common anthocyanidins, the stability is influenced by the pattern of substitution in the B-ring, decreasing with the number of hydroxyls and increasing with that of methoxyls. Pelargonidin would be the most stable anthocyanidin, followed by malvidin, peonidin, petunidin, cyanidin and delphinidin. B-ring substitution also affects the color increasing the blue tint with the number of substituents. Nevertheless, anthocyanidins are quite unstable and suffer easy degradation in slightly acidic to neutral mediums as those existing in foods and beverages. Both glycosylation and acylation are stabilizing factors, so that anthocyanins are more stable than their parent aglycones (Iacobucci and Sweeny, 1983).

As above indicated, anthocyanins are usually glycosylated at position 3; further glycosylation at position 5 improves the stability and, thus, 3,5-*O*-diglycosides are more stable than corresponding 3-*O*-glycosides (Hrazdina et al., 1970). Acylated derivatives are generally more resistant to hydration than non-acylated counterparts, showing higher color stability in weakly acidic or neutral solutions. Thus, acylated anthocyanins, such as those present in black carrot, red radish or red cabbage, can provide acceptable color at slightly acidic pH values (Giusti and Wrolstad, 2003). These compounds are not only more stable to pH changes but also against

light and heat. Both aromatic and aliphatic acylation improve stability, but in the first case a blue shift in anthocyanin color is produced that is not observed for aliphatic acylation (Giusti and Wrolstad, 2003).

Bisulfite ions ( $\text{HSO}_3^-$ ), present in food as a result of the addition of sulfite preservatives, act as nucleophiles and attack the flavylium, producing colorless sulfonate adducts, which lead to anthocyanin discoloration. The reaction mostly takes place on C-4 position, which is less sterically hindered than C-2 and it is reversible in a variable extent upon acidification, depending on the anthocyanin and the pH value (Berke et al., 1998). When the position 4 of the pyrylium ring is occupied, the anthocyanins are less susceptible to the nucleophilic attack and subsequently they are totally or partially resistant to bleaching effect of water or bisulfite. This is one of the reasons for the greater color stability of the pyranoanthocyanins and other anthocyanin-derived pigments, as those formed in red wines (de Freitas and Mateus, 2011). Depending on their class, pyranoanthocyanins present different colors that range from yellow to turquoise blue color, through orange, red or purple, which are quite stable within the range of pH existing in most foods and beverages (Oliveira et al., 2014).

The lack of the hydroxyl group in position 3 greatly improves the stability of the anthocyanidins, so that 3-deoxyanthocyanins are much more stable to pH changes than common anthocyanins, showing greater resistance to color bleaching by water or sulfur dioxide, as well as increased stability against ascorbic acid and thermal degradation (Awika et al., 2004; Ojwang and Awika, 2008; Yang et al., 2014). As above indicated, these compounds can be commonly found in nature as free aglycones, and show yellow to orange colors in acidic media (Awika et al., 2004), in contrast with common anthocyanins that possess red to purple hues.

Phenolic compounds with catechol groups are known to possess antioxidant properties, related to their ability to scavenge free radicals by donation of phenolic hydrogen atoms to form relatively stable phenoxyl radicals, and metal chelating capacity (Heim et al., 2002). This activity is expected for cyanidin, delphinidin and petunidin, which would also be the anthocyanins most susceptible to oxidation. The antioxidant capacity of some fruits and vegetables, such as berries, has been related to their anthocyanin content, as well as their protective effects against degenerative and chronic diseases (Heinonen, 2007).

Ascorbic acid, either naturally present or incorporated to food as an additive, induces the degradation of anthocyanins in the presence of oxygen, leading to their bleaching through a mechanism that has been related to ascorbic acid auto-oxidation and may involve the oxidative cleavage of the pyrylium ring (Iacobucci and Sweeny, 1983). Light exposure also speeds anthocyanin degradation by a photo-oxidative mechanism regardless of the pH of the medium, whereas the increase in the temperature leads to the degradation of the anthocyanins by favoring heterocycle ring opening and further cleavage (Furtado et al., 1993).

## Copigmentation and Metal Complexation

In intact plant tissues stabilizing mechanisms exist that contribute to protect anthocyanin color from its degradation and pH-dependent changes. Among them, the most widespread are copigmentation and metal complexation and combinations of both (Brouillard et al., 2010).

Copigmentation consists of a hydrophobic  $\pi$ - $\pi$  molecular non-covalent interaction between the planar polarizable nuclei of the colored forms of the anthocyanins with other organic molecules (i.e., copigments). Copigmentation complexes adopt a vertical stacking (sandwich configuration) that protects the flavylium chromophore from the attack of water and other nucleophilic species like sulfur dioxide, thus preventing at least in part the formation of the colorless adducts. This results in an enhancement and generally a modification in the original color of the pigment containing solution. Thus, at the same time color stabilization and variation can be obtained (Brouillard and Dangles, 1993). The copigmentation effect is evident in weakly acidic to neutral conditions where anthocyanins should mostly exist under colorless forms, and it is well known to occur in plant tissues offering an explanation for the large color variations in flowers and fruits (Goto and Kondo, 1991). However, its contribution to the color in processed foods and beverages is more debatable, due to their lower anthocyanin and copigment concentrations compared to those existing in plant vacuoles. Despite it and the dissociating effects of ethanol on the formation of copigmentation complexes, this process is believed to play a relevant role on color definition in young red wines (Santos-Buelga and de Freitas, 2009).

Copigments are generally colorless and can have different chemical nature, including most polyphenols, but also alkaloids, amino acids, nucleotides, organic acids and some carbohydrates, their efficiency depending on their chemical structures (Escribano-Bailón and Santos-Buelga, 2012). Copigmentation may also occur among anthocyanins themselves, in whose case is also referred to as self-association. This is observed at increasing the concentration of anthocyanins in the medium, which results in a positive deviation from Beer's law, and it is accepted to contribute to the color expression in flowers (Hoshino, 1991).

Another-type of copigmentation is intramolecular copigmentation, where the anthocyanin chromophore interacts with other residues of its own molecule. Such residues are generally hydroxycinnamic acids attached to the anthocyanidin chromophore through one or more sugar units that would act as "spacers", allowing the molecule to fold in such a way that the  $\pi$ -orbitals of the aromatic acyl group(s) can interact with the benzopyrylium nucleus and protect it from hydration (Dangles et al., 1993). Intramolecular copigmentation has the entropic advantage of the copigment being directly attached to the chromophore and consequently the non-requirement of bringing together two molecules initially separated in solution. Those structures are found in many plants and give rise to pigments that are colored through a wide range of pH values (Brouillard et al., 2010).

A process that also influences the color of the anthocyanins is metal complexation. Anthocyanins possessing an o-dihydroxyl substitution (catechol group) in their ring B (e.g., derivatives of cyanidin, delphinidin and petunidin) are able to form complexes with di- or trivalent metals leading to changes in color. Metals most commonly involved in the formation of metalloanthocyanins are iron (III), magnesium (II) and aluminium (III). Metals selectively link with the quinonoidal forms of the anthocyanins,

especially with the anionic quinonoidal bases that result from the deprotonation of the hydroxyls on 4' and 7, which show high acidity at weakly acidic pH values (Brouillard et al., 2010). Metal complexation and hydration are competitive processes, so that as a result of the association with the metal cation, anthocyanin equilibria are displaced to the formation of quinonoidal bases, provoking a bathochromic shift of the absorption spectrum and a change of the color to more violet hues (Dangles et al., 1994). Ternary complexes anthocyanin:metal:copigment can also be formed where the metal links to both pigment and copigment, strengthening the copigmentation effect (Takeda et al., 1990). This type of associations has been indicated to contribute to the blue color in some flowers (Goto and Kondo, 1991; Goto et al., 1986).

## Occurrence in Food and Dietary Intake

As above indicated, most of the anthocyanins occurring in foods are derived from six anthocyanidins: cyanidin, delphinidin, petunidin, peonidin, pelargonidin, and malvidin, being cyanidin glycosides the most commonly found in fruits and vegetables.

The most commonly eaten anthocyanin sources belong to the fruits in family Rosaceae (blackberries, raspberries, strawberry, cherries, plums, apples), whose composition is based on cyanidin derivatives as major anthocyanins (Andersen and Jordheim, 2013). The total anthocyanin content reported to occur in fruits varied from a few milligrams to more than 1000 mg per 100 g (fw), with higher levels present in some commonly consumed berries, such as blackcurrants, blackberry, blueberries or chokeberry (Andersen and Jordheim, 2013; Clifford, 2000). Anthocyanins are also abundant in certain cereals and leafy and root vegetables, such as pigmented potatoes, eggplant, cabbage, beans, or red onion, with higher values found in purple corn and purple sweet potato (*Ipomoea batatas*) reaching contents as high as 1400 mg/100 g (Andersen and Jordheim, 2013; Clifford, 2000).

Anthocyanins in the vegetables are considerably more complex than those of the fruits. The proportion of anthocyanins without acyl groups and just one or two monosaccharide units is 74% in fruits, whereas above 77% of the anthocyanins in the vegetables have one or more acyl groups, generally aromatic acyl groups. The families Brassicaceae (red cabbage, radish), Apiaceae (purple carrot), Solanaceae (purple potato), and Convolvulaceae (purple sweet potato) are especially rich in anthocyanins with aromatic acylation. Among fruits, only 23% of the anthocyanins contain acyl groups and 11% have just one aromatic acyl group (Andersen and Jordheim, 2013).

The qualitative and quantitative anthocyanin content in processed products have been much less studied than the anthocyanin content of intact plant sources, except for red wine. The anthocyanin composition in processed products usually reflects that of the original fruit or vegetable, although there are huge variations in their contents depending on the methods of processing and storage conditions. In red wines the intact anthocyanins (mainly malvidin-3-O-glucoside and its derivatives) are present in considerable amounts in young wines (accounting for around 200 mg/L to more than 500 mg/L). Anthocyanin levels notably decrease during wine ageing and storage, until their almost completely disappearance, at the same time that they are replaced by other more stable anthocyanin-derived pigments (de Freitas and Mateus, 2011; Fulcrand et al., 2006). Although less studied, similar reactions may also take place in other processed products like jams or juices during processing and storage (Fukui et al., 2002).

There are large variations in the anthocyanin intake depending on the country, season and dietary habits, especially related to the consumption of fruits, berries and red wine. A first estimation of the average daily intake of anthocyanins was made by Kühnau (1976) that situated it in the range of 180–215 mg, although further reports offer much lower daily consumptions. Dietary intakes of 3.1 mg/day (Chun et al., 2007) and 12.5 mg were estimated for US adults (Wu et al., 2006), whereas mean values of 47 mg/day (Ovaskainen et al., 2008) and 82.5 mg/day (Heinonen, 2007) were calculated in Finland and explained by the high berry consumption. An estimate of 18.9 mg/day was made by Zamora-Ros et al. (2010) for a Spanish adult population, with a relevant contribution of red wine, which accounted for up to 46% of the anthocyanin intake. In general, Andersen and Jordheim (2013) estimated that the average adult intake of anthocyanins in Western countries could be on the scale of 10 mg/day. More studies are, however, required regarding anthocyanin consumption according to the country and the consumers' profiles, taking into account that not only total intake is important but also qualitative composition should have an influence on their putative health promoting effects. Moreover, attention will also have to be paid to the increasing popularity of food supplements and the developing market for functional foods, as they may contribute substantially to a rise in the dietary intake levels (Santos-Buelga et al., 2014).

Actually, a serious limitation to investigate the relation between anthocyanin consumption and health promotion is the difficulty to make adequate estimations of their dietary intake. Data on anthocyanins and other phytochemicals contents in selected foods are already collected in some databases, such as the US flavonoids database (<http://www.ars.usda.gov/Services/docs.htm?docid=6231>), the Canadian FoodDB (<http://foodb.ca/>), or the European eBASIS (Bioactive Substances in Food Information Systems; <http://ebasis.eurofir.org/Default.asp>), Phenol-Explorer (<http://phenol-explorer.eu/>) and PhytoHub ([www.phytohub.eu](http://www.phytohub.eu)). Also, the EU PlantLIBRA initiative (PLANT food supplements: Levels of Intake, Benefit and Risk Assessment; [www.plantlibra.eu](http://www.plantlibra.eu)) was fostered with the aim of gathering knowledge on plant food supplement bioactive compounds. However, accurate data on the qualitative and quantitative anthocyanin composition in foods and beverages are not always available and they are also difficult to obtain, owing to their structural diversity, distribution across a wide range of products, and the strong influence of agronomic and environmental factors on their contents and profiles (Andersen and Jordheim, 2013; Santos-Buelga et al., 2014). Besides, further changes may take place during food processing, storage and culinary preparation, owing to their instability and the formation of anthocyanin-derived products, whose significance and putative biological activities are still to be established. In these circumstances, the description of adequate biomarkers could represent a promising alternative to traditional dietary assessments in order to estimate the exposure to different phytochemicals, including anthocyanins and other polyphenols (Zamora-Ros et al., 2014).

## Anthocyanins as Food Additives

Anthocyanins are approved as natural food colorant additives in both the European Union and the United States. They are usually employed in the form of extracts or concentrated juices obtained from different edible plants, so that they may also contain other components of the original plant material, such as organic acids, tannins, sugars or minerals. In the EU, the anthocyanins receive the common code of E-163 regardless of their origin ([Commission Directive, December 2008](#); [Regulation \(EC\) No 1333/2008 of the European Parliament and of the Council of 16, December 2008](#); [Commission Regulation, November 2011](#)), indicating that, at least from a regulatory point of view, they are looked upon as one homogeneous group of harmless compounds ([Andersen and Jordheim, 2013](#)). Several sources are authorized for their extraction, including grape skins, black currants and other berries, purple corn or red cabbage. In the United States, FD&C numbers are only given for synthetic food dyes approved for their use in foods, drugs, and cosmetics, whereas natural colorants are exempt from batch certification. Grape color and grape skin extracts (enocianina) and fruit and vegetable juices are included in this latter category ([US Food and Drug Administration, 2015](#)).

The interest in anthocyanins and other natural pigments as food colorants to replace synthetic dyes has increased significantly over the last years due to safety issues and consumers' concerns. However, the applications of anthocyanins as food colorants are seriously limited due to their problems of stability. They are generally unsuitable for foodstuffs that do not have a sufficiently acidic pH or that contain sulfites, because of the color changes that they suffer in those conditions. Also, they are susceptible to heat degradation, so that they are not well suited for products submitted to high processing temperatures, such as extruded foods. Typical products for anthocyanin addition are soft drinks, acid dairy products like yogurts, or sugar candies and jams, as well as low water activity products like some snack foods. Acylated anthocyanins, as those present in some vegetables like colored potatoes, black carrot, red radish or red cabbage, usually possess greater heat and light stability, so that they are better candidates for their use as colorants ([Giusti and Wrolstad, 2003](#)). The recent description of several classes of anthocyanin-derived pigments, such as pyranoanthocyanins, with greater stability against pH changes and showing a diversity of colors from yellow to bright blue, has opened promising expectations regarding their use as food colorants ([Oliveira et al., 2014](#)). Moreover, owing to their putative health-promoting effects, anthocyanins have also been proposed for their use as nutraceuticals in the formulation of functional foods or dietary supplements, making them multifunctional food additives ([He and Giusti, 2010](#)).

## Overview

Flavor plays an important role in food selection and consequently overall nutrition. Flavor is the integrated response to the simultaneous perception (total sensation) of the taste, odor and chemical feeling factors (somatosensory perceived) characteristics of a substance, and is often influenced by the color, shape, texture and overall appearance or esthetic quality of the product. Although the peripheral sensory organs for detection of taste and smell stimuli are quite distinct, their signals are integrated in the orbitofrontal and other areas of the cerebral cortex of the brain to generate the perception of “flavor” and to mediate food recognition (Chaudhari and Roper, 2010). It is generally accepted by most researchers that olfaction (aroma) plays the dominant role in the flavor of food (Spence, 2015).

This chapter provides an overview of the chemicals responsible for aroma or odor perception and to a lesser degree on the physiology and mechanisms involved in odor perception. The discussion is mainly focused on some important and well-defined aroma compounds and in some cases chemical pathways for the formation of specific aroma compounds are provided. Throughout this chapter it is recognized that more detailed information for certain subjects is covered in much greater detail by other publications. Especially useful resources are provided in the *Further Reading* and *Relevant Websites* sections provided at the end of this chapter.

## Olfaction and Odor Perception

The olfactory system of humans is capable of detecting and discriminating a multitude of odorants with diverse chemical structures and widely varying concentrations (Zarzo, 2007; DeMaria and Ngai, 2010). Odorants are transported, by either orthonasal or retronasal pathways, to the olfactory mucosa, which contains millions of bipolar olfactory neurons (Hutchins, 2017). Each neuron contains a single dendrite with multiple (10–20) cilia that are embedded in the surface mucosa and each cilium contains numerous receptor membrane proteins which can interact with different odorant molecules (Menini et al., 2004). Unbound hydrophilic odor molecules diffuse across the layer of mucus, whereas hydrophobic odors must become bound to a specific odorant binding protein to be transported to each cilium for interaction with specific receptors. All of these receptors have the same general structure, seven hydrophobic transmembrane regions, but the amino acid sequence within the cylinders spanning the membrane are extremely diverse which permits the discrimination of a large number of odorants.

Odorant molecules bind reversibly to the odorant receptors which are composed of a diverse group of G-protein coupled receptors. The binding of an odorant activates adenylyl cyclase leading to the formation of cAMP, which triggers a cascade of events that ultimately lead to a nerve signal (Firestein, 2001). Individual odorant molecules stimulate multiple receptors and neurons across the olfactory mucosa to produce spatial patterns of activity that code for its odor character and intensity (Malnic et al., 1999).

## Odor Quality

The way in which people perceive and classify the odor quality of an aroma substance is as much a matter of perceptual learning and memory as it is sensitivity to the odorant (Stevenson, 2001). In general, people can discriminate among individual odors, but are generally poor at naming them (Jöhnson et al., 2005; Stevenson et al., 2007; Frank et al., 2011; Kaeppler and Mueller, 2013). The perceived odor quality of a single odorant is mainly related to its chemical structure. However, food aromas are not composed of single odorants but are instead complex odorant mixtures. The recognition and categorization of perceived smells emanating from odorant mixtures is complex (Thomas-Danguin et al., 2014). Studies have shown that people can identify only about three odorants in mixtures containing up to eight odorants (Laing and Jinks, 2001). But people do not generally perceive and process odor mixtures in this way, but instead as a global mixture percept, referred to as odor object perception (Rescorola et al., 1985). This means that complex olfactory information is coded and stored in the brain as perceptual odor objects which are later recalled. Odor objects or odor quality attributes are believed to be concentration invariant and mainly a function of the defined ratios of the perceived odorants in a mixture (Cleland et al., 2007). For example, a strawberry or a mixture of strawberry aroma components in the correct ratios would be perceived, stored and later recalled as a strawberry odor object. In some instances, people may respond to only a single odorant or just a few odorants in a food containing a complex mixture of odorants. These are often the character-impact odorants of that food, or if these odorants are considered to be unusual or foreign to that food they might be perceived as off-odors or taints.

## Aroma Substances

Not all volatile compounds have perceivable odors in foods. In many food products it is possible to identify thousands of volatile compounds; however, only a few (estimated to be ~3%) of these are actually odor-active and contribute substantially to the overall aroma or flavor of the product (Dunkel et al., 2014). Often a volatile compound has a detectable odor at high concentrations, but

cannot be detected at the low levels at which it is typically found in a food product. Therefore, when we speak of aroma substances, we generally refer to only those volatile compounds that have perceivable odors at relatively low concentrations and which exceed their odor detection thresholds.

### Odor Threshold and Odor Activity (Value)

The human nose is an extremely sensitive and specific chemical detector. One measure of the potency of an aroma substance is its odor detection threshold. The odor detection threshold of a substance is the lowest concentration required to elicit an odor response. Some odorants can be detected at sub parts-per-trillion (ppt, ng/L) levels, while others must be present at parts-per-billion (ppb, µg/L), parts-per-million (ppm, mg/L) or even higher concentrations in order to elicit odors. **Table 1** illustrates the enormous odor threshold differences that exist among aroma compounds with the same aliphatic nine-carbon backbone structure but which differ in their functional groups. In addition to general structural features the stereochemistry and absolute configuration (chirality) of a molecule is often also important to its perceived odor quality and odor detection threshold (Brenna et al., 2003). For example, linalool, which has a single chiral center (at carbon 3), can exist in two chiral forms (3S and 3R). It is known that the S and R enantiomers can evoke different neural responses in humans and therefore each possesses a distinct odor (Sugawara et al., 2000) and odor detection threshold, e.g., 0.8 ppb for the 3R-enantiomer versus 7.4 ppm for the 3S-enantiomer (Padrayuttawat et al., 1997).

Thresholds can vary widely both within and across individuals. In addition, some people lack sensitivity to specific odor-active compounds. That is, they are *anosmic* to these odor stimuli. To further complicate matters, detection thresholds for specific aroma compounds depend on their vapor pressures, which are influenced by temperature and the food matrix (or medium) in which they exist. Also, some aroma compounds may undergo odor quality (attribute) changes as a function of concentration (Gross-Isseroff and Lancet, 1988).

One way of gauging or estimating the impact of a compound on a food's aroma is based on its odor-activity value (OAV), sometimes referred to as aroma value or odor unit. An OAV is a dimensionless number and is defined as the ratio of the concentration of an odorant in a food to its odor detection threshold value of the odorant in a suitable matrix (i.e., which mimics that of the food). Based on this concept, compounds having high OAVs should make the greatest contribution to the overall aroma of the food under investigation. However, this assumes that the aroma compounds are below levels that saturate the olfactory receptors. In fact, the olfactory sense can only accommodate a relatively narrow range of response differential for most aroma compounds. The effect of concentration (dose) on the perceived odor intensity can vary greatly among different aroma compounds. This relationship is governed by the Stevens' Power Law (Stevens, 1971). For this reason OAVs do not necessarily allow for accurate ranking of aroma compounds by intensity (or odor importance) in a food. Nevertheless, OAVs are still a common way of providing a preliminary ranking of the relative importance of aroma compounds in foods. As an example, the concentrations and OAVs for the main aroma components of a lemon-lime carbonated beverage are compared in **Table 2**.

**Table 1** Odor detection thresholds for some aliphatic nine-carbon aroma compounds

Compound	Odor Quality	Threshold (µg·L <sup>-1</sup> ) <sup>a</sup>
Nonanoic acid	Fatty, soapy	3000
Nonan-1-ol	Melon	50
Nonanal	Pungent, fatty	1
(E)-2-nonenal	Fatty, hay	0.08

<sup>a</sup>Odor detection threshold in water (Buttery et al., 1988).

**Table 2** Concentrations, odor thresholds and odor-activity values (OAV) for selected potent aroma components of a lemon-lime flavored carbonated beverage

Compound	Cncn (µg·kg <sup>-1</sup> )	Threshold (µg·L <sup>-1</sup> )	OAV
Octanal	585	0.7	836
limonene	3220	10	322
Decanal	341	2	171
Linalool	483	6	80.4
Nonanal	61.5	1	61.5
Geranyl acetate	248	9	27.6
Geranial	874	32	27.3
1,8-Cineole	19.0	1.3	14.6
Geraniol	321	40	8

### Aroma Analysis by Combined Instrumental-Sensory Methods

Being able to distinguish the predominant and characterizing aroma components of a food system, so called character-impact components, from the other odorless or less important aroma components is a difficult task, and sometimes this is not feasible if a large number of compounds make a seemingly equal contribution to the aroma. Individual aroma-significant volatile components are generally present at low parts-per-million ( $\mu\text{g}\cdot\text{kg}^{-1}$ ), parts-per-billion ( $\text{ng}\cdot\text{kg}^{-1}$ ), and sometimes part-per-trillion ( $\text{pg}\cdot\text{kg}^{-1}$ ) levels, making the detection and identification of these compounds difficult. Nonetheless, due to modern advances in analytical chemistry, especially application of instrumental-sensory techniques, like gas chromatography-olfactometry (GC-O) combined with GC-mass spectrometry and sensory analysis of aroma models, significant progress has been made toward our understanding of the aroma chemistry of foods (Grosch, 2001; Marsili, 2007; Dunkel et al., 2014). Such efforts have eventually led to the identification of character-impact components in various foods. Some examples of character-impact compounds are given in Table 3.

### Formation and Occurrence of Aromas in Foods

There are numerous ways in which flavor systems can be classified. In foods there exists a great diversity of classes (alcohols, aldehydes, ketones, acids, esters, amines, etc.) of aroma compounds. The diversity of chemical structures indicates the involvement of numerous chemical reactions in the formation of food aromas. Even in aroma systems as seemingly different as vegetables and cooked meats there are numerous common reactions that produce similar or overlapping aroma profiles. In this discussion, the chemistry of aroma components will focus on a few general categories, with the understanding that inevitably there will be some overlap in the chemical pathways involved in aroma formation.

### Aroma Biogenesis in Plants

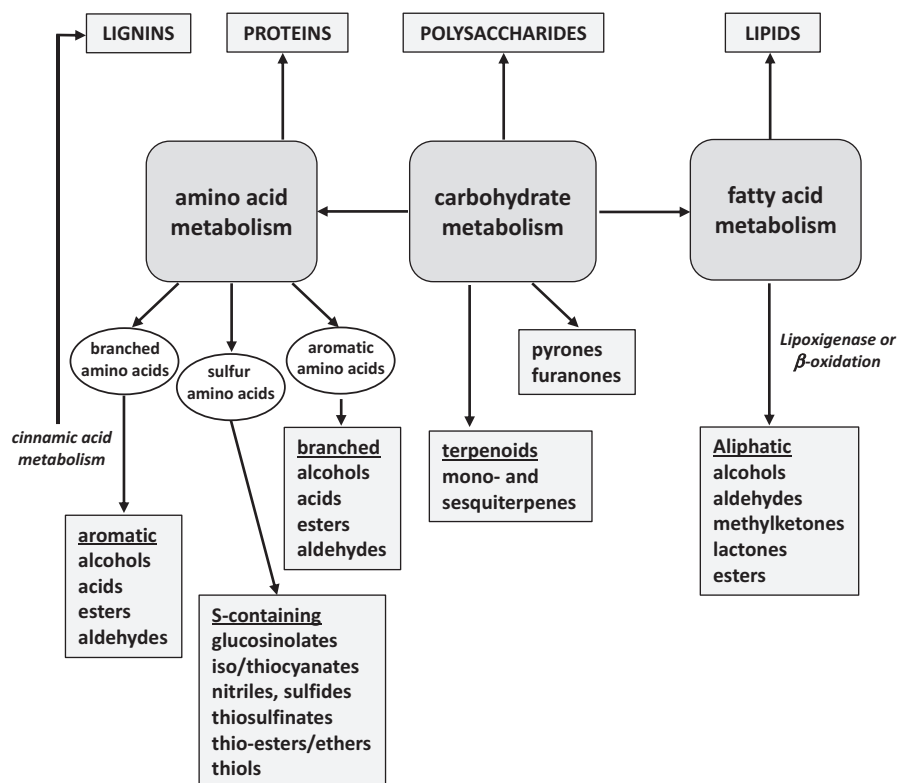

The volatile profiles of fruits and vegetables are composed of a large number of different compound classes, and depending on species, variety, cultivar and/or other factors, one or more these classes may predominate (Cadwallader, 2005; Schwab et al., 2008a). Among the thousands of volatile compounds identified in plants, only a relative few actually contribute to the distinctive aromas of specific fruits and vegetables. The great diversity of the chemical structures indicates the involvement of various biosynthesis pathways and chemical reactions in the formation of plant-derived aroma compounds. In fruits and vegetables there are some common reactions that produce similar or overlapping aroma profiles. The biogenesis and occurrence of aroma compounds in plants has been previously reviewed (Cadwallader, 2005; Schreier, 1986; Leahy and Roderick, 1999; Schwab et al., 2008a). This discussion presents a brief overview of some pathways involved in the biogenesis of aroma compounds in fruits and vegetables. The references cited provide additional information for each pathway mentioned.

The major biosynthetic pathways involved in the formation of aroma compounds in plants are shown in Fig. 1 (Schwab et al., 2008b). Monoterpene ( $\text{C}_{10}$ ) and sesquiterpene ( $\text{C}_{15}$ ) hydrocarbons and their oxygenated derivatives (terpenoids) are formed by enzymes known as terpene synthases (Degenhardt et al., 2009). Acyl pathways play a central role in the metabolism of fatty acids, terpenes, amino acids, and carbohydrates (Tressl and Albrecht, 1986; Leahy and Roderick, 1999). Lipoxygenase and associated enzymes (hydroperoxide lyases, alcohol dehydrogenases and isomerases) are responsible for the breakdown of fatty acids, in particular linoleic and linolenic acids, into  $\text{C}_6$ ,  $\text{C}_8$  and  $\text{C}_9$  volatile aldehydes and alcohols important in the aromas of green plants (Hatahaka, 1996). Fatty acid metabolism, e.g.,  $\beta$ -oxidation of linolenyl-CoA, results in the formation of volatile esters, ketones and alcohols. Hydroxylated fatty acids ( $\text{C}_8$ – $\text{C}_{12}$ ) are also formed *via*  $\beta$ -oxidation and may cyclize (spontaneously) to form  $\gamma$ - and  $\delta$ -lactones (Engel et al., 1989). Branched-chain and aromatic esters are formed *via* amino acid metabolism to give typical fruity aromas (Wyllie et al., 1996). In strawberries, the character-impact compound 2,5-dimethyl-4-hydroxy-3(2H)-furanone is formed *via* metabolism of carbohydrates (Schwab et al., 2008b). Metabolism of carotenoids leads to the formation of aroma significant  $\text{C}_{10}$  and  $\text{C}_{13}$  norisoprenoids (Winterhalter and Rouseff, 2002). Volatile sulfur-containing compounds are of particular importance in the aromas of some plants such as members of the Cruciferae family and *Alliums* and are formed by the action of specific enzymes released after tissue disruption (Cadwallader, 2005).

**Table 3** Examples of some character-impact aroma compounds in foods

Compound	Aroma Quality	Product	Threshold ( $\mu\text{g}\cdot\text{L}^{-1}$ ) <sup>a</sup>
(E,Z)-2,6-nonadienal	Fatty, melon	Fresh-cut cucumber	0.001
2-Methyl-3-furanthiol	Meaty, sulfurous	Cooked meat	0.0004
1-Octen-3-one	Metallic, mushroom	Mushroom	0.005
2-Acetyl-1-pyrroline	Roasted, nutty	Aromatic rice	0.1
Methional	Potato, sulfurous	Potato products	0.2
4-Hydroxy-2,5-dimethyl-3(2H)-furanone	Burnt sugar, caramel	Strawberry, pineapple	0.6
1-(p-Hydroxyphenyl)-3-butanone	Floral, raspberry	Raspberry	10
Vanillin	Vanilla-like	Vanilla	20

<sup>a</sup>Odor detection threshold in water (Rychlik et al., 1998).

**Figure 1** Main pathways and precursors involved in the formation of aroma compounds in plants. Adapted from Tressl, R., Albrecht, W., 1986. Biogenesis of aroma compounds through acyl pathways. In: Parliament, T.H., Croteau, R. (Eds.), *Biogenesis of Aromas*. ACS Symposium Series 317 American Chemical Society, Washington, DC, pp. 114–133 and Schwab et al. (2008).

### Thermal Generation of Aromas

The *Maillard* reaction between amino acids (or other amines) and sugars (or other carbonyls) plays a predominant role in the formation of aroma in thermally treated food (Motttram, 2007). This complex reaction leads to the formation of hundreds of volatile compounds that can be grouped into many chemical classes (Fig. 2). The *Strecker* degradation is an important reaction associated with the *Maillard* reaction which involves the oxidative deamination and decarboxylation of an  $\alpha$ -amino acid in the presence of a dicarbonyl compound to produce a volatile aldehyde, so called *Strecker* aldehyde (Fig. 2). Table 4 contains a list of some of the common odor-important *Strecker* aldehydes, their amino acid precursors and odor detection thresholds. The *Strecker* degradation of cysteine is of particular importance since it leads to the formation of the highly reactive intermediate compounds hydrogen sulfide and ammonia. Hydrogen sulfide can react to form various potent heterocyclic sulfur compounds, e.g., 2-methyl-3-furanthiol, a potent character-impact aroma component of cooked meat (Motttram, 1998a,b).

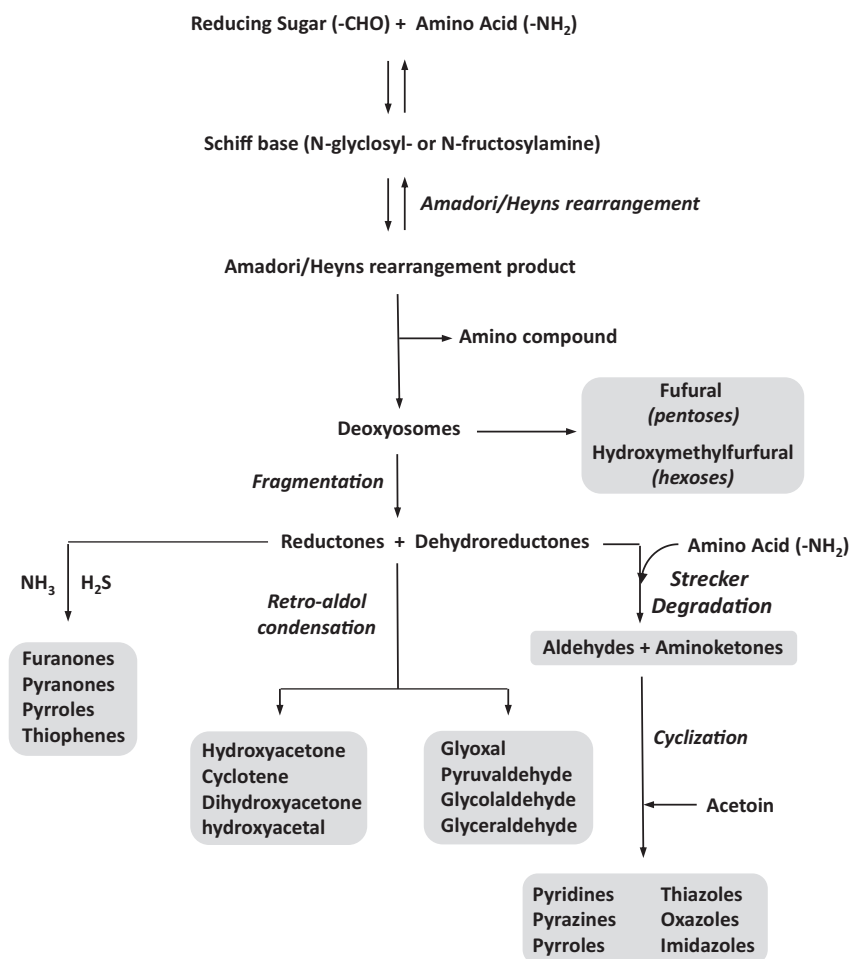

### Lipid Degradation as a Source of Aromas

Degradation of lipids by hydrolytic and oxidative processes leads to the formation of numerous volatile aroma compounds in foods (Table 5). Hydrolytic rancidity is caused by the hydrolysis (lipolysis) of fats or oils (triglycerides) which leads to the release of pungent, rancid or sweaty smelling short-chain free fatty acids such as butyric acid. Lactones, with fruity or coconut-like aroma characteristics, also may be produced from hydroxy fatty acids released by lipid hydrolysis (e.g., in dairy products). In general, oxidation of fats and oils, especially polyunsaturated lipids, is of greater importance than lipolysis, since it is a source of volatile aldehydes and ketones with low odor detection thresholds (Pegg and Shahidi, 2007). These compounds are generally unstable and may be transformed to other volatile compounds through further chemical reactions. For example, the retro-aldol condensation of unsaturated aldehydes, e.g., (*E,E*)-2,4-decadienal to form (*E*)-2-octenal (Table 5), is an important reaction that can further impact the aroma of lipid-containing foods (Josephson and Lindsay, 1987). It is important to note that in addition to forming aroma-active compounds, the oxidative and thermal degradation of lipids gives rise to many volatile compounds (e.g., carbonyls) that also can take part in the *Maillard* reaction (Zhang et al., 1994).

### Fermentation-Derived Aromas

Fermentations have been used for millennia to preserve foods and for modification of food flavors. This section will briefly focus on flavors derived by yeast and lactic acid bacteria fermentations. The aroma components of fermented products can be derived

**Figure 2** Formation of aroma compounds by the Maillard reaction. Adapted from Ho, C.-T., 1996. Thermal generation of Maillard aromas. In: Ikan, R. (Ed.), The Maillard Reaction: Consequences for the Chemical and Life Sciences. John Wiley and Son Ltd. pp 27–53.

**Table 4** Aroma-active Strecker aldehydes found in foods

Compound	Odor Quality	Amino Acid Precursor	Threshold ( $\mu\text{g} \cdot \text{L}^{-1}$ ) <sup>a</sup>
Acetaldehyde	Pungent, yoghurt	Alanine	25
Methylpropanal	Malty, green	Valine	1
2-Methylbutanal	Malty, bug	Isoleucine	2
3-Methylbutanal	Malty	Leucine	0.2
Phenylacetaldehyde	Floral, honey	Phenylalanine	4
Methional	Potato, sulfurous	Methionine	0.2

<sup>a</sup>Odor detection threshold in water (Rychlik et al., 1998).

through primary metabolism or by residual enzymes produced by the organism. The biosynthetic pathways and reactions involved formation of fermentation aromas are often analogous to those previously discussed for aroma biogenesis in plants. Extensive reviews have been published on flavor chemistry of fermented dairy products (Singh et al., 2007), fermented meat products (Toldrá, 2008) and alcoholic beverages (Piggot, 2012). Of particular interest in recent years has been the application of fermentation technology (biotechnology) for the sustainable production of natural aroma compounds (Berger, 2007; Gupta et al., 2015).

### Off-Odors and Taints

Off-odors (off-flavors) and taints can cause severe problems in foods, leading to economic losses due to product recalls, reduced consumer confidence and to potentially a tarnished brand image. Owing to its importance to the food industry numerous

**Table 5** Some important lipid-derived aroma compounds

Compound	Odor Quality	Precursor	Mode of Formation
Butyric acid	Cheesy, fecal	Tributyryl	Hydrolysis (lipolysis)
Hexanal	Green, cut-grass	Linoleic acid	Oxidation
(E)-2-hexenal	Green, cut-leaf	Linolenic acid	Oxidation/isomerization
via (Z)-3-hexenal			
Nonanal	Pungent, fatty	Oleic acid	Oxidation
(E)-2-nonenal	Fatty, hay	Linoleic acid	Oxidation/isomerization
via (Z)-3-nonenal			
(E,Z)-2,6-nonadienal	Fresh-cut cucumber	Linolenic acid	Oxidation/isomerization
via (Z,Z)-3,6-nonadienal			
(E,E)-2,4-decadienal	Fatty, fried	Linoleic acid	Oxidation
(E,E,Z)-2,4,7-decadienal	Fatty, fishy	Linolenic acid	Oxidation
(Z)-4-heptenal	Rancid, fishy	(E,Z)-2,6-nonadienal	Retro-aldol condensation
(E)-2-octenal	Fatty, nutty	(E,E)-2,4-decadienal	Retro-aldol condensation

comprehensive reviews have been published on this subject (Goldenburg and Matheson, 1975; Saxby, 1982; Whitfield, 1986; Mottram, 1998a,b; Jelén, 2006; McGorin, 2007; Pegg and Shahidi, 2007; Reineccius, 1991). For the sake of this discussion off-odors are considered to be the occurrence of any atypical odors resulting from compounds formed by internal deterioration of the food, including chemical reactions and microbial spoilage; whereas, taints result from contamination of the food by foreign chemicals derived from the environment or other external sources (Whitfield, 1986).

Off-odors in foods may result from oxidation, light-catalyzed reactions, nonenzymatic browning, chemical reactions and interactions among food constituents, enzymatic reactions and microbial spoilage. Many of the reactions involved in the formation of off-odors are the same or analogous to those already discussed in previous sections. Oftentimes, compounds that impart a positive aroma character in one instance may cause an off-odor when present in the wrong context or at elevated levels. For example, lipid degradation caused by autoxidation and/or lipolysis is a common source of either desirable aromas or off-odors in foods (Pegg and Shahidi, 2007).

In addition to chemical reactions, certain aspects of plant and animal metabolism can also lead to formation of off-odors. The so called “boar taint” off-odor associated with meat derived from intact male pigs has been attributed to the steroid 5- $\alpha$ -androsterone or “androst-16-en-3-one” which has an ammoniacal and urine-like odor. This is sometimes accompanied by the fecal-smelling tryptophan metabolite 3-methylindole (skatole) (Bonneau, 1982).

As mentioned above, taints as opposed to off-odors, originate from external sources. Taints may be introduced into food materials as a result of exposure to environments or packaging materials contaminated by either synthetic chemicals or chemicals produced or transformed by microbial action. Some common taints of chemical and microbial origins include halogenated phenolic compounds (e.g., trichloroanisole) which cause cork taint in wine (Simpson and Sefton, 2007), as well as the musty/earthy smelling geosmin and 2-methyl isoborneol in aquaculture products (Whitfield, 1988, 1998; Rimando and Schrader, 2003).

## Conclusions

Much has been learned over the past 50 years with respect to our understanding of olfaction and odor perception and on the identities and origins of volatile foodborne odorants involved food aromas. This above discussion is just a small sampling of what is known and available in the vast literature on the subject. However, despite our already great understanding of the subject, the identification and characterization of food aromas will continue to be of interest to food chemists concerned with food quality.

FDA Food and Drug Administration.

### Introduction

While no single factor is responsible for the recent, dramatic increases in overweight and obesity, a scientific consensus has emerged suggesting that consumption of sugar-sweetened products, especially beverages, is casually linked to increases in risk of chronic, debilitating diseases including type 2 diabetes, cardiovascular disease, hypertension and stroke (Swithers, 2015). Sweeteners have been used extensively in food and beverages for decades, yet there continues to be controversy about their net effects on energy balance. There has been renewed interest in this discussion in recent years in the wake of a number of prospective cohort studies in which it was observed that the risk of weight gain was increased in a dose responsive manner among participants consuming diet beverages compared to those who did not consume them (Fowler et al., 2008, 2015). Recognizing our desire for sweet flavours, the food industry has developed and supplied sugar free alternatives designed to satisfy our cravings, referred to as sugar substitutes, artificial sweeteners or non-nutritive sweeteners. Nowadays they occupy a large portion of commercial space on the supermarket shelves worldwide.

Sweeteners are functional food additives that impart sweetness in food (DuBois and Prakash, 2012). Some of the low-calorie sweeteners currently approved by different international authorities as direct food additives include acesulfame, aspartame, cyclamate, saccharin and sucralose. On the other hand, there is a wide range of natural, unrefined sweeteners which aside from providing sweetness to the product, contain various bioactive compounds, such as vitamins, minerals or polyphenols that are known to exhibit positive health effects and contribute to the concept of functional food. Natural sweetener can be further divided into saccharide and non-saccharide sweeteners (Surana et al., 2006). There are many other natural alternatives to sugar that are available, though not widely used, despite the fact that natural non-refined sugar alternatives potentially contain beneficial bioactive compounds, especially polyphenolic compounds, known for their antioxidant properties. Some of these natural sugar alternatives include plant saps/syrups (eg, maple syrup, agave nectar), syrups made from raw sugar and grains (eg, molasses, barley malt, and brown rice syrup), honey, fruit or vegetable sugars (eg, date sugar, carrot). Among the natural alternatives to sucrose that can be used as sweeteners with low glycemic index are lucuma (*Pouteria obovata*) and yacon (*Smallanthus sonchifolius*), which - undergo less refining process and may therefore provide a substantial content of other beneficial nutrients and bioactives. Likewise, the use of Stevia and liquorice (*Glycyrrhiza glabra*) are also well known in confectionery industry, but they still do not have a wider application due to the aftertaste that often occurs in the products. Black locust (*Robinia pseudoacacia*) is a tree native and widely spread in the southeast European region, appreciated for its medicinal properties (prepared and consumed as tea) and culinary uses (the flower nectar is used for production of honey, flowers are fried, added to dishes or used for preparation of beverages), mostly due to its specific sweet taste and mild, flowery aroma (Belšcak-Cvitanovic et al., 2015). Sweetener can be broadly divided into two categories, natural and artificial or synthetic sweetener.

### Artificial Sweeteners: An Alternative to Limiting Table Sugar in the Diet

Sensory properties of food are highly influenced by the sensational properties like taste, smell texture and appearance (Sorensen et al., 2003). The selection and consumption of food plays a crucial role in the regulation of human appetite and nutrient intake. A sweetener is a food additive, which mimics the effect of sugar on taste. Therefore, they are called sugar substitutes. Consumers often select foods that are composed of low calorie sweetener because they want the taste of sweetness without added calories.

Artificial sweeteners are being used as sugar substitutes in considerable and increasing amounts in food and beverages, especially by those who are diabetic and/or obese (Benton, 2005). They have also been used in other personal care and pharmaceutical products such as toothpastes (Zygler et al., 2009). Although, from the beginning of their use, there has been a controversy over their risk as potential carcinogens (Weihrauch and Diehl, 2004), these sweetener compounds are generally considered to be safe for use in food stuffs (Kroger et al., 2006; Ahmed and Thomas, 1992; Cohen et al., 2008). Artificial sweeteners are becoming increasingly used

to sweeten beverages, such as soda, juice, coffee and tea. In an era where obesity has become a serious health problem with large populations affected, sweeteners are a way to replace sucrose consumption. These products have been considered as safe in a recently published position article from the Academy of Nutrition and Dietetics (Caballero, 2007; Fitch and Keim, 2012). Acesulfame-k, aspartame, cyclamate, saccharin and sucralose are currently approved as artificial sweeteners as direct food additives. Others are continually being developed and are gradually used in more foodstuffs, especially because they contribute to longer shelf-life. In terms of environmental degradation, among the five most commonly used artificial sweeteners named above, only aspartame decomposes under normal usage conditions, and safety clearance was given to the intake of even its breakdown derivatives (US FDA, 2006; EU, 2003; US FDA, 1983). The number of times that a sweetener is sweeter than sucrose is called sweetener potency. The potency of a sweetener is compared with sucrose mainly in the threshold levels of the sweetener and sucrose (Yasuura et al., 2014). Sugars and sugar alcohols, such as sucrose and xylitol, are low-potency sweeteners, whose sweetener potencies are about 1 and under. On the other hand, sweeteners which have a sweetener potency exceeding 10 are called high-potency sweeteners, such as saccharin and aspartame. Interestingly, low-potency sweeteners, such as sucrose, exhibit higher sweetness intensity than high-potency sweeteners at very high concentrations. That is why low-potency sweeteners are also called high-intensity sweeteners (Hayes, 2008; Cardello et al., 1999; Farkas and Hid, 2011).

### Acesulfame—k

Acesulfame—k, a high intensity sweetener, is a potassium salt of 6-methyl-123-oxathiazine-4 (3H)-one 2, 2-dioxide with molecular formula  $C_4H_4KNO_4S$  and molecular weight of 201.24 was developed as sweetener by Hoechst. Synthesis of Acesulfame-K involves the treatment of acetoacetamide with at least two equivalents of sulfur trioxide. This results in formation of N-sulfoacetoacetamide, which is then dehydrated by sulfur trioxide to form oxathiazinone dioxide. Neutralization with potassium hydroxide gives Acesulfame-K (Clauss et al., 1993). Acesulfame—k is a white crystalline, water soluble powder, which is roughly 120 times sweeter than sucrose. It is heat stable so it can be used in cooking and baking. Acesulfame-K or Ace-k is often blended with other sweeteners (usually sucralose or aspartame) whereby each sweetener masks the other's after taste and exhibit a synergistic effect by which the blend is sweeter than its components. The European Commission's Scientific Committee on food reevaluated this sweetener and supported its safety but recommended an ADI from  $9 \text{ mg kg}^{-1}$  to  $15 \text{ mg kg}^{-1}$  bw per day. The amount of acesulfame-K added to food products is very small because of its intense sweetening power and because it is often used in combination with other sweeteners. The EDI is estimated at 20% of the ADI because of its intense sweetening power.

### Alitame

L-aspartic acid, D-alanine, and a novel C-terminal amide moiety are the main component of Alitame. It is 2000 times sweeter than sucrose without the bitter or metallic qualities of high-intensity sweetener (Auerbach et al., 2001). This sweetener blends with other high-intensity sweeteners to maximize the quality of sweetness. From an oral load of alitame, 7% to 22% is unchanged and excreted in the feces. The remaining amount (78% to 93%) is hydrolyzed to aspartic acid and alanine amide. An ADI of  $0\text{--}1 \text{ mg kg}^{-1}$  body weight was allocated on the basis of the no-observed-adverse-effect-level (NOAEL) of  $100 \text{ mg kg}^{-1}$  body weight/day to an 18 month study in dogs. Joint FAO/WHO Expert Committee on Food Additives (JEFCA) reviewed safety data on alitame in 2002 and postponed making ADI or other toxicology recommendations about alitame until findings of a 90-day tolerance study were made available. In the FDA petition, the estimated daily intake as a sole sweetener in all products is  $0.34 \text{ mg kg}^{-1}$  bw per day. The level at which no observed adverse effects occurred in animals was  $100 \text{ mg kg}^{-1}$  (Auerbach et al., 2001). Alitame has already been approved in Mexico, Colombia and China as well as Australia and New Zealand.

### Aspartame

Aspartame was discovered in 1965 by James Schlatter. It is an artificial, non-saccharide sweetener, L-aspartyl-L phenylalanine methyl ester that is a methyl ester of the dipeptide of the amino acids aspartic acid and phenylalanine. Under strongly acidic or alkaline conditions, aspartame may generate methanol by hydrolysis. Under more severe conditions, the peptide bonds are also hydrolyzed, resulting in the free amino acids. It is slightly soluble in water. The solubility increases with higher or lower pH as well as with increased temperature (Mazur et al., 1970; Mazur and Ripper, 1979). Intestinal esterases hydrolyze aspartame to aspartic acid, methanol, and phenylalanine. These components are found in much greater amounts in the normal diet in fruits, vegetables, meat, and milk. For example, a serving of nonfat milk provides about six times more phenylalanine and 13 times more aspartic acid, whereas a serving of tomato juice has about six times more methanol than an equal volume beverage sweetened 100% with aspartame. In 1981, the FDA approved aspartame as a sweetener for a number of dry uses (eg, tabletop sweetener, cold breakfast cereal, gelatins and puddings) and in chewing gum. This approval was expanded in 1983 to include carbonated beverages. The first safety assessment of aspartame carried out in Europe was published by the Scientific Committee on Food (SCF) in 1984 and ADI for aspartame of  $40 \text{ mg kg}^{-1}$  bw per day was established. The Council on Scientific Affairs of The American Medical Association in 1985 concluded that "Available evidence suggests that consumption of aspartame by normal humans is safe and is not associated with serious adverse health effects". In European Food Safety Authority's (EFSA's) first ever full risk assessment of the food additive aspartame, the experts concluded that aspartame and its breakdown products are safe for human consumption at current levels of exposure. Aspartame is used in low-calorie soft drinks, foods, and sweeteners because aspartame is approximately 200 times sweeter than sugar. Aspartame is a low calorie option for people who should or need to limit their sugar intake (Ishii, 1981).

## Neotame

Neotame is one of the newest artificial sweetener, a derivative of aspartame. Another similar compound, alitame, is pending approval before the FDA. Neotame is 7000 to 13,000 times sweeter than sugar and has no calories. Synthesis of neotame involve the hydrogenation of L- $\alpha$ -aspartyl-L-phenylalanine I methyl ester and 3-3 dimethylbutyraldehyde produced in-situ by the hydrolysis or cleavage of a 3-3-dimethylbutyraldehyde precursor. Neotame is an odorless white to gray-white powder with a strong sweetness and is readily soluble in alcohols and slightly soluble in water (Prakash et al., 2002; Prakash, 2007). Globally, neotame is approved for use in multiple countries in North America, South American, Europe, Africa, Asia, and Australia. In June 2003, the JECFA confirmed the safety of neotame and granted an ADI of 2 mg kg<sup>-1</sup> bw per day.

## Saccharin

Saccharin, the first artificial sweetener, was discovered serendipitously, as were most artificial sweeteners. Constantine Fahlberg was researching on the oxidation mechanisms of toluenesulfonamide, during research, a substance accidentally splashed on his finger; he later licked his finger and noticed the substance had a sweet taste, which he traced back to saccharin (Arnold, 1983). Since that time, a number of compounds have been discovered and used as food additives for their sweetener properties. Saccharin has been in use since 1900 and obtained FDA approval in 1970. Saccharin has no calories and is 300 times sweeter than sugar (Food and Drug Administration, 2006). Synthesis involves diazotization of methyl anthranilate and then treatment of the diazonium salt with sulfur dioxide and chloride gas to give the sulfonyl chloride which is then treated with ammonia to give saccharin (Tarbell and Tarbell, 1978). The label must state saccharin in the ingredient declaration, the amount of saccharin listed per fluid ounce for beverages, milligrams in the dispensing unit for cooking or tabletop use, and milligrams per serving for processed goods. The FDA lists the ADI for saccharin at 5 mg kg<sup>-1</sup>.

## Sucralose

Sucralose was accidentally discovered in 1976 when Tate & Lyle, a British sugar company, was looking for ways to use sucrose as a chemical intermediate. This non-nutritive sweetener is made from sucrose by a process that substitutes 3 chloride atoms for 3 hydroxyl groups on the sucrose molecule (Food and Drug Administration, 2006). Sucralose is 600 times sweeter than sugar and contains no calories. Sucralose was approved by the FDA in 1998 for use in 15 food categories, including a tabletop sweetener under the brand name Splenda. In 1999, sucralose was approved as a general-purpose sweetener. The FDA concluded from a review of more than 110 studies in human beings and animals that this sweetener did not pose carcinogenic, reproductive, or neurologic risk. According to European Food Safety Authority's (EFSA's) ADI of sucralose is 40 mg kg<sup>-1</sup> bw per day.

## Artificial Sweetener Use and Health Effects

The nutritive sweeteners include the monosaccharide polyols (e.g., sorbitol, mannitol, and xylitol) and the disaccharide polyols (e.g., maltitol and lactitol). They are approximately equivalent to sucrose in sweetness (Dills, 1989). The non-nutritive sweeteners, better known as artificial sweeteners, include substances from several different chemical classes that interact with taste receptors and typically exceed the sweetness of sucrose by a factor of 30 to 13,000 times. Nutritive sweeteners (eg, sucrose, fructose) are generally recognized as safe by FDA, yet concern exists about increasing sweetener intakes relative to optimal nutrition and health. In the United States, estimated intakes of nutritive sweeteners fall below this, although one in four children (ages 9 to 18 years) can surpass this level. In addition to their sensory qualities, nutritive sweeteners add functional properties to foods through their effects on physical (eg, crystallization, viscosity), microbial (eg, preservation, fermentation), and chemical (eg, caramelization, antioxidation) characteristics (Davis, 1995). Nutritive sweeteners are easily digestible except in the cases of rare genetic abnormalities of carbohydrate metabolism (eg, galactosemia, inherited fructose intolerance) (Rumessen, 1992). Over the years, the effects of artificial sweetener use on health have been a concern among health professionals as well as the public for a variety of reasons (Jones and Elam, 2003). One area involves the safety of sweeteners for use by children, when sweetener intakes are high relative to body weight, and pregnant women, when the goal of the diet is to support maternal and fetal health (Kaiser and Allen, 2002). Concern about sweetener intakes has shifted from diabetes in the 1960s, to hyperactivity and behavior issues in children in the 1990s, and to the etiology of obesity in the 2000s. A key recommendation related to the use of non-nutritive sweeteners is to control total energy intake and increase physical activity to manage body weight (US Departments of Agriculture and Health and Human Services, 2010). Eating patterns that are low in energy density improve weight loss and weight maintenance, and may be associated with a lower risk of type 2 diabetes in adults. Substituting non-nutritive sweeteners for higher-energy foods and beverages can decrease energy intake, but evidence of their effectiveness for weight management is limited.

Dental caries are the localized destruction of dental hard tissue by acidic material from bacterial fermentation of dietary carbohydrate (American Academy of Pediatric Dentistry, 2011). Factors that control the development of dental caries include microbiological shifts in the biofilm, salivary flow, buffering capacity of saliva, frequency and kind of dietary sugars consumed,

length of time oral bacteria have to ferment the fermentable carbohydrate and create organic acids, tooth susceptibility, preventive behaviors such as cleaning of teeth (Selwitz et al., 2007), and exposure to fluoride (National Institutes of Health, 2001). Use of polyol-based gum can reduce the risk of dental caries in children, with the greatest benefit in xylitol-based gums, but non-nutritive sweeteners do not promote dental caries (Makinen et al., 1995). A child who consumes more than three nutritive sweetener-containing snacks or beverages between the meals per day is considered at increased risk for dental caries. Xylitol is considered cariostatic and anticariogenic and aids in the prevention of dental caries. It is very soluble in water and sparingly soluble in ethanol. Human tolerance studies indicate that consumption exceeding 50 g per day leads to diarrhoea. The estimated intakes of non-nutritive sweeteners in children are below the established acceptable daily intakes for all approved sweeteners. As a percentage of ADI, they are as low as 10.4% for aspartame to as high as 60% for acesulfame-K. It has been suggested that caregivers may want to limit intake of saccharin by young children because of the limited amount of data available for its use in children (Council on Scientific Affairs, 1985). The wide range of nutritive and non-nutritive sweeteners available in the food supply, as well as blending these sweeteners in food and beverage systems, should continue to keep estimated intakes of non-nutritive sweeteners in children well below the acceptable daily intakes.

Obesity is another complex problem, and its cause cannot simply be attributed to any one component of the food supply such as sweeteners. The causes of obesity are multifactorial, and the focus on any single factor no doubt oversimplifies the issue. Nevertheless, with regard to recent and rapid increases in the prevalence of obesity, scientific evidence has implicated a number of dietary factors as likely contributors. Most recently, special attention has been focused on the extremely high levels of consumption of sugars in general and sugar-sweetened beverages in particular. For example, in the US overall consumption of sugar-sweetened soft drinks in 2001 was roughly 37 gallons per capita (USDA, 2008). The prevalence of obesity has increased substantially at the same time as the consumption of non-nutritive sweeteners has increased (Sylvetsky et al., 2012). The question is, do these sweeteners maintain a highly sweet food environment to increase risk of obesity through appetite, intake, and energy regulation mechanisms? Some evidence primarily from studies with animals suggests that high intakes of sweets (nutritive sweeteners alone or in mixtures with fat) promotes weight gain through changes in neuropeptide control of appetite, intake, and energy expenditure (Levine et al., 2003). In 2012 over 70% of adults reported that they consumed sugar-sweetened beverages (SSB; soft drinks or fruit drinks with added sugar; Kumar et al., 2014), with over 25% reporting daily intake. A recent meta-analysis also showed strong links between SSB consumption and increased body weight (Malik et al., 2013). Thus, the rise in prevalence clearly relates to all factors that cause an energy imbalance.

Pregnancy is a time of special concern because the focus is on maternal and fetal health. All FDA-approved nutritive sweeteners and non-nutritive sweeteners are approved for use by the general public, which includes pregnant and lactating women. The position of the Academy is that use of nutritive sweeteners is acceptable during pregnancy (Position of the American Dietetic Association, 2008). The safety of acesulfame-K, aspartame, sucralose, and neotame in pregnancy has been determined with rat studies; the scientific community accepts rats and some other animals as appropriate models for reproductive toxicology testing that are applicable to human beings. At high doses, there was no change observed in fertility, size of litter, body weight, growth, or mortality for acesulfame-K, sucralose, or neotame (Food and Drug Administration, 1998, 1998, 2002).

## Conclusions

Artificial sweeteners add to the pleasure of eating. Consumers can enjoy a wide range of sweeteners in a wide variety of foods and beverages. Artificial sweeteners are safe for use within the approved regulations. Artificial sweeteners are those that sweeten with minimal or no carbohydrate or energy. They can increase the palatability of fruits, vegetables, and whole-grain breads/cereals and thus have the potential to increase the nutrient density of the diet while promoting lower energy intakes. They are regulated by the Food and Drug Administration as food additives or generally recognized as safe. The Food and Drug Administration approval process includes determination of probable intake, cumulative effect from all uses, and toxicology studies in animals. Five non-nutritive sweeteners are approved by FDA, those are acesulfame-K, aspartame, neotame, saccharin, sucralose. They have different functional properties that may affect perceived taste or use in different food applications. There is a chance that, continuous exposure to artificial sweeteners could persistently alter sweet preferences, leading to enhanced intake of sugars throughout life and it could interfere with learning of basic relations between sweet tastes and the delivery of calories, which in turn could negatively affect regulation of metabolic processes. Artificial sweeteners could alter the composition of the gut microbiota, which in turn can contribute to metabolic dysregulation. Thus, consumers must be aware of science-based information about particular artificial sweetener and supportive research on the use of that to promote eating enjoyment, optimal nutrition, and health.

## Betalains

Delia B Rodriguez-Amaya<sup>a,b</sup>, <sup>a</sup> University of Campinas, São Paulo, Brazil; and <sup>b</sup> Universidade Federal da Fronteira Sul, Parana, Brazil

### Introduction

Betalains are water-soluble nitrogen-containing vacuolar pigments, consisting of the red to red-violet betacyanins and the yellow-orange betaxanthins (Fig. 1). They are immonium conjugates of betalamic acid with *cyclo*-Dopa (cyclo-3,4-dihydroxyphenylalanine) and amino compounds (amino acids, amines, or derivatives), respectively. Examples are betanin (betanidin-5-O- $\beta$ -glucoside) of red beet and indicaxanthin (betalamic acid linked to proline) of cactus pear, the first structurally characterized betalains.

Glycosylation and acylation result in a diversity of betacyanin structures. The betanidin aglycone is usually linked with glucose, occasionally with glucuronic acid, sophorose, rhamnose, and apiose, at the C-5 or C-6 position. Further modification occurs by aliphatic or aromatic acid esterification of the sugar moiety. Malonic, 3-hydroxy-3-methyl-glutaric, caffeic, *p*-coumaric, cinnamic, and ferulic acids are typical acid substituents (Strack et al., 2003). To date, about 78 plant betalains have been identified and characterized (Slimen et al., 2017).

The biosynthesis of betalains is discussed in detail in review articles (Esatbeyoglu et al., 2015; Khan and Giridhar, 2015; Strack et al., 2003). Betalains are found in numerous sources (flowers, fruits, roots, leaves, stalks, seeds, grains) in the plant kingdom. In food, however, their occurrence is limited, the red beet being regarded for a long time as practically the sole source of betacyanin. More recently, other edible sources have been investigated, such as *Ullucus tuberosus*, an important root crop in the Andean region of South America (Cejudo-Bastante et al., 2014); *Basella rubra*, known as Malabar spinach, a leafy vegetable that accumulates pigments in its fruits (Kumar et al., 2015, 2016); prickly (cactus) pear (*Opuntia ficus-indica* and *Opuntia stricta*) (Castellar et al., 2003; Melgar et al., 2017; Moßhammer et al., 2005a,b; 2006; Stintzing et al., 2002b, 2003); red-purple pitaya (dragon fruit) *Hylocereus polyrhizus* (Herbach et al., 2006a, 2007; Moßhammer et al., 2005b; Stintzing et al., 2002a; Wybraniec et al., 2001) and *Amaranthus* leaf and grain (Stintzing et al., 2004; Cai and Corke, 2000; Cai et al., 2005).

Being minor pigments in red beet, betaxanthins have received much less attention. Food sources of betaxanthins are yellow varieties of Swiss chard, beet, and cactus fruits (Kugler et al., 2004; Stintzing et al., 2002b; Strack et al., 2003).

### Physical and Chemical Properties

Betacyanins and betaxanthins exhibit absorption maxima at 532–550 nm and 457–485 nm, respectively (Khan, 2016). The conjugated double bond system of the betalamic acid moiety constitutes the chromophore responsible for these absorptions and consequently, the vivid color. The bathochromic shift of 50 to 70 nm of betacyanins compared to betaxanthins is due to conjugation of the aromatic ring's double bonds of *cyclo*-Dopa, extending the electronic resonance system. Glycosylation of betanidin causes a hypsochromic shift (Stintzing et al., 2004) while esterification with aliphatic acids has little impact on the maximum absorption of betacyanins (Stintzing et al., 2002a; Wybraniec et al., 2001). Acylation with aromatic acids results in a bathochromic shift (Heuer et al., 1992).

As with other natural pigments, stability is a major concern with betalains. It is enhanced by high betalain content, high degree of glycosylation and acylation, low  $a_w$ , pH 3 to 7, antioxidants, chelating agents, low temperature, protection from light, and nitrogen atmosphere (Herbach et al., 2006a,b). Conversely, degrading enzymes (peroxidase, polyphenol oxidase, glucosidase), low degree of glycosylation and acylation, high  $a_w$ , metal cations, pH < 3 or > 7, high temperature, exposure to light, O<sub>2</sub>, and H<sub>2</sub>O<sub>2</sub> lowers stability.

The lower oxidation–reduction potential of betanidin as compared to betanin coincides with its greater susceptibility to destruction by molecular oxygen (von Elbe and Attoe, 1985). Glycosylation increased the half-life of betanidin and isobetanidin by about 17 times in O<sub>2</sub>-saturated solutions. Betacyanin stability may be increased by substitution with aromatic acids, the

**Figure 1** Structures of betacyanins and betaxanthins.

6-O— being more effective than the 5-O-substitution, explained by intramolecular stacking that may protect the aldimine bond from hydrolytic attack (Schliemann and Strack, 1998).

It is widely known that betalains are stable over a broad pH range, from 3 to 7, which makes them well suited for application in low-acid and neutral foods. Betanin is most stable at pH 4–5 (Huang and von Elbe, 1987).

Betanin undergoes water-dependent hydrolysis;  $a_w$  is a crucial factor for betanin susceptibility to aldimine bond cleavage. Lower  $a_w$  improved betanin stability, most effectively at below 0.63 (Kearsley and Katsaboxakis, 1980). In encapsulated beetroot pigments, betanin degradation was greatest at  $a_w = 0.64$  (Serris and Biliaderis, 2001). Greater betanin stability was ascribed to decreasing mobility of the reactants at lower  $a_w$  and by dilution effects at higher  $a_w$ .

Metal cations ( $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Sn}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{Cr}^{3+}$ ,  $\text{Cu}^{2+}$ ) accelerate betanin degradation (Attoe and von Elbe, 1984; Czapski, 1990; Sobkowska et al., 1991). EDTA can prevent metal-catalyzed betanin degradation by pigment stabilization and complex formation with metal ions (Attoe and von Elbe, 1984).

Ascorbic acid showed a protective effect in purple pitaya juice and pigment preparations (Herbach et al., 2006a,b) and on Amaranthus pigments (Cai and Corke, 1999). Added to the juice prior to storage, it prevented the detrimental effects of light exposure (Herbach et al., 2007). Addition of 0.25% ascorbic acid, pH 4.0, and pasteurization at 65 °C for 30 min were selected as the best processing conditions to retain betacyanin content in red-fleshed pitaya juice (Wong and Siow, 2015). Ascorbic acid and Se synergistically protected and regenerated betalains efficiently after thermal degradation in *Rivina humilis* L. berry juice (Khan and Giridhar, 2014).

### Alterations During Processing and Storage of Food

Decomposition of betalains may be catalyzed by degrading enzymes. Several polyphenol oxidases were isolated from red beet (Escribano et al., 2002). A betalain oxidase catalyzed betanin degradation to *cyclo*-Dopa-5-O- $\beta$ -glucoside, betalamic acid, and 2-hydroxy-2-hydro-betalamic acid (Zakharova et al., 1987).

Degradation of betalain during thermal processing has been reported in many papers (e.g. Herbach et al., 2004a,b, 2006a; 2007). The color shift of red beet juice to orange on thermal treatment was attributed to the formation of yellow and orange-red degradation products (Herbach et al., 2004b).

Betacyanin undergoes isomerization, deglycosylation, dehydrogenation, hydrolysis, and decarboxylation (Fig. 2). The predominating reaction differs with different betacyanin (Stintzing and Carle, 2007). Betanin was mainly hydrolyzed into betalamic acid and *cyclo*-Dopa-5-O-glucoside. Decarboxylation and combined decarboxylation/dehydrogenation predominated with hylocerenin (3-hydroxy-3-methylglutaryl-betanin). Phyllocactin (malonyl-betanin) yielded betanin and various yellow and red dehydrogenated and decarboxylated derivatives.

Betacyanins are generally accompanied by their respective isobetacyanins, but isomerization can be induced by acidic or alkaline conditions (Schwartz and von Elbe, 1983; von Elbe et al., 1981). It has also been observed during thermal treatment of red beet juice (Herbach et al., 2004b; von Elbe et al., 1981).

The glucose moiety of betanin may be cleaved in the presence of  $\beta$ -glucosidase, under strongly acidic conditions, or at high temperature (Herbach et al., 2006b). This deglycosylation results in increased susceptibility towards oxidation (Stintzing and Carle, 2004).

Yellow neobetainin (14,15-dehydrobetainin) is an endogenous pigment, as in red beet (Alard et al., 1985; Kujala et al., 2001) and prickly pear (Strack et al., 1987). It can also be generated on heat exposure (Herbach et al., 2004b). Dehydrogenation of phyllocactin and hylocerenin on thermal treatment of purple pitaya juice resulted in the formation of the corresponding yellow neo-derivatives (Herbach et al., 2004a).

At pH above 6 or during thermal processing, betanin is cleaved to the bright yellow betalamic acid and the colorless *cyclo*-Dopa-5-O- $\beta$ -glucoside (Schwartz and von Elbe, 1983). The aldimine bond may be protected from cleavage by acylation with aromatic or aliphatic acids (Schliemann and Strack, 1998; Herbach et al., 2005). Partial regeneration of betanin occurs after short-term heating (Czapski, 1985; Huang and von Elbe, 1985; von Elbe et al., 1981). Ascorbic, isoascorbic, metaphosphoric, and gluconic acids improved the regeneration of red beet juice pigments after heating (Han et al., 1998).

Betanin may be decarboxylated at the C-2, C-15, or C-17 position (Herbach et al., 2005). The monodecarboxylated betanins are subsequently transformed to di- and tridecarboxylated betanins (Wybraniec, 2005). Decarboxylation at either C-2 or C-15 do not alter the betanidin chromophore, thereby maintaining the color of the original betacyanin. On the other hand, a carboxyl substituent in conjugation with the conjugated double bond system is eliminated in 17-decarboxybetanin, which thus exhibit an orange hue (Herbach et al., 2006b). Monocarboxylated betanin, phyllocactin, and hylocerenin were shown to be considerably more stable towards degradation than nondecarboxylated betacyanins (Huang and von Elbe, 1987; Herbach et al., 2006c). Isobetainin and neobetainin are also decarboxylated in a manner similar to that of betanin (not shown in Fig. 2) (Wybraniec, 2005).

During heating of *Basella alba* L. fruit juice, the principal decarboxylation products of major gomphrenins (simple and acylated betanidin-6-O- $\beta$ -glucoside) were 2-, 17-, and 2,17-decarboxy-gomphrenins (Kumorkiewicz and Wybraniec, 2017). Their diastereomers, as well as minor levels of their dehydrogenated derivatives were also found.

On prolonged thermal treatment of red beet, a diversity of betacyanin degradation products may be formed by multiple decarboxylation or by combined decarboxylation and dehydrogenation of betanin (Herbach et al., 2006b). Mixtures of mono-, di-, and tridecarboxylated betacyanins, together with their corresponding neobetacyanins were identified in purified extracts of red beet and purple pitaya (Wybraniec, 2005; Wybraniec and Mizrahi, 2005). Main products were 17-decarboxy-betacyanin,

**Figure 2** Alterations of betanin during processing and storage of food. Based on Herbach, K.M., Stintzing F.C., Carle, R., 2004. Impact of thermal treatment on color and pigment pattern of red beet (*Beta vulgaris* L.) preparations. J. Food Sci. 69, C491–C498; Herbach, K.M., Stintzing, F.C., Carle, R., 2006. Betalain stability and degradation – structural and chromatic aspects. J. Food Sci. 71, R41–R50.

17-decarboxy-isobetanin, 2-decarboxy-betanin, 2,17-didecarboxybetanin, 2,17-didecarboxyisobetanin, and 14,15-dehydrogenated-neobetanin. Heating of betanin, phyllocactin, and hylocerenin resulted in decarboxylated neo-derivatives together with the corresponding decarboxylated betacyanins (Herbach et al., 2005).

## Betalains as Food Colorants

Concern about food safety and strong demand for more natural products have stimulated efforts for the replacement of artificial food dyes by natural pigments, strengthened in more recent years by the potential health benefits of the latter. Natural colorants, however, are usually less stable, more costly, and not as easily utilized as synthetic dyes, besides having weaker tinctorial strength, interaction with food components, and limited range of hues (Sigurdson et al., 2017; Wrolstad and Culver, 2012).

Betanin extracted from beetroot has been commercialized as a natural food colorant, approved by the European Union and the U.S. Food and Drug Administration. It is used mainly to color such foods as dairy products, confectionery, ice cream, desserts, beverages and sausages (Obón et al., 2009). Its use is, however, restricted by its high nitrate content and its earthy flavor caused by geosmin and pyrazine derivatives (Lu et al., 2003; Stintzing and Carle, 2004). Alternative sources such as purple and yellow cactus pear and purple pitaya are therefore being explored.

Along with continued search for new and economically viable sources, appropriate pretreatment and extraction methods (Ngamwonglumlert et al., 2017), advances in processing technology and stabilization (Celli and Brooks, 2017), availability of wide spectrum of color, better quality of pigments devoid of off-flavor, and possibility of developing betalain-fortified formulations containing certain other bioactive and nutritional components could be expected (Khan and Giridhar, 2015).

Microencapsulation of betalains can be a successful strategy to improve stability, make handling easier during processing, and ensure bioavailability of microcapsules to be used as food colorants (Otálora et al., 2015). Microencapsulation of beetroot juice (Janiszewska, 2014; Pitalua et al., 2010) or extract/pigment (Azeredo et al., 2007; Serris and Biliaderis, 2001), pulp and cactus pear extract (Vergara et al., 2014), and Amaranthus pigments (Cai and Corke, 2000) has been tested.

## Health Benefits

Various health-promoting biological activities have been attributed to betanin and betalain-rich foods such as: scavenging of free radicals/reactive oxygen species, inhibition of lipid peroxidation and LDL oxidation, prevention of DNA-damage, induction of antioxidant (e.g. paraoxonase 1, glutathione peroxidase, heme oxygenase 1) and phase II detoxifying enzymes (e.g. glutathione S-transferase, NAD(P)H dehydrogenase [quinone] 1), gene regulatory activity (e.g. Nrf2-dependent signaling pathway); anti-inflammatory (e.g. inhibition of cyclooxygenase-2), anti-proliferative and anti-microbial activities (Esatbeyoglu et al., 2015; Gandía-Herrero et al., 2016; Gengatharan et al., 2015; Khan, 2016; Ninfali et al., 2017). Most of the studies have, however, been conducted in vitro with cells and animal models; human studies are lacking.

The antioxidant, anti-inflammatory, antiangiogenic and GST-inducing activities of betalains from pitaya fruit peels were enhanced by encapsulation in maltodextrin–gum Arabic and maltodextrin–pectin matrices (Rodriguez et al., 2016).

## Concluding Remarks

The coming years will witness continued intense research on betalains. Research topics will include: new and economically viable sources of both betacyanins and betaxanthins, optimization of processing to control alterations of betalains, efficient and green extraction and stabilization methods, production of high quality betalain colorants with wide color spectrum and free from off-flavor, and human studies to evaluate betalain's health benefits.

### Glossary

**Antioxidants** Compounds that inhibit or reduce the ability of oxidizing compounds (e.g., singlet oxygen and free radicals).

**Isomerization** Process that changes arrangement of atoms in a molecule without adding or removing anything from the original molecule.

**Oxidation** Chemical reaction that involves combination of oxygen with another substance or process that involves loss of electron.

**Oxidative stress** Presence of excessive level of oxidizing compounds known as free radicals in a cell; lack of antioxidant compounds that can eliminate free radicals.

**Pro-vitamin A** Substances in food that can be converted into vitamin A in organism.

### Introduction

Carotenoids are among the most widely distributed pigments and naturally exhibit red, orange and yellow colors. Carotenoids are lipid-soluble pigments, which can be found in many kinds of fruit, vegetables, fungi, flowers and some kinds of animals (Ötles and Cagindi, 2008). Photosynthetic bacteria, algae, fungi and plants can produce carotenoids through biosynthesis, whereas carotenoids found in humans as well as animal cells (e.g., lutein and zeaxanthin in human eyes and astaxanthin in salmon) are only from diets (Ellison, 2016; Kaczor et al., 2016). More than 750 different structures of carotenoids have so far been isolated from natural sources; about 500 structures have been fully characterized (Rodriguez-Amaya, 2016). Based on their structures, carotenes and xanthophylls are two main subclasses of carotenoids (Ngamwonglumlert et al., 2017). Different carotenoids structures naturally possess different physical, chemical and functional properties as well as stabilities.

Carotenoids exert several beneficial functions. The compounds can help, for example, attract insect pollinators in flowers, indicate maturity in fruit, absorb visible light in photosynthesis and defend light-induced damage of cells in the cases of photosynthetic bacteria, algae and green plants (Lerfall, 2016). Carotenoids are also essential for human health. For instance, lutein and zeaxanthin in human eyes are responsible for the filtering of the high-energy wavelengths of blue light, resulting in the reduction of oxidative stresses on the retina (Roberts et al., 2009). Some carotenoids provide additional health benefits since they play essential roles as pro-vitamin A and antioxidants. Based on their various benefits, carotenoids have long been utilized by nutraceutical and pharmaceutical industries (Ötles and Cagindi, 2008; Alcaïno et al., 2016). In addition, various carotenoids are used in many food-related industries as food colorants in lieu of the synthetic ones.

This chapter aims to provide basic information on carotenoids in terms of their occurrences, sources, structures, properties and stabilities. Relationships between the carotenoids structure and some selected properties as well as stability are outlined. The chapter ends with some sample applications of carotenoids as food colorants.

### Occurrences, Structures and Sources

The origin name of carotenoids is from carrot (*Daucus carota*) as they are the major pigments in a carrot root (Kaczor et al., 2016). Carotenoids, which are polyisoprenoid compounds consisting of eight isoprene units, are essential for all photosynthetic organisms due to their important photoprotective, antioxidant and visible-light absorbing roles. Plants, algae, bacteria and some fungi can naturally produce carotenoids through biosynthesis (Ötles and Cagindi, 2008; Lohr, 2009; Lerfall, 2016).

Carotenoids biosynthesis occurs in plastids, which are chloroplasts in the case of green tissues or chromoplasts in the case of yellow or red tissues. Carotenoids are synthesized from a C5 compound (isopentenyl pyrophosphate, IPP), which is obtained from the cytosolic mevalonic acid (MVA) as well as plastid methylerythritol 4-phosphate (MEP) pathways. Three IPP units and one unit of its allylic isomer (dimethylallyl diphosphate, DMAPP) are merged to form a C20 compound (geranylgeranyl pyrophosphate, GGPP), which is a precursor of the carotenoids biosynthesis, with GGPP synthase as the catalyst. Two molecules of GGPP are condensed together by the activation of phytoene synthase (PSY) enzyme, leading to the formation of 15-*cis*-phytoene, which is a C40 carotenoid skeleton. Phytoene later undergoes a series of dehydrogenation (desaturation reaction) and isomerization, with the activation of phytoene desaturase (PDS) and  $\zeta$ -carotene desaturase (ZDS) enzymes, resulting in the transformation of the colorless phytoene into red lycopene, which is the origin compound that can be transformed into a large variety of carotenoids structures (Ötles and Cagindi, 2008; Rosas-Saavedra and Stange, 2016). Other structures of carotenoids can thus be considered as lycopene derivatives.

Structures of carotenoids have been classified into two main subclasses, which are carotenes and xanthophylls. Carotenes consist of pure hydrocarbons, while xanthophylls consist of hydrogen, carbon and one or more oxygen-containing functional groups (Ötles and Cagindi, 2008; Alcaïno et al., 2016; Ngamwonglumlert et al., 2017). In the xanthophylls structure, various forms of oxygen groups (hydroxy, methoxy, carboxy, keto and epoxy groups) can be found. The presence of oxygen in the structure leads to many structural derivatives and the higher polarity of xanthophylls in comparison to that of carotenes. Common carotenes found in green plants and algae are  $\beta$ -carotene, while common xanthophylls found in plants are lutein, antheraxanthin, neoxanthin, violaxanthin and zeaxanthin (Nobel, 2009).

Carotenoids are naturally found in the form of all-*trans* isomer; an exception is noted in the case of neoxanthin, which is exclusively present in the form of 9'-*cis*-isomer (Lohr, 2009). However, all-*trans*-isomer can easily be isomerized to *cis*-isomer when the former is being exposed to heat and light (Provesi and Amante, 2015). Although the transformation of carotenoids structure from *trans*- to *cis*-isomer is noted to slightly reduce the color saturation of the pigments (Ngamwonglumlert et al., 2017), change in the carotenoids color is indeed more affected by the change in the number of conjugated double bonds in their structure. The characteristic color of carotenoids changes from colorless (phytoene) to yellow, red and pink when the number of conjugated double bonds increases as listed in Table 1. In addition, the color of carotenoids can also change to green, purple or blue when they form complexes with proteins (carotenoproteins). Crustacyanin, for example, is a dark blue pigment found in lobster shell (Lerfall, 2016; Alcaïno et al., 2016).

Carotenoids play essential roles in nutrition, vision, enhancement of immune function and prevention of cellular differentiation (Arscott, 2013; Rosas-Saavedra and Stange, 2016). Unfortunately, humans and animals cannot synthesize carotenoids. Carotenoids found in human and animal cells are thus acquired from dietary intake. Among many carotenoids,  $\beta$ -carotene, lutein, zeaxanthin and lycopene (Fig. 1) are the major carotenoids found in food sources (Boon et al., 2010; Arscott, 2013) and are well known to exert many health benefits. Food and plant sources of the four major carotenoids and their carotenoid contents are listed in Table 2.

## Functional Properties

Consumption of carotenoids-rich foods as well as carotenoids supplements has become more popular as a number of researchers have reported that carotenoids can help reduce the risks of several degenerative disorders, including cancer, cardiovascular and ophthalmological diseases due to their antioxidant properties (Stahl and Sies, 2003). In addition, diets containing carotenoids are important for human health since some carotenoids are pro-vitamin A or can be converted into vitamin A in human body. Antioxidant and conversion mechanisms of carotenoids into vitamin A are of focus here.

### Antioxidant Property

In human body, reactive oxygen species (ROS), which are singlet oxygen ( $^1\text{O}_2$ ) and free radicals, are naturally generated during respiration and metabolism. The generated singlet oxygen and free radicals normally have a beneficial role of killing pathogenic organisms that attack the body. However, ROS generation is an uncontrolled process; this, in combination with the fact that humans also typically obtain additional free radicals from such exogenous sources as air pollution, tobacco smoke and pesticides, may result in exceeding ROS level in the body. When the ROS level is excessive, oxidative stresses occur. ROS would react with fatty acids in cell membranes, enzymes, nucleic acids and endothelial cells, leading to cell damage and cell deterioration, mutation and/or inflammation, which are related to aging and occurrence of degenerative disorders, chronic diseases and cancer (Stahl and Sies, 2003; Lerfall, 2016).

Consumption of carotenoids-rich sources has been reported to reduce the risks of several disorders and diseases that are caused by oxidative damage as carotenoids are a potent natural antioxidant. The antioxidant property of carotenoids is due to physical scavenging of ROS.

### Scavenging of Singlet Oxygen

The role of singlet oxygen quencher is based on the conversion of excess energy of such oxygen into heat. The process of singlet oxygen quenching consists of two main steps: (1) energy transfer between singlet oxygen and carotenoids molecules and (2) return to the ground state of carotenoids as shown in Eqs. (1) and (2), respectively. Carotenoids would first interact with singlet

**Table 1** Characteristic colors of carotenoids pigments

Pigment	Number of conjugated double bonds	Color
Phytoene	3	Colorless
$\zeta$ -Carotene	7	Light yellow
4,4'-Diaponeurosporene	9	Yellow
Capsanthin	10	Red
$\beta$ -Carotene	11	Orange
Bacterioruberin	13	Pink

**Figure 1** Structures of major carotenoids found in foods. Reprinted with permission from Rao and Rao (2007) and Zhang et al. (2018).

oxygen ( $^1\text{O}_2$ ) through the absorption of the energy of the oxygen, resulting in the formation of triplet ground state oxygen ( $^3\text{O}_2$ ) and triplet excited carotenoids. The triplet excited carotenoids would then return to the ground state by converting the excess energy to heat. In this process, the damage effect that is caused by the excited carotenoids is mostly neglected since the excited carotenoids possess low energy and short lifetime. After the excited carotenoids have returned to the ground state, they can be reused to quench another singlet oxygen (Stahl and Sies, 2003; Edge and Truscott, 2010; Fiedor and Burda, 2014; Lerfall, 2016).

The influence of various carotenoids on the singlet oxygen quenching ability has been demonstrated; most of the works were carried out in organic solvents (e.g., benzene, methanol and toluene). The results show that four major carotenoids found in foods, which are  $\beta$ -carotene, lutein, zeaxanthin and lycopene, possess high ability to quench singlet oxygen. This is probably because the triple energy levels of those carotenoids are closer to that of the singlet oxygen and hence the facilitated energy transfer (Stahl and Sies, 2003; Edge and Truscott, 2010). Many researchers also investigated the relationship between the quenching efficiency of carotenoids and the number of conjugated double bonds in the carotenoids structure and reported that the number of conjugated double bonds is related to the triple energy level. Carotenoids containing the larger number of conjugated double bonds exhibit a closer triple energy level to that of singlet oxygen and hence the enhanced quenching efficiency (Edge et al., 1997; Conn et al., 1991; Edge and Truscott, 2010).

The ability to quench singlet oxygen of carotenoids not only depends on the number of conjugated double bonds but also on other factors, including stereo-structure and functional groups in the carotenoids molecule. For example, Mascio et al. (1991) reported that lycopene (11 conjugated double bonds) possesses a higher quenching rate than astaxanthin (13 conjugated double bonds) although it has the smaller number of conjugated double bonds. All-*trans*- $\beta$ -carotene has also noted to exhibit a higher quenching rate than 15-*cis*- and 9-*cis*- $\beta$ -carotene although they all have similar numbers of conjugated double bonds (Conn et al., 1991; Edge and Truscott, 2010). The rate constants of singlet oxygen quenching of some selected carotenoids are listed in Table 3.

**Table 2**  $\beta$ -Carotene, lutein, zeaxanthin and lycopene contents in some selected food and plant sources

Source	Carotenoids content (mg/100 g)

### Scavenging of Free Radicals

Other antioxidative role of carotenoids is free radical scavenging. Radical adduct formation, electron transfer and allylic hydrogen abstraction (or hydrogen atom transfer) are the three accepted possible interactions to quench free radicals by carotenoids (Krinsky and Yeum, 2003; Fiedor and Burda, 2014); these are shown in Eqs. (3)–(6).

Radical adduct formation:

Electron transfer:

or

<sup>a</sup>Source: Edge and Truscott (2010).

<sup>b</sup>Source: Conn et al. (1991).

Allylic hydrogen abstraction:

Carotenoids-free radicals interaction mechanism depends on the species of free radicals (e.g., sulfur-containing, nitrogen dioxide and peroxy radicals) and solvent that are used to test the scavenging ability. For example, carotenoids would interact with thiyl radical ( $RS^\bullet$ ) through the process of radical adduct formation, while they would interact with thiyl sulfonyl radical ( $RSO_2^\bullet$ ) through radical adduct formation and electron transfer (Everett et al., 1996). In a non-polar solvent, carotenoids would react with acylperoxy radicals via radical adduct formation but would interact with those radicals via both radical adduct formation and electron transfer in a polar solvent (Edge and Truscott, 2010). Other interactions between carotenoids and various species of free radicals are listed in Table 4. However, relationships between the carotenoids structure and the carotenoids-free radicals interaction mechanism have never been established.

There are three types of products from the carotenoids-free radicals interactions: (I) adduct radical ( $R$ -Carotenoid $^\bullet$ ) from radical adduct formation, (II) carotenoids radical cation ( $\text{Carotenoids}^{\bullet+}$ ) or anion ( $\text{Carotenoids}^{\bullet-}$ ) from electron transfer and (III) neutral carotenoid radical ( $\text{Carotenoids}^\bullet$ ) from allylic hydrogen abstraction. Among the various types of the products,  $\text{carotenoids}^{\bullet+}$  are mostly studied as they possess strong oxidizing activity and long lifetime. This radical can play a role as pro-oxidant since it is well known to be able to interact with oxygen, other carotenoids and other biological substrates such as water-soluble antioxidants and amino acids (Edge and Truscott, 2010). El-Agamey et al. (2004) noted that  $\text{carotenoids}^{\bullet+}$  (i.e.,  $\beta$ -carotene, zeaxanthin, astaxanthin,  $\beta$ -cryptoxanthin and lycopene radical cations) could oxidize amino acids (i.e., tryptophan, cysteine and tyrosine), resulting therefore in protein damage. Removing and/or repairing  $\text{carotenoids}^{\bullet+}$  is thus necessary; this can be achieved through the oxidation of  $\text{carotenoids}^{\bullet+}$  by other antioxidants such as another carotenoids and ascorbic acid. Transferring the oxidizing radicals from lipid phase to aqueous phase through an interaction between  $\text{carotenoids}^{\bullet+}$  and water-soluble antioxidants such as ascorbic acid is one of the interesting ways to reduce the risk of additional lipid oxidation (El-Agamey et al., 2004).

### Pro-vitamin A Ability

Besides the antioxidant activity, ability to serve as pro-vitamin A is another most important property of carotenoids. However, only carotenoids that contain at least one unsubstituted  $\beta$ -ionone ring at the terminal end possess the ability to be pro-vitamin A (Chandrika, 2009; Lerfall, 2016). For this reason,  $\beta$ -carotene and  $\alpha$ -carotene are noted to be pro-vitamin A, whereas lycopene, lutein and zeaxanthin are not. Among the many types of carotenoids, all-*trans*- $\beta$ -carotene is well recognized as the most important precursor of vitamin A. Transformation of  $\beta$ -carotene into vitamin A (or retinol) in humans and mammals has long been investigated and the process predominantly occurs in intestine (Tang, 2010). Two different pathways for the cleavage of  $\beta$ -carotene as well as other carotenoids into retinol, which are central cleavage pathway and eccentric cleavage pathway, have been proposed (Rodriguez-Amaya, 2016).

Central cleavage or symmetric cleavage is the pathway that involves the activity of 15,15'-dioxygenase (BCO1) to break the central 15,15'-double bond of  $\beta$ -carotene to yield two molecules of retinal. Retinal can then be reversibly converted into retinol

**Table 4** Interactions of carotenoids with various free radical species and their products in different solvents

Carotenoid	Free radical	Solvent	Result
All- <i>trans</i> - $\beta$ -carotene <sup>a</sup>	$\text{NO}_2^\bullet$	$\text{N}_2$ -saturated <i>tert</i> -butanol/water mixture (50:50, v/v)	Interaction: Electron transfer Product: $\beta$ -carotene $^{\bullet+}$

via the reaction of retinal reductase; retinal can otherwise be irreversibly transformed into retinoic acid via the reaction of retinal dehydrogenase (Rodriguez-Amaya, 2016). The conversion of  $\beta$ -carotene into retinol through the central cleavage pathway is shown in Fig. 2.

The other alternative route, which is the eccentric cleavage or asymmetric cleavage pathway, involves the activation of dioxygenase 2 (BCO2). BCO2 activates the cleavage of double bond in the polyene chain beside the central 15,15'-double bond, yielding  $\beta$ -ionone and several  $\beta$ -apo-carotenals, which can subsequently be transformed into retinal and then retinol as shown in Fig. 3.

Conversion efficiency of carotenoids into vitamin A is related to the absorption and bioconversion abilities and also depends on the status of vitamin A and pro-vitamin A in the body. The efficiency increases when vitamin A status becomes low, but decreases when a high dose of pro-vitamin A is consumed (Rodriguez-Amaya, 2016). This occurs to prevent the toxicity that may occur due to excess vitamin A level. Excess consumption of pro-vitamin A (e.g.,  $\beta$ -carotene and  $\alpha$ -carotene) have nevertheless never been reported to be related to toxicity, but can simply cause deep yellow or orange coloration of skin (Francis, 1996; Lerfall, 2016). On the other hand, vitamin A deficiency (VAD) is known to lead to several disorders. VAD has been reported to be directly linked to night blindness and reduction of immune function, which causes an increase in the risks of morbidity and mortality, especially in infant and preschool-age child due to bacterial or viral infection (Haskell, 2013).

## Carotenoids Stability

Change in the molecular structure as well as degradation of carotenoids normally begin even during the process of material preparation. Most preparation processes (e.g., chopping and grinding) cause tissue disruption and hence increased surface area exposing to oxygen, which leads to the oxidation of carotenoids (Yahia and de Jesús Ornelas-Paz, 2010). Heat, light and enzymes are the important factors stimulating the oxidation reaction, which are the main cause of the losses in both the activity and color of carotenoids (Ngamwonglumlert et al., 2017). Carotenoids can be oxidized into the primary oxidation products, which are apo-carotenoids and epoxides, which subsequently degrade into secondary degradation products, which are low molecular weight or volatile compounds (Borsarelli and Mercadante, 2010).

To prevent the oxidation of carotenoids due to the activity of such enzymes as lipoxygenase, short-time thermal treatment (i.e., blanching) can be conducted (von Elbe and Schwartz, 1996; Bahçeci et al., 2005). However, although blanching can help inactivate the oxidative enzymes, a number of researchers have reported that blanching as well as other thermal processes may lead to change in carotenoids structure through isomerization. Heat is a major factor inducing carotenoids isomerization from *trans*- to *cis*- isomers. Although transformation from *trans*- to *cis*-isomers only slightly leads to a decrease in the color

**Figure 2** Central cleavage pathway of  $\beta$ -carotene. Adapted from [Harrison et al. \(2012\)](#).

**Figure 3** Eccentric cleavage pathway of  $\beta$ -carotene. Adapted from [Harrison et al. \(2012\)](#).

saturation without a significant change in the hue (Ngamwonglumlert et al., 2017), such a change may affect the antioxidant activity of carotenoids. Bohm et al. (2002), for example, noted that all-*trans*- $\beta$ -carotene has higher antioxidant activity than 13-*cis*- $\beta$ -carotene.

Food processing generally leads to degradation of carotenoids through both oxidation and isomerization. Increasing temperature and processing time as well as large amount of oxygen concentration lead to extensive degradation of carotenoids. Fratianni et al. (2010), for example, investigated the effect of temperature on the degradation of carotenoids in orange juice (*Citrus sinensis* Osbeck) during microwave pasteurization. Increasing pasteurization temperature resulted in the more extensive loss of carotenoids. Total carotenoids,  $\alpha$ -carotene,  $\beta$ -carotene, lutein and zeaxanthin contents of the juice pasteurized at 70 °C for 60 s did not change, while those of the sample pasteurized at 85 °C for 60 s decreased by about 50%, 57%, 66%, 54% and 58%, respectively. Chen et al. (1995) earlier compared the change in the carotenoids content of carrot juice subjected to pasteurization and sterilization. Carrot juice undergone pasteurization (110 °C for 30 s) suffered less extensive loss of  $\alpha$ -carotene than the juice undergone sterilization (121 °C for 30 min) due to the use of the lower heating temperature and shorter heating time of the former. Isomerization of  $\alpha$ -carotene into 9-*cis*-, 13-*cis*- and 15-*cis*- $\alpha$ -carotenes was noted in both the pasteurized and sterilized products; sterilized product nevertheless possessed lower contents of 13-*cis*- and 15-*cis*- $\alpha$ -carotenes than the pasteurized one due to the compound degradation at extended heating time.

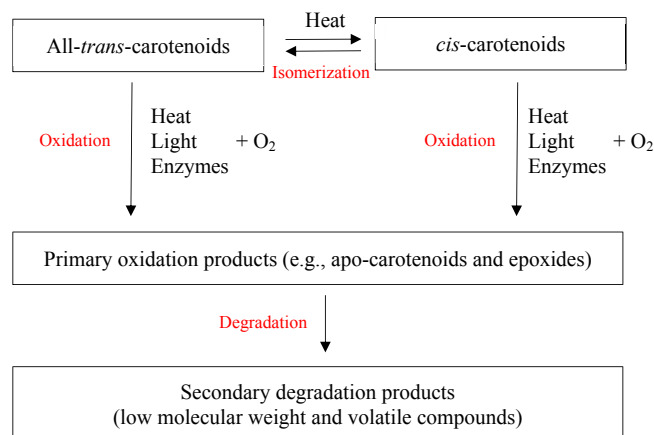

To retain food quality as well as to prevent degradation of carotenoids due to heat, non-thermal techniques such as high-pressure processing (HPP) and pulsed electric field (PEF) treatment have been proposed. Knockaert et al. (2012), for example, compared the quality of tomato puree (in terms of its lycopene content) obtained from thermal and non-thermal preservation techniques. Lycopene content of the puree obtained from mild pasteurization (60 °C for 1 min) and from HPP at a milder condition (450 MPa at 20 °C for 15 min) were not significantly different. However, pasteurization at a more intense condition (90 °C for 10 min) resulted in the loss of lycopene content by about 14%, while the content of the product treated by HPP at a more intense condition (600 MPa at 20 °C for 15 min) was not altered. Tomato puree sterilized at 120 °C for 1.5 min suffered more extensive loss of lycopene than the puree treated by HPP at a sterilization condition (600 MPa at 117 °C for 1.5 min). Lycopene content decreased by about 38% and 5% after sterilization and HPP at the sterilization condition, respectively.

Cortés et al. (2006) investigated the effect of high-intensity PEF on carotenoids in orange juice; the results were also compared with those of the sample undergone pasteurization. The juice treated by PEF (at 30 kV/cm for 100  $\mu$ s) suffered less extensive losses of total carotenoids,  $\alpha$ -carotene,  $\beta$ -carotene, lutein and zeaxanthin than the pasteurized juice (treated at 90 °C for 20 s). Total carotenoids,  $\alpha$ -carotene,  $\beta$ -carotene, lutein and zeaxanthin were lost by about 7%, 7%, 4%, 7% and 16% after PEF and 13%, 34%, 10%, 12% and 17% after pasteurization, respectively.

Structural changes and degradation of carotenoids through isomerization, oxidation and degradation to low molecular weight or volatile compounds are shown in Fig. 4.

## Applications as Food Additives

Carotenoids have long been used as a colorant to yield yellow-orange or red color in foods. Carotenoids can be directly added into foodstuffs or indirectly added by mixing into animal feeds such as in chicken feed to give a color to egg-yolk. Oil-based extract, emulsion and dried powder are the most popular forms of commercially available carotenoids. Carrot, annatto, marigold, paprika, saffron and tomato are usually used as sources of carotenoids. Some carotenoids are permitted for use in foods, while some are restricted to such specific uses as animal feeds. Such allowance depends on the regulation of each country.

**Figure 4** Structural changes and degradation of carotenoids. Adapted from Borsarelli and Mercadante (2010).

### Astaxanthin

Astaxanthin, which is a keto-carotenoid derivative of canthaxanthin, is an orange-red pigment found in green algae, red algae and bacteria. The United States permits the use of astaxanthin from *Haematococcus* sp. as a pigment source in animal and fish feeds, while the use in foods is still not permitted. Limitation of the use is less than 80 mg/kg of finish product. Suspension, water- or oil-dispersion and freeze-dried products can be found in the market (Delgado-Vargas and Paredes-López, 2003; Solymosi et al., 2015).

### β-Carotene

β-carotene, the most widely distributed carotenoids, is usually used as a colorant to yield yellow-orange color in various foods (Francis, 1996). β-carotene obtained from halo-tolerant algae (*Dunaliella salina*) or fungi (*Blakeslea trispora*) is permitted for use as food additive in Europe, while β-carotene extracted from vegetables such as carrot and grass alfalfa is only permitted for feed additive (Delgado-Vargas and Paredes-López, 2003; Kendrick and Limited, 2012). Although there is no evidence indicating that oral consumption of β-carotene is related to toxicity or harm to humans, hypercarotenemia, which results in orange skin coloration, may be observed when consuming food containing β-carotene at a higher concentration for an extended period of time (Francis, 1996).

### Bixin

Bixin, which is an oil-soluble red-brown pigment, can be extracted from the resinous coating on the seed of annatto (*Bixa orellana*). Water-soluble annatto extract can be prepared by saponification; the extract has been used as a colorant for foods as well as cosmetic and textile products (Delgado-Vargas and Paredes-López, 2003; Britton, 1996). Oil-soluble annatto is, on the other hand, more suitable for use in oily foods such as dairy spreads, salad dressings and extruded snacks (Delgado-Vargas and Paredes-López, 2003). Dried powder of annatto extract has also been applied in sausage to replace the use of nitrite (Zarringhalami et al., 2009). Maximum use level, which has been established by JECFA, of annatto extract depends on the type of foods. For example, limitation for the use in cakes, cookies, and pies is 15 mg/kg of a final product, while limitation for the use in processed meat and poultry is less than 50 mg/kg of a final product (Delgado-Vargas and Paredes-López, 2003).

### Canthaxanthin

Canthaxanthin is a red keto-carotenoid, which is naturally found in bacteria, algae and some fungi (Esatbeyoglu and Rimbach, 2017). However, most commercially available canthaxanthin is chemically synthesized. This is because natural canthaxanthin is generally found at lower concentrations (Sanchez et al., 2013). Canthaxanthin is used as poultry feed additive to yield red color in skin and yolks (Esatbeyoglu and Rimbach, 2017). The European Union permits the use of canthaxanthin in feedstuff at a maximum content of 25 mg/kg of final feedstuff (Oehlenschläger and Ostermeyer, 2016), while the United States allows the use of this pigment in broiler chicken and salmonid fish feeds at a concentration below 30 mg/0.45 kg of solid or semi-solid feed or below 30 mg/0.74 L of liquid food (Harp and Barrows, 2015). Canthaxanthin is also permitted for use as food additive. ADI of canthaxanthin when used as a food colorant has been defined by JECFA as 0–3 mg/kg of body weight (Esatbeyoglu and Rimbach, 2017).

### Capsanthin and Capsorubin

Capsanthin and capsorubin are orange-red pigments generally obtained from paprika (*Capsicum annum*). Paprika powder and oleoresin, which is an oil-based mixture containing oil, fat, wax and pigment, are the major forms that are widely used in foods, especially in spice mixes, sauces and emulsified processed meats (Delgado-Vargas and Paredes-López, 2003; Kendrick and Limited, 2012). Besides enhancing the color of food, the other aim of adding paprika is to add flavor. Both paprika and paprika oleoresin are allowed in general foods in the United States (Harp and Barrows, 2015). However, the limitation for use of paprika as food colorant is its hot and spicy flavor, which may not be desirable in some products.

### Crocetin and Crocin

Crocetin and crocin are yellow pigments that are normally obtained from saffron (*Crocus sativus*). Saffron powder as well as extract are used as both colorant and spice (Delgado-Vargas and Paredes-López, 2003; Britton, 1996). However, the use of saffron powder and extract as food colorant is limited due to its high cost and is restricted only in the United States. The European Union has not approved saffron for its use as colorant but allows its use as spice (Solymosi et al., 2015; Harp and Barrows, 2015). In Japan and China, crocin extracted from fruit of gardenia yellow (*Gardenia jasminoides* and *Gardenia augusta*) has been approved for use in foods. On the other hand, the use of crocin obtained from the fruit has not been permitted in the United States and European Union (Solymosi et al., 2015).

### Lycopene

Lycopene extracted from tomato (*Lycopersicon esculentum*) is permitted for use as colorant in the United States and European Union to yield red color in food (Delgado-Vargas and Paredes-López, 2003; Solymosi et al., 2015; Harp and Barrows, 2015). Besides

tomato, lycopene extract from fungus *B. trispora* has been approved for use in the European Union (Harp and Barrows, 2015). Lycopene extracted from tomato suffers one important limitation, however; the intense flavor of tomato may not be favored by some consumers (Britton, 1996).

### Lutein and Zeaxanthin

Lutein and zeaxanthin, which are pigments that give yellow color, are usually obtained from petals of marigold flower (Kendrick and Limited, 2012). In the European Union, dried petals and oleoresin of lutein and zeaxanthin are permitted for use in poultry and fishery feeds, while the purified oleoresin is permitted for use as additives in various kinds of foods such as pastas, vegetable oils, margarine and baked products (Delgado-Vargas and Paredes-López, 2003). On the other hand, the United States allows the use of the dried petals and extracts only in chicken feed (Harp and Barrows, 2015).

To enhance the color stability of carotenoids when being used as colorants, some antioxidants such as ascorbic acid are added into food to prevent the oxidation of carotenoids. Addition of ascorbic acid at a maximum level (400 mg/kg) has been noted to help increase the color stability of carotenoids (Kendrick and Limited, 2012). Products containing carotenoids should also be kept in a low-oxygen environment and in dark.

### Conclusions

Occurrences, sources, structures, selected properties, stabilities and applications in food of carotenoids are here outlined. Properties, including color, antioxidant and pro-vitamin A activities, as well as stability of carotenoids are related to their structures. *Trans*-carotenoids normally possess higher antioxidant activity than *cis*-ones. Only carotenoids containing at least one unsubstituted  $\beta$ -ionone ring at the terminal end (i.e.,  $\beta$ -carotene and  $\alpha$ -carotene) exhibit pro-vitamin A activity. Heat induces isomerization of carotenoids structure from *trans*- to *cis*-isomers, while completed degradation of carotenoids is generally due to oxidation.

Foods processed under high oxygen-concentration environment (e.g., hot air drying) and high temperature (e.g., sterilization) suffer more extensive losses of carotenoids. Processes involving low oxygen concentration (e.g., vacuum microwave drying and low-pressure superheated steam drying) and non-thermal processes (e.g., high pressure processing and high-intensity pulsed electric field) have therefore been proposed to alleviate such losses.

For utilization of carotenoids as a coloring agent, regulations and limitations, which depend on the type of carotenoids, must be considered. Some carotenoids are permitted for use in foods as colorant, additive or spice, while some are restricted only for animal feeds.

### Acknowledgements

Financial support provided by the Thailand Research Fund (TRF, Grant number RTA 5880009), which allowed for the completion of the chapter, is greatly appreciated.

# Clarifying Agents

Harsh P Sharma, Aditya Madan, and DC Joshi, Anand Agricultural University, Gujarat, India

## Introduction

In broader terms, “clarification” is the crucial step, in either juice processing or wine/beer making, which removes suspended solids and clarity compromising colloids, to achieve the required degree of clarity and sensory attributes. Clarification is a process by which the semistable emulsion of colloidal plant carbohydrates that support the insoluble cloud material of a freshly pressed juice or wine is “broken” such that the viscosity is dropped and the opacity of the cloudy juice is changed to an open splotchy appearance. Manufacturers and processors can clarify the juice or any other beverage by either using mechanical separations (centrifugation or filtration) alone or a combination of clarifying/fining agents and mechanical separations.

Kilara and Van Buren (1989) classified ways for attaining clarification as enzymatic and nonenzymatic where nonenzymatic clarification involves breaking the emulsion by other means, the most common of which is heat. Other techniques include addition of gelatin, casein, and tannic acid–protein combinations (Kilara and Van Buren, 1989). Additionally, the uses of honey and combined honey–pectinase treatments have been found to be effective clarification agents. It is believed that the proteinaceous component of honey is responsible for a synergistic effect when honey and pectinase are used in combination (McLellan et al., 1985).

## Need for Clarification

Fruit juices, beer, wine, and many beverages face a major problem of haziness. The interaction between natural phenolic substances and pectic and proteinaceous substances causes the formation of clarity compromising colloids. The consumers’ expectations for clarity and sensory quality attributes have prompted many manufacturers of juice and beverage makers to incorporate clarifying/fining agents during their processing.

## Clarifying Agents

Proteins and polyphenols are the most common substances that require clarification in wines and fruit juices. There is one other contributing cause of suspended haze that we often overlook, for example, entrained carbon dioxide. Moving the wine into a warmer area from a cold cellar can frequently reduce this contributor. Clarifying agents can be classified according to their composition as shown in Fig. 1.

Generally, conventional clarifying procedures can be achieved by centrifugation, enzymatic treatment, applying clarifying agents such as gelatin, bentonite, silica sol, polyvinylpyrrolidone (PVPP), or a combination of these compounds (Sin et al., 2006). A number of agents, including gelatin, bentonite, activated carbon, casein, ion-exchange waxes, and PVPP, have been studied for the removal of polyphenols from fruit juices (Balik, 2003; Fang et al., 2006; Stankovic et al., 2004; Turkyölmaz et al., 2012). Zoecklein et al. (1999) compared desirable effects and potential problems for different clarifying agents in their decreasing order of activity or effectiveness (Table 1). The strong negative charge of the bentonite surface exerts an important action on positively charged proteins of the juice that enables its flocculation. Effective use of clarification agents requires optimization of their methods of preparation and determination of the suitable concentrations needed to achieve the desired clarification.

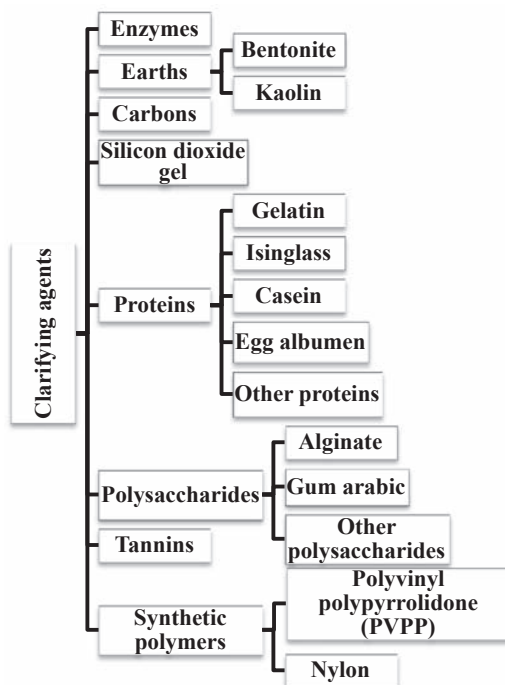

## Enzyme as a Clarifying Agent

Enzymes are effective protein catalysts for biochemical reactions. Enzymes are classified into six groups according to the reaction catalyzed and denoted by an EC (Enzyme Commission) number, viz., EC1: Oxidoreductases, EC2: Transferases, EC3: Hydrolases, EC4: Lyases, EC5: Isomerases, and EC6: Ligases. Systematic nomenclature is the addition of the suffix *-ase* to the enzyme-catalyzed reaction with the name of the substrate (Bayindirli, 2010).

Fruit juice contains pectin and other polysaccharides, so it may lead to fouling during membrane filtration. Enzymatic treatments lead to the degradation of pectin. Enzymatically clarified juice resulted in viscosity reduction and cluster formation, which facilitates separation through centrifugation or filtration. As a result, the juice presents higher clarity, as well as more concentrated flavor and color (Abdullah et al., 2007).

Enzymatic treatments lead to an increase in the clarity of juice. Juice clarity can be determined in terms of absorbance and transmittance at 660 nm using ultraviolet–visible spectrophotometer. An increase in enzymatic concentration increases the rate of clarification by exposing part of the positively charged protein, thus reducing electrostatic repulsion between cloud particles which caused these particles to aggregate into larger particles and eventually settle out (Sin et al., 2006). Clarity showed the lowest absorbance value at highest enzyme concentration, where lower absorbance indicates a clearer juice, is being produced. It was also observed that the absorbance values decreased with increasing incubation time at fixed temperatures (Table 2).

Modified from Zoecklein, B.W., Fugelsang, K.C., Gump, B.H., Nury, F.S., 1999. Fining and fining agents. In: Wine Analysis and Production. Springer, Boston, MA, pp. 242–271.

In general, the time required to obtain a clear juice is inversely proportional to the concentration of enzyme used at a constant temperature (Kilara, 1982). At the lowest temperature, the clarity of banana juice was found to increase rapidly at the beginning of the reaction but slowed as the reaction progressed. The temperature increases the rate of enzymatic reactions, hence the rate of clarification, as long as the temperature is below the denaturation temperature of the enzyme. A similar behavior for the clarity was observed for the changes in incubation time in case of banana juice (Lee et al., 2006). The clarity of centrifuged litchi juice increased with an increase in enzyme concentration. Among the different concentrations used for the optimization of pectinase, the litchi pulp added with 500 ppm of pectinase resulted in maximum transmittance of 80% at 660 nm. The clarity of mosambi juice decreases with time up to 90 min and increases thereafter. Similarly at constant time and temperature, the clarity decreases with enzyme concentration and remains constant and increases thereafter. From both the observations, it is evident that there exists an optimum enzyme concentration and time for the juice clarity (Rai et al., 2003).

#### **Effect of the Enzymes on Viscosity of Juice During Clarification Process**

The use of enzymes leads to the drop of fruit juice viscosity and disintegrating the jelly structure and making it easier to obtain the fruit juices (Singh et al., 2012). The effect of different enzymes on viscosity of different juices is presented in Table 3. The high concentration of pectin leads to colloid formation, which constitutes one of the main problems during the processing of clear fruit juices (Sulaiman et al., 1998). The depectinisation of fruit juices through the use of pectinases has been presented as an efficient

alternative to reduce turbidity, in many studies (Kashyap et al., 2001; Landbo et al., 2007). Pectinases degrade pectin, hence resulting in a reduction in viscosity and cluster formation, which facilitates separation through centrifugation or filtration. As a result, the juice presents higher clarity, as well as more concentrated flavor and color (Abdullah et al., 2007; Kaur et al., 2004). Pectinase enzymes used in grape juice macerate increased the juice clarity and filterability by 100% according to Brown and Ough (1981). For clarified fruit juices, a juice that has an unstable cloud or whose turbidity is considered “muddy” is unacceptable to be marketed as clear juices (Viquez et al., 1981).

## Proteins as Clarifying Agents

All proteins have an isoelectric point, which is a pH at which they carry no net charge when they are in solution. Most of the proteins are least soluble at their isoelectric point. For instance, casein precipitates when it attains neutrality under acidic conditions. However, certain proteins such as ovalbumin form stable solutions when they attain their neutrality (Hornsey, 2007). Attraction of positively charged proteins such as gelatin, isinglass, and casein toward negatively charged materials forms the basis for clarification. Proteins have a high affinity for polyphenols and interact with phenolic compounds by hydrogen bonding between the phenolic hydroxyl and the carbonyl oxygen of the peptide bond (Zoecklein et al., 1995).

### Gelatin

Gelatin is prepared from hydrolysis of collagen from skin and bones of animals. Collagen can either be acid treated (Type A gelatin) or alkali treated (Type B gelatin). Enzymatic hydrolysis of collagen is also one of the methods to obtain gelatin. In food industries, for many years, gelatin has been used as a clarifying agent, stabilizing agent, and as a protective coating material (Salgues and Bidan, 1984; Adler-Nissen, 1985).

During juice and beverage processing, gelatin aids clarification by forming flocs in the liquids. The isoelectric point of gelatin is pH 4.7 and hence carries positive charge in juice or wine and thereby attracts the negatively charged phenolic substances and suspended particles, which then causes neutralization and settling of heavy flocs. These heavy flocs are later removed by sedimentation, centrifugation, or any other filtration technique. To retain a certain level of astringency in the beverages, little quantities of tannins should be added by the manufacturers before addition of gelatin. The concentration of gelatin to be added plays a crucial role in successful clarification of beverages, as the excess or insufficient amounts of gelatin can lead to the problems such as overgluing, undesirable color loss, or retention of haze. Different grades of gelatin are available in both solid as well as liquid forms. Commercially, gelatin is rated depending on its purity and ability to absorb water "bloom". A bloom number of 75 or 100 is suitable for wines, and the usage levels for fining of wines usually range from 0.2 to 0.8 lb (1000 gallons)<sup>-1</sup> (or 0.024–0.096 g L<sup>-1</sup>). However, much larger doses, up to 4 lb (1000 gallons)<sup>-1</sup> (or 0.48 g L<sup>-1</sup>), are required for juice fining (Morris and Main, 1995). The positive aspect of using gelatin is that it can be used in additive-free products, as it is categorized as an ingredient and not an additive.

### Isinglass

Isinglass, protein fining agent, is produced from sturgeon collagen (Boulton et al., 1996). It is available in sheets or flocculated forms. It is beneficial to work with flocculated form of isinglass as it does not require rinsing to remove fishy odors. For efficient clarification, the triple helical structure of isinglass plays a vital role (Jackson, 2000). Keeping in mind, the denaturation temperature of this structure (29°C), maintaining low temperatures during its preparation, is very important (Boulton et al., 1996). However, if hot water is used for preparation, it undergoes partial hydrolysis and thereby resulting in the formation of smaller molecules. The molecular weight is reduced from 140 000 to 15–58 000, resulting in the differences in fining characteristics and a product that is more gelatinlike in its activity (Rankine, 1984).

Isinglass is principally used in white still and sparkling wines for improvement in clarity, cleaning up the aroma, and modifying the finish to give brilliant and softer wines without significantly modifying tannin levels with typical usage levels in the range of 0.2–0.5 lb (1000 gallons)<sup>-1</sup> (or 0.024–0.06 g L<sup>-1</sup>) (Morris and Main, 1995). With an isoelectric point 5.5, it carries a net positive charge at the pH of the wine, which electrostatically attracts negatively charged particles (Rankine, 1984; Margalit, 2004; Troost, 1988).

Isinglass removes phenolics and tannins from beverages without significantly affecting color, astringency, and body than most other protein fining agents because it is less active toward condensed tannins than either gelatin or casein (Rankine, 1984). Use of isinglass is most suitable for obtaining brilliant, softer wine, and it also reinforces the yellow color in case of white wines (Ribéreau-Gayon et al., 2006). Other advantages over gelatin include the enhanced clarification at lower concentrations with lesser dependability on temperature (Ribéreau-Gayon et al., 1972).

Despite its advantages, there are certain issues with the use of isinglass. Many people wish to avoid drinking alcoholic beverages that have been clarified with isinglass because of the specific allergic reactions toward fish and fish products, and therefore, alternatives to isinglass are sought for (Walker et al., 2007). Also, it produces excessive lees (sediments that form during and after fermentation, which may include grape cell remains, seeds, dead yeasts and bacteria, precipitated tannins, and tartarate salts), and when the contact period of isinglass with wine increases, it tends to impart objectionable fishy odor (Zoecklein et al., 1999; Zoecklein, 2002).

### Casein

Casein is a heterogeneous group of four phosphoproteins and phosphoglycoproteins ( $\alpha_1$ -casein,  $\alpha_2$ -casein,  $\kappa$ -casein, and  $\beta$ -casein) with molecular weight ranging from 11.6 to 24.1 kDa and an average isoelectric point of 4.6 (Evans, 1982; Fox and Mulvihill, 1982). This protein is characterized by sequences of hydrophobic and hydrophilic amino acids, resulting in an amphiphilic character with micelle-forming properties (Weber et al., 2007). Being an insoluble protein at 4–5 pH, it is prepared and added to wines in the form of alkaline solution (O'Neal et al., 1950; Boulton et al., 1996). Caseinates are readily soluble in water and hence wine-makers generally prefer potassium or sodium caseinate. However, when it is used in the form of sodium caseinate, it results in the wine with increased contents of sodium. With an isoelectric pH of 4.6, casein carries a positive charge, which causes flocculation in acidic media such as wine. It adsorbs and mechanically removes suspended materials as it settles (Marchal et al., 2002b).

Caseins are most commonly used to reduce haziness and tannin concentrations. Also, it is used to remove undesirable odors and is sometimes used as a substitute for carbon for color modification of juice and white wines. The usage levels for wines typically ranges from 0.2 to 2 b (1000 gallons)<sup>-1</sup> (or 0.024–0.24 g L<sup>-1</sup>) (Morris and Main, 1995).

Caseins are not as effective as gelatin or bentonite for stabilization of wines. Greater stability was reported by Cruess (1963) for Muscatel and sherry wines fined with bentonite as compared with those fined with casein. But, if caseins are used along with other fining agents, it can improve the quality of beverage. For example, Dambrouck et al. (2005) reported that casein assisted in producing better quality of champagne than using bentonite alone. Manufacturers should also consider allergic problems faced by some consumers toward casein fractions.

### Egg Albumen

Egg albumen is one of the oldest fining agents used for reducing the harshness of red wines. Peynaud (1984) reported that about 12.5% (w/w) protein can be found in fresh egg whites. The principal proteins in egg white are albumen (water soluble) and globular proteins (soluble in neutral dilute salt solutions). To aid solubility of egg white, addition of small amounts of sodium chloride is a common practice.

Albumen is primarily used to remove excess tannins and thereby reducing astringency in wines. Studies have been conducted on the ability of albumen clarify wines and its impact on finished quality (Meunier, 2003; Bonerz et al., 2004; Castillo-Sánchez et al., 2006). Having an isoelectric point between 4.55 and 4.90 (Boulton et al., 1996), albumen carries positive charge that attracts negatively charged tannins. Egg albumen is suitable for red wines but not for white wines, as high levels of tannins are required for flocculation. Usage level for wines varies from 1 to 8 egg whites per 60 gallon barrel, with an average of 2–4 (Morris and Main, 1995). However, care has to be taken to avoid excessive frothing and warming while addition to avail better dissolution in wines.

### Other Proteins

Increasing consumer concerns about possible allergies from animal-based proteins, stricter rules imposed by regulatory agencies altogether with the risk of bovine spongiform encephalopathy has prompted manufacturers and researchers to look for the alternatives to animal-based proteins for the purpose of clarification. In view of this, plant- and vegetable-based fining agents as alternative to animal-based proteins have started gaining attention from many researchers. Potatoes and peas have already been accepted and allowed in some winemaking regions (Iturmendi et al., 2013). Marchal et al. (2002a) showed very good clarification of Burgundy wine with the help of gluten proteins. Zeins as potential clarifying agents for red wine have also been reported (Simonato et al., 2013). Wheat gluten and isolates from pea, lentil, and soybean, used as fining agents, have shown to effectively reduce turbidity in white wine (Granato et al., 2014).

## Polysaccharides as Clarifying Agents

Many plant- and seaweed-based polysaccharides function as stabilizers, gelling agents, and viscosity modifiers in a wide range of food products. Polysaccharides such as alginates, carrageenan, and other seaweed-based extracts attain negative charge at lower pH and hence can bind and precipitate positively charged proteins from aqueous solutions (Cabello-Pasini et al., 2005). This forms the basis for clarification of juices and other beverages.

### Alginate

The most abundant polysaccharide which is extracted from brown seaweed is alginate. On dry basis, alginate comprises about 18%–40% of the biomass in brown algae (Moe et al., 1995; Whistler and BeMiller, 1997). It is present in seaweed as a mixed salt of sodium, potassium, calcium, and magnesium (Draget, 2009). *Ascophyllum nodosum*, *Durvillaea antarctica*, *Durvillaea potatorum*, *Laminaria digitata*, *Laminaria hyperborea*, *Laminaria saccharina*, *Laminaria japonica*, *Ecklonia maxima*, *Macrocystis pyrifera*, *Lessonia nigrescens*, and *Lessonia trabeculata* are some of the common species of algae, which are cultivated to produce alginate (McHugh, 2003; Helgerud et al., 2009). In its structure, alginic acid contains three kinds of polymer segments, viz., D-mannuronic acid units, L-guluronic acid units, and alternating D-mannuronic acid and L-guluronic acid residues (Black, 1950; Hoppe and Schmid, 1962). The proportion of these polymer segments also varies depending on the type of brown algae used.

Alginic acid is insoluble, but sodium, potassium, or ammonium salts are readily soluble and hence are preferred for most food and industrial uses. Among the most widely used compound is the sodium alginate, referred as algin. Alginates have found numerous applications in the food industry, and it can act as thickening, stabilizing, emulsifying, suspending, film-forming, or gel-forming agents without affecting the flavors. Gibsen and Rothe (1955) have reported many such applications of alginate. Apart from these applications, alginates can also be used during juice processing (Moncrieff, 1953), beer (Steiner, 1953), and winemaking (Kulzhinskaya, 1951) in the form of clarifying agent.

### Other Polysaccharides

Other polysaccharide-based clarifying agents may include gum arabic (Vivas et al., 2001), guar gum (Wang et al., 2010), carob gum (Cairns et al., 1986), xanthan gum (Erkan-Koç et al., 2015), carboxymethylcellulose (Genovese and Lozano, 2001), agar-agar (Rehman et al., 2014), gellan, λ-carrageenan, and xanthan (Ghafoor et al., 2008), and many others.

## Synthetic Polymers as Clarifying Agents

### Polyvinylpolypyrrolidone

PVPP is a synthetic, high-molecular-weight clarifying agent made up of cross-linked monomer of polyvinylpyrrolidone. PVPP has long been used in the beverage industry as a polyphenol adsorbent (Siebert and Lynn, 1997, 1998). Although, it has been called as a “protein-like” fining agent, insoluble PVPP interacts with only few reactive groups. Hence, PVPP is used for binding and removing smaller phenolic compounds such as catechins and anthocyanins, which are responsible for causing browning and bitterness in wines. However, PVPP, along with charcoal and casein, can remove resveratrol, a component that imparts certain health benefits (Castellari et al., 1998). Typical usage level of PVPP for wines ranges from 1 to 6 lb (1000 gallons)<sup>-1</sup> (or 0.12–0.72 g L<sup>-1</sup>) (Morris and Main, 1995).

### Nylon

Nylon is a synthetic fiber that comprises of repeating polymer units linked by peptide bonds. It is mainly used for clarification of wines, and its use is legal in many countries. On its surface, nylon has carbonyl functional groups, which can adsorb phenols and similar compounds. Successful reduction in color of white table wines and slowed browning with very little effect on the quality of wine has been reported by Fuller and Berg (1965). However, it is less preferred to PVPP because of its lesser efficiency of adsorption (Caputi and Peterson, 1965; Fuller and Berg, 1965; Rossi and Singleton, 1966; Boulton et al., 1996).

## Tannins as Clarifying Agents

For clarification, tannins made from oak wood or grape pomace are used (Zoecklein et al., 1995; Jackson, 2000; Lee and Noble, 2003). In solution, tannin is negatively charged and forms complex with positively charged gelatin to form flocs and thereby cause clarification. When compared with bentonite, tannins are less popular because of its lower adsorptive capacity (Ribéreau-Gayon et al., 2006). Tannin is also used for adjusting astringency in juices and wines.

## Bentonite as a Clarifying Agent

Bentonite is arguably the most frequently used fining agent. It is volcanic clay discovered in Wyoming. When hydrated, it can grow 20 times its size. Bentonite must be hydrated before being added to the wine or fruit juices, otherwise it would just sink to the bottom and absorb all parts of the wine and not just the particles intended. After hydration, bentonite is able to attract positively charged particles because it has a negative charge itself.

When a 5% (w/v) suspension of bentonite is made up with warm water, a pale green–gray milky liquid results if the concentration of bentonite reaches 10%–15% (w/v), forming a gelatinous paste. These thicker slurries will form a gel when left to stand but will liquefy on agitation, i.e., they are thixotropic. This is due to the presence of positive charges on the edges of the plates, which are electrostatically drawn to the negatively charged faces of adjacent plates and thus form a contact at an angle. This means that although bentonite primarily acts by an adsorptive interaction between the flat, negatively charged platelet surfaces and positively charged proteins, a certain amount of binding with negatively charged wine constituents may occur. Bentonite is now widely used for the adsorption of proteinaceous material from wines but was originally used for clarifying vinegar.

## Dietary Fiber (Psyllium, $\beta$ -Glucan)

Lilian E Figueroa<sup>a</sup> and Marina Dello Staffolo<sup>a,b</sup>, <sup>a</sup> Planta Piloto de Ingeniería Química – PLAPIQUI (UNS-CONICET), Bahía Blanca, Argentina; and <sup>b</sup> Departamento de Ing. Química, Facultad de Ingeniería, Universidad Nacional de La Plata (UNLP), La Plata, Argentina

© 2019 Elsevier Inc. All rights reserved.

### Overview

$\beta$ -glucans and psyllium are recognized as functional and bioactive ingredients and they are included in the complex dietary fiber group.  $\beta$ -glucans are found in bacteria, edible mushrooms, yeast and grains, such as oat, barley, rye, and wheat (Mittmesser and Combs, 2017). It can be purchased like a food additive (VITACEL<sup>®</sup> Oat Fibre, Germany) or it can be extracted from above-mentioned sources for scientific studies. Psyllium is a term used to designate both plantago plants and a mucilaginous material prepared from seed husks of *Plantago* genus including *Plantago ovata*, *Plantago psyllium*, *Plantago indica*, etc., which grow in certain temperate and subtropical regions (Yu et al., 2008; Cui and Roberts, 2009). It has a long history of use as a dietary fiber supplement to promote the regulation of large bowel function, and the reduction of blood cholesterol levels (Fischer et al., 2004). It can be acquired alone (as particles or powder form, Frontier, USA) or accompanied by other additives like sucrose (Metamucil<sup>™</sup>, USA). Nowadays,  $\beta$ -glucans and psyllium are employed by the food industry and are studied by the world research community in several fields of science (chemistry, food science, nutrition, medicine, materials science, microbiology, etc.).

The basic structures of  $\beta$ -glucans and psyllium are known from past decades. However, small variations, continue to be reported year after year. From a functional point of view,  $\beta$ -glucans and psyllium are soluble in water and they are form gels. Accordingly, they could classify as viscous soluble fibers (Dello Staffolo et al., 2012). Jenkins et al. (1986) mentioned the term viscous soluble fiber in their works about fibers and health benefits. Then, several researchers advance in this topic (McRorie and McKeown, 2017).  $\beta$ -glucans and psyllium differ in that the first is a single chemical substance, while psyllium is a mixture of chemical substances since it is the yield of seed milling.

$\beta$ -glucan and psyllium have been utilized in food industry owing to their health benefits and technological properties. This is consistent with the global trend in creating healthy foods, also called functional foods, to incorporate into the diet of consumers who are concerned about reducing diseases and/or improving their life quality.

### Chemical Structure and Molecular Characteristics

Cereal  $\beta$ -glucan is a polysaccharide that occurs in the subaleurone and endosperm cell walls of cereals seeds, including oats, barley, rye, and wheat. The level of  $\beta$ -glucans in cereals varied between species, as shown in Table 1. Cereal  $\beta$ -glucans are linear homopolymers of glucose bonded by  $\beta$ -(1  $\rightarrow$  4) and  $\beta$ -(1  $\rightarrow$  3) glucosidic linkages. About 90% of the glucose units are arranged in blocks of two or three consecutive (1  $\rightarrow$  4)-linked units separated by a single (1  $\rightarrow$  3)-linkage, which forms the two building blocks of cereal  $\beta$ -glucans: a cellotriosyl (DP3) unit and a cellotetraosyl (DP4) unit, as shown in Fig. 1. The (1  $\rightarrow$  3)-linkages act as kinks to disrupt the regularity of the (1  $\rightarrow$  4)-linkages (Nie et al., 2018a). The remaining less than 10% of the polymer chain is mainly composed of longer cellulosic sequences ranging from 5 up to 14  $\beta$ -D-Glcp residues (Fig. 2).

The DP3/DP4 ratio (the fingerprint of each grain) in oat  $\beta$ -glucan is typically 2:1; in barley and wheat are 3:1 and 4:1, respectively. However, small variations in the trisaccharide–tetrasaccharide ratio has been reported within the same species, which may arise from several factors including differences between species, growing-conditions, extraction-conditions, and analytical methods. Some studies have suggested the presence of amino-acid residues and inner C-6 carbon-bound phosphomonoesters in the oat  $\beta$ -glucan molecule although, these additional structures have not always been observed (Wang and Ellis, 2014; Comino et al., 2016).

Cereal  $\beta$ -glucans in aqueous solution adopt a disordered random coil conformation with an expanded, semi-flexible chain conformation whose shape fluctuates continually under Brownian motion. In addition, there is molecular aggregation among  $\beta$ -glucan molecules through hydrogen bonding, which imparts great stiffness (thus high solution viscosity) to the polymer. These aggregates could be effectively eliminated in 0.5 M sodium hydroxide, but not with other treatments (6 M urea or ultrasonic treatment). The success of obtaining an aggregate-free solution allowed the measurement of true molecular weight and conformational

**Table 1** Amount (w/w) of  $\beta$ -glucans in four common cereals

Cereal	$\beta$ -Glucan content
Barley	3%–11%
Oat	3.2%–6.8%
Rye	1%–2%
Wheat	0.5%–1%

From Cui and Roberts (2009).

**Figure 1** Building blocks (trisaccharides and tetrasaccharides) of cereal  $\beta$ -glucans. From Cui and Roberts (2009).

**Figure 2** Chemical structure of oat  $\beta$ -glucan. G represents a glucose unit and the numbers indicate the linkage sites; the ratio of  $m/n$  is approximately 2. From Wang and Ellis (2014).

properties of single molecules (Li, 2007; Nie et al., 2018a). The aggregation behavior was also confirmed by NMR relaxation techniques (Wu et al., 2017). The oat  $\beta$ -glucan had an average molecular weight of  $2.0 \times 10^3$  kDa whereas barley  $\beta$ -glucan had  $1.79 \times 10^3$  kDa average molecular weight (Shah et al., 2017). Even so, this value could vary to some extent owing to the complexity and polydispersity of natural polysaccharides (Nie et al., 2018a). Li et al. (2012) proposed that as molecular weight increased, the degree of aggregation decreased, due to the lower diffusion rate of large molecules. These authors also used computer modeling techniques to calculate those molecular parameters and visualize the shape of the random coil polysaccharide in aqueous solution. Fig. 3A illustrates the active site for the formation of junction zones between two  $\beta$ -D-glucan molecules. Fig. 3B shows the 3D molecular model with a moderately extended sinuous chain conformation. The conformational parameters of cereal  $\beta$ -glucans were calculated by RMMC simulation, which are in good agreement with experimental results and also revealed that chain stiffness increased with the tri/tetra ratio. Furthermore, the conformation of  $\beta$ -glucans could be modified by physical (ultrasonic, irradiation, microwave, extrusion, dough formation, baking, cooking/boiling) and chemical (carboxymethylated, sulfated and phosphorylated) methods (Comino et al., 2016; Honcu et al., 2016; Wang et al., 2017).

Psyllium material obtained by milling psyllium seed husks mainly contains hemicellulose, cellulose, and lignin (Dello Staffolo et al., 2011). In most of the *Plantago* species analyzed to date, it has been found that psyllium hemicellulose is a highly branched heteroxylan which consists of a xylan backbone with both (1 $\rightarrow$ 4) and (1 $\rightarrow$ 3) linkages and side chains attached to the O-2 or O-3 position (Fig. 4). Psyllium polysaccharide is composed of xylose (57%), arabinose (22%), 10%–15% uronic acid, and trace amounts of galactose, rhamnose, glucose, and mannose. However, these percentages fluctuate depending on *Plantago* genus species from polysaccharides were extracted as well as, the extraction method employed (Nie et al., 2018b). Although most psyllium polysaccharides found are heteroxylans, there are still some exceptions. Biringanine et al. (2012) described a *Plantago palmata* polysaccharide that presents an unbranched galacturonan domain.

The different extraction techniques (water or alkaline) produce several heterogeneous fractions of psyllium polysaccharides: some fractions contain uronic acids while other fractions are neutral polysaccharides as noted by different research groups. The presence of soluble and gel fractions observed by Guo et al. (2009) is in agreement with the findings of Al Assaf et al. (2003) who fractionated psyllium polysaccharides into three fractions: a water-soluble fraction (Mw 1–3 million Dalton), a gel fraction (Mw 9–20 million Dalton), and a matrix fraction (insoluble). Edwards et al. (2003) reported molecular weights of  $2.2 \times 10^6$  for water extracted and  $1.6 \times 10^6$  for 0.1 M NaOH extracted psyllium polysaccharides using size exclusion chromatography coupled with multiangle laser light scattering. Comparing the data of Al-Assaf's group and Edward's group, it was found that the water-extractable polysaccharides were in the same order and the difference existed between the polysaccharides extracted from alkaline solutions (Cui et al., 2013).

Currently, most commercial products containing ground psyllium seeds husk utilize the *P. ovata* species. Saghir et al. (2008) studied the psyllium polysaccharide extracted from *Plantago ovata* and found it a main chain consisted of  $\beta$ -(1 $\rightarrow$ 4)-linked Xylp;

**Figure 3** (A) Side and top view of single helix structure of six consecutive cellotriosyl units. (B) Snapshot view of a  $\beta$ -D-glucan molecule in random coil shape (Li et al., 2012).

some Xylp residues carried a single Xylp moiety at its O-2, and other Xylp residues have trisaccharide branches at position 3 with a sequence of L-Araf- $\alpha$ -(1 $\rightarrow$ 3)-D-Xylp- $\beta$ -(1 $\rightarrow$ 3)-L-Araf.

Psyllium polysaccharides prepared from different species have in common the gelling and strong water-absorbing capacities. These features can be explained because psyllium gum is an anionic polysaccharide which could bear a negative charge due to ionized carboxyl groups. Therefore, the intermolecular electrostatic repulsion owing to homo-charges makes the polysaccharide chains fully extended and interpenetrated with each other to form intermolecular cross-linking which induces gelation (Farahnaky et al., 2010). Moreover, the swelling behavior could be a result of the entanglement of polysaccharide chains and development of inter- and intramolecular hydrogen bonds between the polysaccharide and water, which would cause more and more water to be trapped within the polysaccharide chains (Rao et al., 2011). It is noteworthy that psyllium polysaccharide is rich in calcium, which has a significant influence on its gelling properties (Yin et al., 2015).

## Functional Properties

Likewise, the chemical structure, molecular weight, and molecular weight distribution are fundamental  $\beta$ -glucans properties that regulate their overall functionality: solubility, hydration, conformation, and gelation in aqueous systems, which is relevant for the food industry and physiological behavior (Nie et al., 2018a). A higher (DP3/DP4) ratio causes reductions in solubility, promoting the gel-forming properties (Brennan and Cleary, 2005). High-molecular-weight oat  $\beta$ -glucan solutions exhibit typical viscoelastic flow behavior and do not form a gel within a reasonable time period. Freshly prepared barley and wheat  $\beta$ -glucan solutions are also viscoelastic fluids as demonstrated in Fig. 5 (Cui and Roberts, 2009).  $\beta$ -glucan gelation capacity is in the order of wheat > barley > oat, which is the same as the order of the tri/tetrasaccharides ratio of these cereals. The gelation rate of  $\beta$ -glucan solutions usually decreases with increased molecular  $\beta$ -glucan weight as shows Fig. 6 (Cui et al., 2013). Subsequent findings allowed researchers to propose the following hypothesis. The gelation rate and strength of cereal  $\beta$ -D-glucans are determined by a combination of the mobility of the polymer chains and the entanglement density of the “junction zone” of the polymer chain in solutions. An increase in the tri/tetra ratio in the  $\beta$ -D-glucans leads to a more rigid conformation in dilute solutions, and easier formation of gels at higher concentrations; smaller molecular weight  $\beta$ -D-glucans have higher mobility, which have more opportunity to interact with neighboring chains to form entanglements; this results in a higher degree of aggregation. The association of

**Figure 4** (A) Proposed consensus psyllium structure extracted from ispaghula husk (*Plantago ovata*) (B) The possible structure of polysaccharide (PLP-2) from the seeds of *Plantago asiatica* L. Xylp: xylopyranose, Araf: arabinosefuranose, Galp: galactopyranose, Rhap: rhamnopyranose. R, may be T-linked GlcAp, 1,6-linked Glcp, 1,4-linked Glcp, 1,3,6-linked Glcp or 1,3,4-linked Galp. (A) From Edwards et al. (2003). (B) From Nie et al. (2018b).

three-dimensional networks (entanglements) or the aggregates at higher concentrations leads to the formation of gel (Nie et al., 2018a).

Psyllium polysaccharide could be dissolved in strong ammonia solution and dimethyl sulfoxide. However, it is insoluble in acetone, alcohol, ether, chloroform dichloromethane, dimethylamine, trimethylamine, diethylether, and ethylacetate (Nie et al., 2018b). Besides, psyllium gum does not completely dissolve in water due to its high molecular weight. It forms a gel-like paste or dispersion when hydrated (Cui et al., 2013). Freshly prepared psyllium gum dispersion (1%) exhibits a Newtonian plateau at low shear rates and shear thinning flow behavior at higher shear rates. However, upon aging, psyllium gum dispersions form cohesive gels (Izydorczyk et al., 2005a,b). Psyllium gel is thermally stable, with  $G'$  and  $G''$  decreasing with increased temperature. No melting is observed unless the temperature exceeds 80 °C (Fig. 7), where a deeper decrease of  $G'$  was observed (Haque et al., 1993). It was also found that the psyllium gel exhibits an extensive swelling property in water and 0.1 M HCl solution, whereas no swelling was observed in 0.5 M NaOH solution (Rao et al., 2011).

Farahnaky et al. (2010) investigated the effect of concentration, temperature, and pH on the dynamic rheology of psyllium gels. The results showed that psyllium gel at 2%-3% concentration was a weak gel, since the dynamic storage modulus ( $G'$ ) was larger

**Figure 5** Viscoelastic properties of wheat b-glucan: freshly prepared versus standing for 2 hours at room temperature (25 °C) ( $M_w = 3.4 \times 10^4$ , measured at 25 °C). From Cui and Roberts (2009).

**Figure 6** Increase in gelation rate corresponding to decrease in molecular weight. From Cui and Roberts (2009).

than the viscous modulus ( $G''$ ), and there was no obvious melting point found for psyllium gel, indicating that the melting process was a continuous and long process. As for the pH value, the maximum functional properties of psyllium gels were observed at a pH of 4 and 7. It can be explained as net electrostatic repulsion decreases at low pH values, and the interaction of molecules also decreases, which leads to a reduction in gel elasticity. In addition, that the gel elasticity decreases in a higher pH value environment might be attributed to an alkaline depolymerization reaction, which results in fewer junction zones.

When  $\text{Ca}^{2+}$  is added to the gel, the gel becomes more resistant to temperature; meanwhile, its bioavailability is reduced (Cho et al., 2001). Guo et al. (2009) reported that when the psyllium polysaccharide solution was added to with 50 mM  $\text{Ca}^{2+}$ , the spectrum of  $G'$  and  $G''$  showed less frequency dependency, and lower  $\tan \delta$ , which meant the psyllium gel appeared more typical of a true gel in the presence of  $\text{Ca}^{2+}$ . On the contrary, by adding  $\text{Ca}^{2+}$ , the gel strength became much stronger and it was more tolerant of higher temperatures and the microstructure of the gel changed from fibril strand gel to aggregated gel (Fig. 8). Yin et al. (2015) treated psyllium gels with ethylenediaminetetraacetic acid (EDTA) to remove calcium ions. They found that its intrinsic viscosity decreased significantly; however, adding  $\text{Ca}^{2+}$  increased the apparent viscosity of psyllium gels increased considerably. In addition to modifying the rheological behavior of psyllium dispersions and gels, calcium binding also causes a decrease in its bioavailability and absorption in the digestive tract (Rodríguez et al., 2008). A reduction in the availability of glucose and iron has also been observed in chemical digestive models (Rodríguez et al., 2008; Dello Staffolo et al., 2011).

**Figure 7** Temperature dependence of  $G'$ ,  $G''$  and  $\tan$  for 1% (w/v) isabgol (from *Plantago ovata*) on (A) heating and (B) cooling at  $1 \text{ deg. min}^{-1}$ . Measurements were made at  $10 \text{ rad s}^{-1}$  and 2% strain. From Haque et al. (1993).

## Functionality and Health Promotion Relationship

$\beta$ -glucans and psyllium are viscous soluble fibers inducing thickening when mixed with liquids. An increase in the viscosity of food may have several effects, including slowing down the small intestinal transit time, reducing the interaction between food nutrients and digestive enzymes, and increasing the time for nutrient diffusion, by increasing the thickness of the unstirred water layer. A mechanism for viscous dietary fibers in appetite regulation has been reported. Viscous soluble fibers can absorb large quantities of water, and increase stomach distension, which may trigger afferent vagal signals of fullness. Besides, more time and effort are required to masticate foods rich in dietary fibers, and this allows more signals mediating satiety sensations to the brain. Viscous dietary fibers increase the viscosity of the digesta in the small intestine and therefore prolong small intestine transit time and absorption rate of nutrients. These, in turn, affect gastric emptying and signaling to the central nervous system (Brownlee, 2011; Nie et al., 2018b; McRorie and McKeown, 2017).

This mechanism that influences the absorption of nutrients in the first portion of the digestive system, generates effects related to health promotion and life quality improvement such as: regulation of glycaemia (FDA, 2017; Wood, 2011; Gibb et al., 2015), hypocholesterolemia (Wolever et al., 2011; Wei et al., 2009), hypolipemia (Choi et al., 2010; Rahbar et al., 2014), body weight decrease (Salas-Salvadó et al., 2008; Galisteo et al., 2010). Likewise, these effects have secondary consequences as decreased risk of cardiovascular disease (Code of Federal Regulations, 2010; FDA, 1998; McRae, 2017) and cancer prevention (Dahm et al., 2010; Kaczmarczyk et al., 2012; Sohn et al., 2012).  $\beta$ -glucan and Psyllium possess other abilities in relation with health benefits such as immune enhancement (Zhao et al., 2014) and antioxidant activity (Kofuji et al., 2012; Gong et al., 2015).

## Functional Foods

In recent years  $\beta$ -glucans as emulsion stabilizers, bulking agents, fat replacers, and healthy ingredients, have been incorporated and studied in the following food groups. For example, in bakery products have been developed two-layer flat bread (Izydorczyk et al., 2008), cookies and peanut spreads, muffins (Moriarty et al., 2011), and batter and sponge cake (Majzoobi et al., 2015). However, in yeast-leavened bread,  $\beta$ -glucan could produce high water retention, poor crumb texture, and loaf volume. These effects are dependent on the concentration of  $\beta$ -glucan in the bread as well as the molecular weight (Cui and Roberts, 2009). It has been also studied durum wheat pasta and noodles (Izydorczyk et al., 2005a,b). In this type of foods, slight differences in color have been observed as a disadvantage, in comparison with pasta without fiber (Quinde-Axtell et al., 2005). Among milk products, it has been developed: yogurts (Brennan and Tudorica, 2008), cheeses, and ice creams. Chicken meat patties and sausages (Huang et al., 2011) are examples of processed meats products. In beverages, Lyly et al. (2009) studied the perceived satiety with healthy volunteers. Currently, the best-selling beta glucan-containing foods are bread, cereals bars, breakfast cereals, snack foods, and oat and barley-based products, such as whole oats, oat bran, oat meal, barley flour, etc. However, from time to time other types of foods with beta glucans, as functional ingredients appear but, they do not achieve to stabilize in the market. An exception could be pasta including cereal bran, which can be found in the market with some discontinuity, many years ago.

Psyllium has been used for decades, in beverages (orange juice, apple, etc.) to which pharmaceutical formulas like Metamucil are added (Chan and Wypyszyk, 1988). Probably, the first use of Psyllium as a food additive was into confectionery and bakery products (Czuchajowska et al., 1992) through its ability to mimicking gluten network. Then, it is continued to work in this area (Zandonadi et al., 2009; Cappa et al., 2013; Raymundo et al., 2014; Fratelli et al., 2018). Among milk products, it has been studied: yogurts (Rodríguez et al., 2008; Ladjevardi et al., 2015; Yadav et al., 2016), dairy desserts (Dello Staffolo et al., 2017). Additionally, psyllium has been employed in confectionery jams (Figueroa and Genovese, 2018) as a stabilizer and a gel filling.

It is estimated from a western diet that the average daily consumption of arabinoxylan in the absence of fiber supplements ranges from 1–5 g/day. To obtain a beneficial effect on post-prandial glucose excursions, the conditions of use for the claim are that 8 g of arabinoxylan-rich fiber derived from wheat endosperm (which is at least 60% arabinoxylan by weight) per 100 g of available carbohydrates should be consumed per quantified portion as part of a meal. To achieve this recommended intake, consumption of fortified foods or arabinoxylan fiber supplements will be required (Kellow and Walker, 2018). In consequence, incorporating psyllium into food, especially at the level required to allow a health claim, is challenging due to its strong water-absorbing and gelling properties. In addition, an unpleasant slimy mouthfeel and undesirable flavor characteristics were reported for some foods containing psyllium. To promote the application of psyllium in foods, some researchers developed an enzyme treatment method to produce psyllium with improved sensory properties and reduced water-adsorbing capacity without altering its hypolipidemic capacity (Allen et al., 2004).

## Conclusions

$\beta$ -glucans and psyllium are viscous soluble fibers with the ability to form gels, which gives them several interesting properties for the food industry, life quality improvement, and treatment of certain diseases. Cereal  $\beta$ -glucans are linear homopolymers of glucose bonded by  $\beta$ -(1  $\rightarrow$  4) and  $\beta$ -(1  $\rightarrow$  3) glucosidic linkages with repeated building blocks of tri and tetrasaccharides. Psyllium hemicellulose is a highly branched heteroxylan which consists of a xylan backbone with both (1  $\rightarrow$  4) and (1  $\rightarrow$  3) linkages and side attached chains.  $\beta$ -glucans and psyllium promote health because they regulate glycemia, cholesterolemia, lipidemia, body weight and

decrease the risk of cardiovascular and cancer diseases. These effects have been well documented and they continue to study for both polysaccharides. A wide range of food products with  $\beta$ -glucans and psyllium have been developed and studied to satisfy functional foods demand by consumers and reach their recommended intakes. In this process, some sensory disadvantages have appeared in some foods that have begun to be solved but even today are the future challenge for food scientists and technologists with the aim of achieving the highest levels of acceptability by consumers.

## Diglycerides

### Diglyceride Structure

Diglycerides or diacylglycerols (DAG), are composed of two fatty acids esterified to the trihydric alcohol glycerol. Since glycerol has three hydroxyl groups available as binding sites, there are two possible structural isomers. A 1,2-DAG has fatty acids esterified to the *sn*-1 and *sn*-2 positions on the glycerol. A 1,3-DAG has fatty acids linked to the *sn*-1 and *sn*-3 positions. Acyl migration occurs within DAG molecules and results in an equilibrium with 1,3-DAG making up 60%–70% of the total concentration (Lo et al., 2008; Matsuo, 2004; Siew and Ng, 1999). This class of molecule is amphiphilic in nature because of the lipophilic fatty acids and the hydrophilic hydroxyl group. As a result, DAGs have surface active properties.

### Synthesis in Plants and Animals

DAGs can be produced in plant and animal cells as a by-product of triglyceride (TAG) biosynthesis (Siew and Ng, 1995). TAGs are synthesized by the addition of fatty acids to glycerol-3-phosphate with the help of fatty acid-CoA esters and acyltransferase enzyme complexes (Belitz et al., 2009). During this process DAGs are produced just prior to the synthesis of TAGs. Therefore, in the event that this process is not completed, a DAG may be formed. Additionally, the hydrolytic activity of lipase enzymes during maturation or harvesting of oil fruits and seeds as well as during the storage of an edible oil can lead to increased levels of DAGs. These enzymes hydrolyse the ester linkages within TAGs, producing DAGs and monoglycerides (MAGs) along with free fatty acids (Cheng et al., 2017). DAGs are typically found within edible oils at very low levels, but depending on the type of oil, method of extraction, and storage conditions they may be found at concentrations up to 10% (Lo et al., 2008; Matsuo, 2004). Edible oils originating from oil fruits, as opposed to oil seeds, are known to contain higher levels of DAGs because they are exposed to water for a longer time, meaning the TAGs are more prone to undergoing hydrolysis reactions (Cheng et al., 2017).

### Industrial Production

While there are many different ways through which DAGs can be formed, DAGs for commercial use are typically produced one of two ways. Either through a direct esterification reaction between glycerol and fatty acids, or by performing glycerolysis between glycerol and a fat or blend of fats. With both of these processes, the amount of glycerol in the reaction will determine the ratio of MAG/DAG/TAG produced. The production of DAGs can be optimized for a specific process by changing the amount of glycerol added as a reactant. A high concentration of glycerol will lead to an increase in the concentration of MAGs produced. Alternatively, performing these reactions with a low amount of glycerol results in a product high in TAGs. Furthermore, glycerolysis is a more cost-effective option because the cost of a fat or oil, whether it be natural or hydrogenated, is less than that of the fatty acids used in a direct esterification process. Additionally, a higher quantity of glycerol is required to perform a direct esterification. This increases the cost further and because lipids have a low solubility in glycerol, the reaction must be performed at a higher temperature (Hasenhuettl, 2008; Lo et al., 2008).

Both processes can be performed either chemically or enzymatically. Chemical esterification and glycerolysis reactions are often faster and more reproducible compared to the enzymatic processes. In addition, in terms of material cost, it is more cost effective to perform these reactions chemically, because the cost of enzymes greatly exceeds that of the chemical catalysts (Gibon and Kellens, 2014). However, with chemical processing, the reaction is run at high temperatures (>200 °C). Besides the energy costs associated with these high reaction temperatures, side reactions occur which lead to colour changes and the production of off-flavours. This decreases the overall quality of the oil, which must be improved through further processing steps (Hasenhuettl, 2008). Furthermore, the lipase enzymes used to catalyze these reactions typically have optimal temperatures in the range of 60–80 °C (Kristensen et al., 2005). Since the reaction temperatures are relatively low when using enzymes, the quality of the oil remains high. As a result, the high cost of enzymes and the lower reaction rates may be offset by the improved quality of the oil (Phuah et al., 2015). Therefore, the use of enzymes represents a very viable means of producing DAGs. In addition, with the push for clean label products in recent years, the use of a biocatalyst is an attractive alternative to chemical catalysts.

When performing enzymatic modifications on lipids, it is important to consider using immobilized enzymes, particularly, enzymes immobilized on a hydrophobic support. Immobilized enzymes are both easier to disperse in oil and easier to separate and recover compared to free lipases. The use of a hydrophilic support encourages the formation of a layer of glycerol surrounding the lipase particles. This creates a barrier, decreasing contact between the lipase and the lipids, reducing the performance of the enzyme. It is for these reasons that lipases immobilized on hydrophobic supports have been known to perform more effectively (Fregolente et al., 2008; Kristensen et al., 2005).

## Diglycerides as Emulsifiers

DAGs are frequently used in food products for emulsification purposes. They are typically found as a mixture of MAGs and DAGs (Kim and Akoh, 2015). In fact, MAGs and DAGs are some of the most commonly used emulsifiers in the food industry. The DAG molecule has only one hydroxyl group, whereas MAGs have two, and so DAGs are therefore more lipophilic compared to MAGs and thus have a lower HLB value. Because of these differences, MAGs are more surface active and are a more sought-after ingredient for emulsification purposes. However, the distillation process used to purify the MAGs, after a mixture of partial glycerides has been produced, adds to the ingredient cost. For this reason, a mixture of MAGs and DAGs is used more frequently. In many cases, a blend of emulsifiers with different HLB values will perform better than one single emulsifier as the emulsifiers work synergistically (ICI Americas Inc., 1976). Therefore, it is often beneficial for food systems to contain a blend of MAGs and DAGs besides simply as a means of reducing cost. While MAGs and DAGs may be found in a wide range of food products as an emulsifier, they are predominantly used in bakery products (i.e. breads and cakes), frozen desserts, and sauces/dressings (Nash and Brickman, 1972). This emulsifier is typically used to increase the volume and improve the crumb structure of baked goods and to extend their shelf life, by preventing staling. In sauces and dressings, this emulsifier acts to keep the water and oil phases from separating, thereby improving the appearance and shelf life.

In addition to DAGs being used directly as an emulsifier, these molecules can be esterified to organic acids, producing a wide range of emulsifiers with different HLB values that can be used for a variety of food applications. In most cases, it is again a mixture of MAGs and DAGs used to produce these esters and they are named accordingly. These include, diacetyl tartaric acid esters of mono- and diglycerides (DATEM), citric acid esters of mono- and diglycerides (CITREM), lactic acid esters of mono- and diglycerides (LACTEM), acetic acid esters of mono- and diglycerides (ACETEM), and tartaric acid esters of mono- and diglycerides (TATEM).

## Proposed Health Benefits

There are several well researched health benefits pertaining to the consumption of DAGs. These include reduced serum TAG levels and anti-obesity effects. Although there has been conflicting research on these health benefits, due mainly to differences in the levels of DAGs consumed and the condition of the test subjects, it is generally regarded that the consumption of DAGs in place of TAGs is beneficial (Phuah et al., 2015). Consumption of DAGs has been shown to reduce fat stores within the body, helping to reduce body mass index and waist circumference. Additionally, several animal studies have demonstrated increased rates of  $\beta$ -oxidation as well as increased activity of the enzymes involved in this process (Lo et al., 2008; Matsuo, 2004).

The energy value and digestibility of DAG oil has been shown to be similar to that of traditional TAG oil (Taguchi et al., 2001). It is therefore believed that the different metabolic fates of DAGs compared to TAGs bring about these positive health effects. The effects arise mainly from the 1,3-DAGs rather than the 1,2-DAGs. When TAGs are metabolized, two of the ester bonds are cleaved to form free fatty acids and 2-MAGs. These molecules are then able to pass through the intestinal wall where they are reassembled into TAGs based on a 2-MAG pathway. They are then packaged into chylomicrons for transport throughout the body. In the case of 1,2-DAGs, the ester bond at position *sn*-1 is cleaved to form 2-MAG and a free fatty acid. These components are therefore able to be used towards assembling TAGs for packaging into chylomicrons. 1,3-DAGs however, will be metabolized to form 1-MAGs and free fatty acids. The body is not efficient at assembling TAGs from 1-MAGs, and so following absorption in the gastrointestinal tract the components are transported to the liver for metabolism rather than being transported and stored throughout the body in adipose tissue. This difference in metabolic pathway between TAGs and 1,3-DAGs is believed to cause the reduced post-prandial serum TAG levels and the decreases in body fat stores observed when DAG oil is consumed in place of traditional TAG oils (Flickinger and Matsuo, 2003; Kim and Akoh, 2015; Lo et al., 2008; Maki et al., 2009; Matsuo, 2004; Teramoto et al., 2004).

## Diglyceride Oil

As a result of the health benefits associated with the consumption of DAGs, oils containing high levels of DAGs have been commercialized. KAO Corporations developed a cooking oil known as Econa oil in Japan and released it to the market in 1999 (Matsuo, 2004). This oil contained around 80% DAGs, compared to conventional cooking oils that contain less than 10%. Enova oil later became available in the United States after Kao Corporations partnered with Archer Daniels Midland (Lo et al., 2008). These products were found to contain high levels of glycidyl esters and were voluntarily removed from the market in 2009 (Gibon and Kellens, 2014).

Glycidyl fatty acid esters (GEs) are classified as a “possible human carcinogen” (group 2) by the International Agency for Research on Cancer because they are hydrolysed to form the carcinogen glycidol in the intestinal tract. GEs are formed because of the high temperatures of the deodorization step during the refining of oils. Furthermore, DAGs are known to be a precursor to GE formation. As a result, most edible oils contain some level of glycidyl esters. Furthermore, oils containing a DAG content of greater than 6% are known to have considerable amounts of glycidyl esters (Cheng et al., 2017).

## Crystallization of Lipids

Pure DAGs crystallize differently from pure TAGs. Additionally, the isomeric form of the DAG changes the crystallization behaviour. When considering DAGs and TAGs that contain the same fatty acids, the melting point of the 1,3-DAG is generally around 10 °C higher than that of the TAG. While the melting point of the 1,2-DAG is approximately 10 °C lower than that of the 1,3-DAG, meaning that it has a similar melting point to that of the TAG (Lo et al., 2008). In the case of TAGs and DAGs containing palmitic acid, 1,3-dipalmitin (1,3-PP) has a melting point of 72.5 °C, tripalmitin has a melting point of 65.5 °C, and 1,2-dipalmitin (1,2-PP) has a melting point of 64.0 °C (Belitz et al., 2009). Furthermore, the two isomeric forms of DAG crystallize in different polymorphic forms. 1,2-DAG can crystallize in either the  $\alpha$ -form or the  $\beta'$ -form, while 1,3-DAG can crystallize in two types of the  $\beta$ -form (Lo et al., 2008).

Besides simply crystallizing differently in the purified form compared to TAGs, small amounts of DAGs have an effect on the crystallization of TAGs in lipid mixtures. Palm oil is notorious for crystallizing slowly. This is believed to be caused by the high DAG content (typically 5%–8%). Siew and Ng (1999) investigated the effects of various DAGs containing palmitic and oleic fatty acids on the crystallization of purified palm oil TAGs. In this study, DAGs were first removed from the palm oil and specific DAGs were later added back to the purified palm oil TAGs at various concentrations (1, 2.5, 5, and 10%). It was found that many of the different types of DAGs increased the induction of crystallization period of the palm oil TAGs. Both isomeric forms of diolein (1,2-OO and 1,3-OO) along with 1,3-PO increased the induction period at all tested concentrations, while addition of 1,2-PO reduced the induction period. This reduction in the induction period was attributed to the ability of the asymmetrical 1,2-PO to form mixed crystals with the palm oil TAGs. Interestingly, at low concentrations, the increase in the induction period was amplified by the disaturated DAGs (1,3-dipalmitin and 1,2-dipalmitin), however, higher concentrations (5%) of 1,3-PP resulted in rapid crystal growth. It was suggested that this was caused by the difference in melting point between 1,3-PP and the TAGs. Upon crystallization, 1,3-PP provides a nucleation site for TAG crystal growth. Furthermore, palm DAGs slowed the rate of crystallization of the palm TAGs. When looking at the effects of the individual DAGs on the crystallization rate, it was observed that low concentrations (1%) of 1,3-PP greatly reduced the rate of crystallization, while higher concentrations (5%) increased the crystallization rate. 1,2-PP decreased the rate of crystallization only slightly when added at low concentrations, but at higher concentrations the rate of TAG crystallization was greatly reduced. Again 1,2-PO appeared to assist in the crystallization process, increasing the rate of crystallization, just as it had reduced the induction period.

Wright and Marangoni (2002) investigated the effects of milk fat DAGs on the crystallization of milk fat TAGs. DAGs were found to delay crystallization by both inhibiting nucleation and reducing the crystal growth rate. These effects also demonstrated a concentration dependence. It was suggested that DAGs primarily composed of the fatty acids that make up the high melting fraction of the milk fat have a greater effect on TAG crystallization because they would become incorporated into the solids portion and disrupt the TAG crystal network. Furthermore, DAGs that contain fatty acids differing from those of the high melting fraction TAGs also have an inhibitory effect on crystallization, however, they do not affect the nucleation because they do not become incorporated into the TAG crystal network in this stage. Additionally, with regards to the different isomers of DAGs containing palmitic and oleic fatty acids, it was determined that the 1,2-DAGs (1,2-PP, 1,2-OO, and 1P,2O) delayed milk fat TAG crystallization at 25 °C while mixtures of 1,2-DAGs and 1,3-DAGs enhanced the crystallization slightly.

Silva et al. (2014) studied the effects of DAGs on the crystallization of TAGs by adding dipalmitin, distearin, and diolein to pure tripalmitin, tristearin, and triolein. Each of the three DAGs delayed the crystallization of both the saturated TAGs, tripalmitin and tristearin. As a result, the crystallization temperature was reduced. The opposite effect was observed with the unsaturated TAG triolein. In this case, each of the DAGs accelerated the crystallization process, with distearin causing the largest rise in crystallization temperature. Furthermore, it was determined that both dipalmitin and distearin acted to stabilize the  $\alpha$  polymorphic form in both tripalmitin and tristearin, effectively delaying the transition to the  $\beta$ -form. Diolein, however, was seen to accelerate the  $\alpha$  to  $\beta$  polymorphic transition of both TAGs.

Because of their influence on the crystallization of TAGs, DAG addition represents a viable method of improving the quality and extending the shelf life of margarine. Hernqvist and Anjou (1983) demonstrated the effectiveness of DAGs at stabilizing the  $\beta'$  polymorph. In this study, the addition of 5% DAGs to margarines made with hydrogenated rapeseed and soybean oils delayed the  $\beta'$  to  $\beta$  polymorphic transition from four weeks to 44 weeks.

In summary, DAGs are a partial glycerol naturally present in edible oils, that can also be produced industrially in high concentrations. This class of lipid is widely used in food products as an emulsifier, and because of the well researched health benefits associated with DAGs, oils high in DAGs have been produced and sold as a healthy cooking oil in both Japan and the USA. DAGs have been shown to have either inhibitory or enhancing effects on TAG crystallization depending on the isomeric form of the DAGs and the fatty acid profile of both the DAGs and the TAGs. Therefore, there are some instances in which it is beneficial to remove DAGs in order to improve the physical properties of the oil and other cases in which adding DAGs to an oil may improve its crystallization behaviour.

### Glossary

**Amphipathic** a chemical compound containing both hydrophobic/lipophilic and hydrophilic properties

**Apolipoproteins** proteins that specifically bind lipids to produce lipoproteins. Their major role is to carry lipids through the circulatory and lymphatic system

**Calcification** impregnation with calcium or calcium salts

**Glycation** formation of a covalent bond between a sugar molecule (such as fructose or glucose) to a protein or lipid molecule

**Isoelectric point** refers to the pH at which a specific molecule bears no net electrical charge

**Lectin** any protein or glycoprotein that is capable of binding to the sugar moieties of glycoproteins and glycolipids present on the surface of cells in most organisms. These proteins help in stimulating lymphocyte proliferation

**Polymorphism** refers to the branching of the genetic tree which is because of two or more alleles present at one DNA position or in one DNA region, each with significant frequency in the population

**Reactive oxygen species (ROS)** chemical species which contains oxygen and are chemically reactive, for instance, superoxide, peroxides, singlet oxygen

### Nomenclature

**TSAA** Total Sulfur Amino acids, i.e. (Methionine + Cystine)

**Quercetin** Plant polyphenol belonging to the flavonoid group and has a bitter taste. It is present in many vegetables, fruits, grains and leaves

## Introduction

The chicken eggs have always been recognized as an excellent source of human nutrition, especially for the dietary protein. The chemical composition of an egg has always fascinated human mind, may be due to the compartmentalized structure of the whole egg. However, only in recent years, with the help of innovative research tools, scientists have revealed the structural and functional diversity of the different components in eggs. These revelations diversify the use of eggs in various processed food products and increase the commercial value of an egg. Egg proteins are well-known for its functional properties and are massively used as an ingredient to enhance the texture or flavor of variety of food products. Additionally, egg proteins are also a potential source of bioactive proteins and peptides. The bioactive egg proteins and peptides can exhibit health beneficial effect above and beyond their known nutritional value. Research of last two decade has highlighted some bioactivity of egg proteins and broadened the use of egg as a critical ingredient of functional foods or nutraceuticals. Subsequently, egg proteins, especially proteins from egg white, are known as a major allergen affecting nearly 2.5% young children in the USA (Caubet and Wang, 2011). Therefore, this chapter briefly discusses the different proteins of egg and their functional and biological properties.

The egg consists of three major portions; a) eggshell, b) egg white, and c) egg yolk. Protein is one of the major component present in all three parts of the egg, and egg white is the prime source of proteins. The following section discusses the major proteins found in each part of the egg.

## Egg Shell Proteins

The eggshell is the outermost layer of an egg and is mainly composed of a foamy layer of cuticle, a calcium carbonate layer, and then two flexible membranes (inner and outer membrane). This whole structure together retains the egg white or albumen and egg yolk inside the egg and also prevent the invasion of any pathogenic bacteria (Burley and Vadehra, 1989).

The organic matter of chicken eggshell and eggshell membrane comprises of a complex mix of proteins and polysaccharides, out of which proteins constitute almost 70% of the total organic matter (Tullet, 1987). The eggshell membrane has been found to contain many bacteriolytic enzymes, such as N-acetylglucosaminidase and lysozyme, and other components which might have a role in preventing the invasion of Gram-negative and Gram-positive bacteria. Moreover, the eggshell membrane hydrolyses

have been found to contain hydroxyproline suggestive of the presence of collagen in the membrane layers (Nakano et al., 2003), the collagen constitutes almost 10% of the total proteinaceous matter in the eggshell.

Eggshell mainly comprises of various ubiquitous proteins which are extensively expressed in different organs. Osteopontin, a phosphorylated glycoprotein, is found in kidney, bones and many body secretions and it was found to be expressed in the uterine epithelial cells during the calcification of the eggshell (Pines et al., 1994). This protein is mainly confined to the mammillae, core of the non-mineralized shell membrane fibers, and the outermost segment of the shell palisade layer (Fernandez et al., 2003). Osteopontin inhibits the precipitation of calcium carbonate in the eggshell, and the protein loses its inhibitory activity upon dephosphorylation with alkaline phosphatase. This suggests that osteopontin might have a role as a modulator in the precipitation of calcium carbonate in the uterine fluid or even as an inhibitor during the termination of the calcification process (Hincke and St Maurice, 2000).

Clusterin is another ubiquitous eggshell secretory protein which is a heterodimeric glycoprotein bonded with disulfide linkages (Mann et al., 2003). This particular protein is found in many tissues and is also present in all the calcified regions of the eggshell. In the uterus, it is secreted by the tubular gland cells into the uterine fluid, irrespective of the shell calcification stage. Clusterin might have a role in preventing premature aggregation and precipitation of eggshell proteins by acting as an extracellular chaperone in the uterine fluid (Mann et al., 2003). There are specific proteins which are unique to the eggshell and are secreted only by the tissues present in the shell. These proteins have been identified in domestic hens only.

Ovocleidin-17 (OC-17) is a 142 amino acid long phosphorylated protein having a C-type lectin domain, and it was the first protein to be purified to homogeneity. This protein is also present as a 23 kDa glycosylated protein in a minor form (Mann, 1999). The tubular gland cells of the uterus secrete OC-17 throughout the calcified part of the shell during the entire calcification period (Hincke et al., 1995; Mann and Siedler, 1999; Reyes-Grajeda et al., 2004). OC-17 modifies the shape of calcium carbonate crystals in vitro (Reyes-Grajeda et al., 2004).

Ovocleidin-116 (OC-116) is an 80 kDa protein with 742 amino acids, and it was the first eggshell protein which was cloned (Hincke et al., 1999). The protein comprises of two disulfide bonds and two N-glycosylations (Mann et al., 2002). OC-116 was named ovoglycan (Fernandez et al., 2001, 2003) and it forms the protein core of the primary proteoglycan of the shell (Carrino et al., 1997). The carbohydrates of OC-116 comprises of 17 different oligo-structures (Nimtz et al., 2004). Eight of them were hybrid-type, four were the high-mannose type, and the rest five had a complex-type structure. When present in the uterine fluid, OC-116 exists as a 116 kDa protein due to glycosylation modification and as a 190 kDa protein after glycation (Arias et al., 1992; Fernandez et al., 1997). This protein is thought to have a role in the modulation of calcite growth.

Ovocalyxin-32 (OCX-32) is released in the uterine fluid by the surface epithelial cells of the uterus during the end of the calcification phase and thus it is mainly confined to the outer regions of the shell, i.e., the vertical crystal layer, cuticle, and the palisade layer (Gautron et al., 2001b, 2003; Hincke et al., 2003). Therefore, it has been suggested that this protein has a role in the termination of the calcification process of the eggshell.

Ovocalyxin-36 (OCX-36) is found in abundance in the uterine fluid during the calcification process, and the expression of this protein is highly upregulated. This protein has been cloned as well (Gautron et al., 2007). It has been reported that OCX-36 has homologous similarities with proteins involved in innate immune responses such as bactericidal permeability increasing proteins, lipopolysaccharide binding proteins, and Plunc family proteins, which suggests the fact that OCX-36 may also be involved in the defence mechanisms to keep the egg pathogen free (Gautron et al., 2007).

Ovocalyxin-25 and -21 are also two other eggshell proteins which are exclusively detected in tissues undergoing mineralization. Database analysis reported that Ovocalyxin-21 has remarkable homologies with brichos domain-containing proteins. The Brichos domain consists of nearly 100 amino acids and comparing the similarities, several functions of the ovocalyxin-21 proteins were postulated including chaperon-like functions (Sanchez-Pulido et al., 2002). Ovocalyxin-25 contains two protease inhibitory domains, one of which is the WAP-type. The matrix protein from the nacreous layer of the pearl and shell of molluscs, known as lustrin A, also has the same inhibitory WAP-type domains (Shen et al., 1997).

## Egg White Proteins

The egg white is made up of four individual layers: chalaziferous layer, thin layer, thick layer, and the chalazae cord. The thin layer accounts for about 23.3% of egg white, which is further separated into two layers, i.e., inner and outer thin layers. The thin inner layer (16.8% of egg white) is attached to the chalaziferous layer, which accounts for about 2.7% of egg white, whereas, the thin outer layer is connected to the inner eggshell membrane. The outer and inner thin layers are separated by the thick or viscous layer which accounts for the most substantial portion of egg white, i.e., 57.3% (Brake et al., 1997; Conrad and Philips, 1938; Li, 2006).

Water is the primary constituent of egg white which accounts for about 84% to 89% of the total egg white or albumen weight. Among albumen solids, proteins are the major constituents (10%–11%), while the minor components include carbohydrates (0.9%), lipids (0.03%), vitamins and minerals (Li-Chan and Nakai, 1989).

Egg proteins are well known for their high nutritional quality, excellent digestibility and comprise of all the essential amino acids necessary for the human nutrition and development (Friedman, 1996). Egg albumen consists of several different protein components which have been identified and characterized through modern high-resolution analytical techniques (Raikos et al., 2006). In a study, 78 egg white proteins were detected using 1-dimensional electrophoresis and liquid chromatography tandem mass-spectrometry (LC-MS/MS) (Mann, 2007). However, among egg white proteins, ovalbumin, ovotransferrin, ovomucoid, ovomucin,

**Table 1** Physio-chemical properties of major and minor egg white proteins

Modified from Powrie, W.D., Nakai, S., 1985. Characteristics of edible and fluids of animal origin: egg. In: Fennema, O. (Ed.), Food Chemistry. New York, Marcel Dekker, pp. 829–855 and Data compiled from Li-Chan, E.C.Y., Powrie, W.D., Nakai, S., 1995.

and lysozyme have been studied extensively due to their abundant presence in egg albumen. Physicochemical characteristics of major egg white protein is provided in **Table 1**. The structure and chemical composition of these proteins are described in details in the following section.

### Ovalbumin

Ovalbumin constitutes about 54% of the total egg albumen and thus it is the primary protein present in egg white. It is a phosphorylated glycoprotein made up of complete three subunits having different phosphate groups along with a carbohydrate group attached to its N-terminal (Li-Chan et al., 1995). Ovalbumin is a member of the serpin (serine protease inhibitors) superfamily despite lacking the inhibitory activity unlike the other serpin-like proteins (Huntington and Stein, 2001). The molecular weight of ovalbumin is 45 kDa and is composed of 386 amino acids along with two genetic polymorphisms seen at 290 (Glu → Gln) and 312 (Asn → Asp) (McReynolds et al., 1978). Among all other egg albumen proteins, ovalbumin is a unique protein as it contains six cysteine residues, two of which are involved in a disulfide bond between Cys74 and Cys121, while the rest four include free sulfhydryl (–SH) groups. One out of the four –SH group is reactive only when the protein is denatured, however, the other three are masked in the native state (Fothergill and Fothergill, 1970).

The amino acid composition analysis of egg albumen revealed that 50% of the total amino acids are hydrophobic while 30% are acidic and charged amino acids, the latter contributing to the acidic isoelectric point (pI) of 4.5. Ovalbumin has a unique amino acid distribution as compared to other glycoproteins. It lacks an N-terminal ladder sequence but contains an acetylated glycine and proline in the N- and C-terminal, respectively, along with carbohydrate moiety attached to the amino acids in the N-terminal (McReynolds et al., 1978; Huntington and Stein, 2001).

Ovalbumin-Y is a chimeric glycoprotein with an amino acid sequence very similar to the native ovalbumin and a carbohydrate group identical to ovomucoid (Hirose et al., 2006). Ovalbumin-Y protein was first identified and characterized by Nau et al. (2005) by 2-Dimensional PAGE and peptide mass fingerprinting. Ovalbumin Y is not phosphorylated unlike ovalbumin; however, it is glycosylated. Three isoforms of ovalbumin Y protein and five isoforms of ovalbumin-related Y protein have been identified via electrophoresis, each protein differing in their pIs. However, this polymorphism could not be explained by genetic variations or by phosphorylation or glycosylation levels (Guérin-Dubiard et al., 2006).

Ovalbumin in its native form is resistant to digestion by trypsin but once it is heat denatured or given an acid or pH change treatment, it becomes susceptible to trypsin digestion. With high pH and temperature dependent denaturation, ovalbumin converts into a thermally stable form known as S-ovalbumin (Pelegrine and Gasparetto, 2006). Sugimoto et al. (1999) demonstrated that storage temperature influences this conversion more than the storage time, where longer storage time at 20–25 °C did not affect the conversion. However, Huang et al. (2012), demonstrated that during storage, the conversion of ovalbumin to S-ovalbumin had been attributed to an increase of pH and change of pH has a direct effect on the conversion rather than temperature. Therefore, despite temperatures of 4 °C, long time storage of eggs may increase the conversion of native ovalbumin to S-albumin by 81% (Huang et al., 2012).

Ovalbumin is also the primary allergen in egg white which is responsible for IgE-mediated allergic reactions (Caubet and Wang, 2011). The ovalbumin epitopes which bind IgE consists of mainly polar, charged and hydrophobic amino acids and these

sequences are mostly made up of  $\beta$ -sheet and  $\beta$ -turn structures. The only allergenic epitope which comprises of an alpha helix is Asp95-Ala102 (Kim, 2002).

### Ovotransferrin

Ovotransferrin is a monomeric glycoprotein which is involved in the transfer of ferric ions to the developing embryo from the hen's oviduct. Ovotransferrin accounts approximately 12% of the entire egg white protein (Desert et al., 2001; Abdallah and El Hage Chahine, 1998). Ovotransferrin belongs to the transferrin protein family and has been reported to have around 50% homology with mammalian lactoferrin and transferrin (Mazurier et al., 1983). Ovotransferrin can bind 2 mol of different metal ions per mole of protein. For, ovotransferrin, lactoferrin and serum transferrin, each lobe binds one carbonate anion and one  $\text{Fe}^{+3}$  atom (Lambert et al., 2005). Such iron complex formation in ovotransferrin inhibits microbial growth that requires iron.

The N and C lobes of ovotransferrin consist of a single iron-binding site located in a deep cleft along with 15 disulfide bridges which maintain the globular structure of the protein (Kurokawa et al., 1999). The N- and C- terminal lobes of ovotransferrin form two sulfide bonds where Ala1-Tyr72 in the N-terminal segment acquires a local-native like confirmation (Mizutani et al., 1997). This interaction between the two lobes is very critical for iron acquisition (Alcantara and Schryvers, 1996). The various metal- and anion-binding properties of the iron binding sites of ovotransferrin can be attributed to the presence or absence of basic amino acid residues (Nadeau et al., 1996).

The process of in-vitro  $\text{Fe}^{+3}$  uptake and release by ovotransferrin are reported to be very similar, but not identical, to lactoferrin and serum transferrin. The  $\text{Fe}^{+3}$  is bound very tightly by the four protein ligands (Tyr92, Asp60, His250 and Tyr191 present in the N-lobe) in a closed interdomain cleft (Abdallah and Chahine, 1999). Ovotransferrin efficiently binds  $\text{Fe}^{+3}$  at pH greater than 7 and releases any bound  $\text{Fe}^{+3}$  at a pH lesser than 4.5 (Guérin-Dubiard et al., 2006). On uptake of  $\text{Fe}^{+3}$ , the transferrins undergo a major conformational transition from the apo structure (open-form/iron-free) to the closed/iron-bound holo formation, suggesting that initial binding occurs in the open form (Mizutani et al., 1999). Both these forms have significantly different physiochemical properties, for instance, the holo-form emits a salmon pink color due to the presence of iron whereas the apo-form does not have any color. Moreover, the apo-form is more prone to physical and chemical changes as compared to the holo-form (Kurokawa et al., 1999).

Apart from the iron-binding capacity, several recent studies have investigated other structural and functional features of ovotransferrin that might be associated with various biological properties. For instance, the embryos of mammal and bird's egg are susceptible to oxidative stress, and thus maintenance of a constant, reducing environment during the development of the embryo can provide protection and although much knowledge is not present currently, however egg white is suggested as the primary target for this. Ibrahim et al. (2006) reported that ovotransferrin is capable of autocleavage at specific sites once it gets reduced by thiol reducing agents. This autocleavage occurs due to a unique chemical reaction between the four tripeptide motifs present on both sides of the two disulfide domains (115–211 and 454–544 residues) of ovotransferrin protein. It has been found that many auto-processing proteins contain these reduction-scissile sequences (His/Cys-X-) which suggest that this sequence is evolutionarily conserved.

### Ovomucoid

Ovomucoid is a glycoprotein which belongs to the Kazal family of protein inhibitors. It constitutes 11% of the total egg white proteins and is thermally stable (Li-Chan and Nakai, 1989). The protein consists of 186 amino acids with a molecular mass of 28 kDa (Kovacs-Nolan et al., 2000). It consists of 9 disulfide bonds and has three different domains which are crosslinked only by the intra-domain disulfide bonds. Ovomucin has trypsin inhibitory effect, and the active site for the trypsin inhibitory activity lies within the Domain II of the protein. However, considerable variations in the inhibitory activities and specificities of the domains have been reported from different avian species (Li-Chan and Nakai, 1989). Chicken ovomucoid is one of the significant egg white allergens, and it plays a crucial role in the pathogenesis of IgE-mediated allergic reactions (Mine and Zhang, 2001, 2002a; Mine and Rupa, 2003a, 2004). This allergenic potential could be attributed to its higher stability towards gastrointestinal digestion and heat treatment (Hirose et al., 2005). Yoshino et al. (2004) reported that the digestibility of ovomucoid by pepsin is much better over the pH range of 1.5–2.5. However, the digestibility loses at a pH of 3.0 or higher. Moreover, pepsin-digested fractions of ovomucoid retain its trypsin-inhibitory activities. Besler et al. (1997) reported that the epitopes on ovomucoid which were responsible for the IgE binding were present only on the protein backbone and not the carbohydrate groups. Nine IgE epitopes (5–16 amino acids) and eight IgG epitopes (5–11 amino acids) were identified within the primary ovomucoid sequence. Through mutational studies of the epitopes, it was found that charged amino acids (lysine, glutamic acid, and aspartic acid), polar amino acids (cysteine, tyrosine, threonine, and serine), and hydrophobic (glycine, leucine, and phenylalanine) are crucial for antibody binding (Mine and Zhang, 2002b). Numerous studies have been conducted to alter the composition and structure of the ovomucoid epitopes responsible for the allergenicity (Mine and Rupa, 2003b). Some of the attempts made include heating in the presence of wheat flour (Kovacs-Nolan et al., 2000; Kato et al., 2001), gamma irradiation along with heating (Lee et al., 2002), deglycosylation by endo-beta-N-acetylglucosaminidases (Yamamoto et al., 1998), and genetic modifications (Rupa and Mine, 2006a). However, none of these modifications made any significant changes to the allergenic epitopes of ovomucoid, suggesting that the epitopes were extremely resistant to any modifications.

### Ovomucin

Ovomucin contributes to about 3.5% of the total egg white proteins. It is a sulfated glycoprotein which is responsible for the jelly-like structure of egg white. The protein consists of two parts: soluble part (8,300 Da), which is the main component of the inner and outer egg white, and the insoluble part (220–270 kDa), which is responsible for the insoluble gel-like fraction of thick albumen (Omana and Wu, 2009). Both fractions are made up of two subunits,  $\alpha$ -ovomucin and  $\beta$ -ovomucin, but have different carbohydrate contents. The soluble fraction consists of 40  $\alpha$ - and three  $\beta$ -subunits, while the insoluble fraction contains 84  $\alpha$ - and 20  $\beta$ -subunits (Robinson and Monsey, 1971; Omana and Wu, 2009). There are two distinct subunits of the  $\alpha$ -subunit, i.e.,  $\alpha 1$  and  $\alpha 2$ , and both the  $\alpha$ -subunits have lesser carbohydrate groups than  $\beta$ -subunits. Acidic amino acids such as glutamic acid and aspartic acids mainly make up the  $\alpha$ -subunit (Omana and Wu, 2009), whereas, serine and threonine primarily make up the  $\beta$ -subunit (Robinson and Monsey, 1971). A study by Toussant and Latshaw (1999) reported that the quality of eggs could be positively correlated with the amount of ovomucin present in the thick albumen. However, a higher concentration of highly glycosylated  $\beta$ -ovomucin containing hexoses, sialic acid, and hexosamines, signifies the inferior quality of eggs. Ovomucin is responsible for many of the functional and biological properties of egg white. It has a significant role in thinning of egg white during prolonged storage. Studies have shown that thinning of egg white can be either due to disruption of the ovomucin-lysozyme complex or the reduction of disulfide bonds leading to the degradation of ovomucin (Abeyrathne et al., 2014). Moreover, it is known for its exceptional emulsifying and foaming properties (Mann, 2007).

### Lysozyme

Egg white lysozyme consists of 129 amino acids and is a 14.4 kDa protein with a pI of 10.7. Lysozyme present in the egg is unique as it is highly soluble and stable as compared to lysozyme present in other foods. Although the lysozyme present in egg exists as a monomer, it is also frequently found as a dimer which leads to its thermal stability. Four unique disulfide bonds stabilize the tertiary structure of egg lysozyme (Kato et al., 2006). Lysozyme tends to bind to negatively charged proteins in the egg albumen such as ovalbumin, ovomucin, and ovotransferrin (Abeyrathne et al., 2014). The chalaza and the chalaziferous layer mainly consists of the lysozyme–ovomucin complex. The complete structure with a resolution of 2 Å and the amino acid composition of lysozyme had been established in the 1960s (Li-Chan and Nakai, 1989). However, still many research is carried out to investigate its structure and function further. Three-dimensional structural analysis, at the resolution of 1.46 Å, revealed the hexagonal crystal form of lysozyme (Blake et al., 1965; Kato et al., 1992). Various studies have also been conducted to investigate the structural changes of lysozyme induced by different conditions, such as aqueous-organic solvent mixtures (Griebenow & Klibanov, 1996), pH variations (Babu and Bhakuni, 1997), co-crystallization in presence of different alcohols (Deshpande et al., 2005), sorbitol (Petersen et al., 2004), in presence of thiol reagents (Raman et al., 1996), and supercritical CO<sub>2</sub> treatment followed by heat treatment (Liu et al., 2004). The first purification of lysozyme was done using the high concentration of ammonium sulfate, however, it led to the modification of the characteristics and morphology of the protein due to the high salt concentration used during extraction (Liu et al., 2004; Abeyrathne et al., 2013). The purification technique which is commonly used nowadays for lysozyme is cation exchange chromatography which makes use of the high pI value of the protein (Abeyrathne et al., 2013). However, due to the small size of the resin granules used in the chromatography, the flow rate is low which makes it a time-consuming process. Crystallographic structures of some of the three major egg white proteins are listed in Fig. 1.

### Minor Proteins in Egg White

Egg white contains more than 50 proteins (Mann, 2007), among which the five major ones are described above. However, there are some other proteins, which although are present in very small amount, play a crucial role in determining the physicochemical and structural properties of the egg. Four of such proteins are described in the following section.

**Figure 1** Crystallographic structure of major egg white proteins. Protein Data Bank.

### Ovoglobulin

Ovoglobulin constitutes 4% of the total egg white proteins and is a minor protein. The protein is made up of two subunits G2 and G3, with molecular weights of 36 kDa and 45 kDa respectively (Ogawa and Tanabe, 1990; Damodaran and Razumovsky, 1998). Ovoglobulin was reported to be completely soluble in high and low ionic strength salt solution and coagulated with heat treatment; these properties were very similar to ovalbumin (Damodaran and Razumovsky, 1998). Ovoglobulin G2, present in chicken eggs, shows polymorphism (Asal et al., 1993). Ovoglobulin has been reported to be crucial for the foaming properties of egg white, even though other biological functions are not well known yet (Sugino et al., 1997b). In a study by Damodaran and Razumovsky (1998), the competitive adsorption of the five major egg white proteins described above, along with ovoglobulin was studied, at low and high ionic strengths, and it was found that at 0.1 ionic strength, only ovoglobulin and ovalbumin were able to adsorb at the interface, while the other proteins were excluded from the interface.

### Cystatin

Cystatin is a cysteine proteinase inhibitor which inhibits the action of thiol proteases, for instance, papain and ficin. Cystatin of the chicken egg contains two disulfide bonds near the carboxy-terminal along with a reactive site which is highly conserved. The pI of phosphorylated cystatin is 5.6, whereas it is 6.5 for the non-phosphorylated form (Guérin-Dubiard et al., 2006), with a molecular weight of 13kDa (Li-Chan and Nakai, 1989). In a study, the effects of storage conditions of eggs, the age of hens, and heat treatment of albumen on the cystatin activity was investigated. The cystatin present in eggs laid by hens, either older than 60 weeks or younger than 30 weeks, had the lowest activity, while eggs laid by hens aged 40–50 weeks had the highest cystatin activity. Furthermore, the eggs stored for 28 days at 15 °C showed a 4%–12% decrease in the cystatin activity. Thermal treatments also decreased the activity (Trziszka et al., 2004). Apart from having proteinase inhibitor activity, cystatin has been reported to have bioactive properties, such as, antimicrobial activity against bacterial pathogens (Wesierska et al., 2005), and inhibitor of bone matrix degradation in the resorption lacunae adjacent to osteoclasts (Brand et al., 2004).

### Avidin

Avidin is well known for its biotin-binding activities and is essentially a tetrameric glycoprotein from egg albumen. All the four monomers of the protein are capable of binding biotin and establishing a strong interaction with a dissociation constant of ~10–15 M (Stadelman et al., 1995; Mine and Yang, 2010). The protein constitutes approximately 0.05% of the total proteins in egg white. Each avidin chain comprises of 128 amino acids which are arranged as eight-stranded antiparallel beta-barrel, where the D-biotin binding site is defined by the inner regions. The secondary structure of avidin mainly comprises of beta-sheets and extended beta-turns (66%), while the rest is made up of  $\beta$ -turns and disordered structures (Stadelman et al., 1995). Avidin has been shown to have insecticidal and antimicrobial activity. The insecticidal activity has been used with genetically engineered and host plant resistance against Colorado potato beetle (Rupa and Mine, 2006a). Bacteriostatic effect of avidin has been reported against *Salmonella typhimurium*. However, the effect is lost on biotin addition (Stadelman et al., 1995). Terminal mannose and N-acetylglucosamine residues of avidin are capable of binding to lectins. Tumor cells express lectins on their cell surface at various levels, which acts as an important biomarker. Thus binding of avidin and cytotoxic agents can be easily detected via cell surface lectins. This mechanism was considered for tumor treatments, and avidin served as a potential vehicle for transport of toxins, drugs, therapeutic genes, and radioisotopes (Yao et al., 1998).

### Ovoflavin

Ovoflavin, also known as riboflavin-binding protein or ovo-flavoprotein, is a phosphoglycoprotein which is present in both egg yolk and white in equal amounts. This protein binds with riboflavin or vitamin B2 and the protein contains the highest selenium (Se) content (1800 ng/g) as compared to other egg proteins (Kiliç et al., 2002). Ovoflavin in egg white constitutes 219 amino acids with the presence of pyroglutamic acid at the amino terminus (96). Although the biological function of ovoflavin is not fully understood its ability to bind minerals and vitamins suggests that it may be involved in nourishing the embryo with vitamins and minerals during development (Hamazume et al., 1984).

## Egg Yolk Proteins

Egg yolk is composed of plasma and granules, located between the thin and thick albumen, supported by the chalazae. Yolk plasma constitutes 80% of the yolk fraction, and its protein content is of 23% on a dry basis (Freschi et al., 2011), composed of Low-Density Lipoprotein (LDL) (15%) and globular glycoproteins (15%) (Laca et al., 2015). Proteins such as livetins present as  $\gamma$ -livetins are mainly IgY antibodies (Chalamaiah et al., 2017), whose functions have been applied as immunological supplements in foods (Yang et al., 2014) and several other industries. Yolk granules nonetheless have a higher concentration of lipids (33%) and proteins (58%) in comparison with plasma (Laca et al., 2014). Their structure formation is mainly composed of non-soluble HDL-phosvitin complexes. Therefore a medium ionic strength has shown to modify its solubility. Protein composition is also dependent on factors

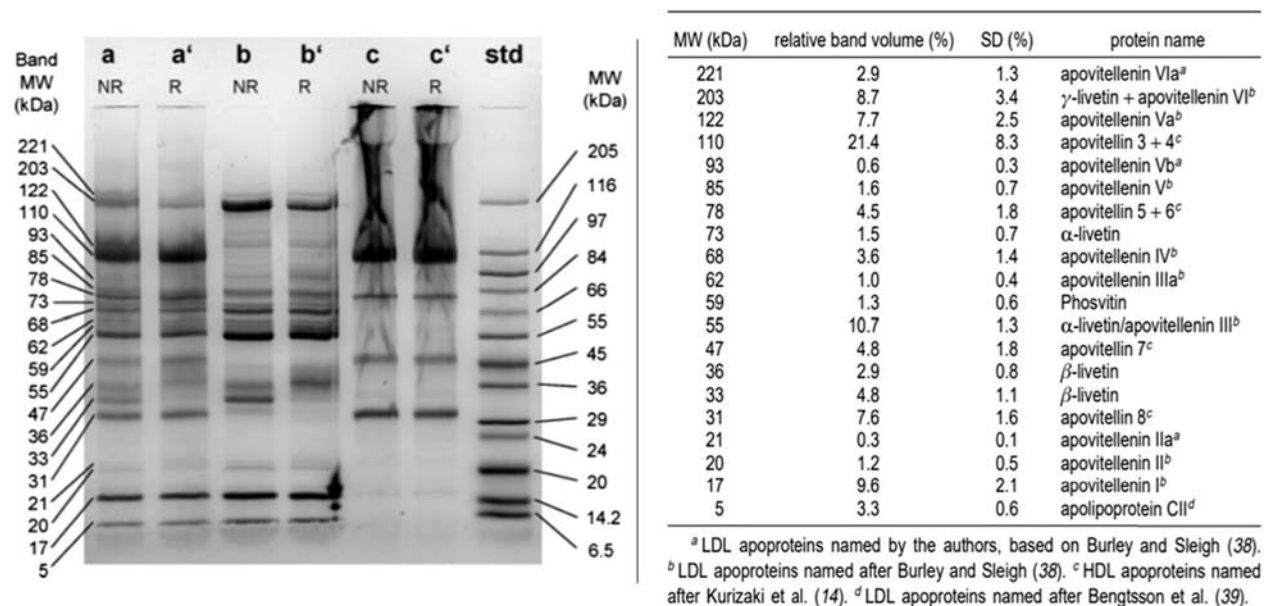

such as feed intake and environment during the hen's productive life. Molecules such as pigments or vitamins determine the color of the egg yolk. Studies supplementing herbs, quercetin, and TSAA with lysine, improved the color, oxidative stability, and reduced yolk protein respectively (Simitzis et al., 2018; Hammershøj and Johansen, 2016; Novak et al., 2004). Also, egg lipid and protein content vary throughout the productive cycle of the hen. In order to maintain egg weight homogeneity, a reduction in the amino acid content is realized. Furthermore, alterations in the environment such as heat and feed intake undermine lipid content in the organism. Heat stress initiates lipid peroxidation in cell membranes due to the release of hormones corticosterone and catecholamines (Asli et al., 2007). The following section describes the three major egg yolk proteins and Fig. 2 depicts all the egg yolk proteins present under reducing and non-reducing conditions.

### Low-Density Lipoprotein (LDL)

LDL proteins are predominant in yolk plasma with an 85% protein composition. Its structure is characterized by a micelle nano-structure containing triglycerides and cholesterol (Anton et al., 2003; Martin et al., 1964). Emulsification properties of LDL is an important application for the food industry. Factors such as heat treatment, ionic strength, particle dispersion and defatting induced protein changes in the structure affecting its functionality (Kiosseoglou, 2003). For instance, amphipathic side chain structure makes the protein interact with hydrophobic and hydrophilic interfaces such as W/O or O/W. Apolipoproteins in LDL micelle adsorb faster than low molecular weight proteins, helped by its structure flexibility (Anton et al., 2003; Mine, 1997, 1998; Martinet et al., 2003). In contrast, granules protein has shown an emulsification property dependent of pH. Specifically, at pH 4, its emulsification capacity is reduced as a result of protein dimer formation (Aluko and Mine, 1998). Due to pH changes and an ionic strength increase, lipoproteins tend to minimize the interaction of granules proteins in an emulsion. The delivery mechanism is among other potential applications of LDL when combined with polysaccharides (Zhou et al., 2016).

### High-Density Lipoprotein (HDL)

HDL is mainly composed of protein, lipids, cholesterol, and minor lipids. Its structure functionality includes antioxidant activity and protective effects against pathogens (Yamamoto et al., 1990; Kassafy et al., 2005). Lipid moiety in HDL influence its electron donating properties which can reduce the generation of reactive oxygen species (ROS). Mechanisms proposed to include the reduction of lipid hydroperoxides to non-reactive species through the electron transfer of methionine amino acid, interfering with lipid oxidation propagation (Elias et al., 2008).

From Guilmineau, F., Krause, I., Kulozik, U., 2005. Efficient analysis of egg yolk proteins and their thermal sensitivity using sodium dodecyl sulfate polyacrylamide gel electrophoresis under reducing and nonreducing conditions. J. Agric. Food Chem. 53, 9329–9336.

## Phosvitin

Phosvitin is a highly phosphorylated molecule with 124 of 217 amino acids binds to phosphate through covalent bonds, being serine the predominant amino acid (Byrne et al., 1984; Lei and Wu, 2012). This characteristic yield a high mineral binding capacity, interacting with 95% of the iron present in egg yolk (Grogan and Taborsky, 1986). The addition of ascorbic acid release the phosvitin bonded iron, thereby increasing the lipid peroxidation in egg yolk (Nielsen et al., 2000). On the other hand, its chemical properties derive from the emulsifying functional property. When in complete protein moiety, emulsifying properties are conferred by the interaction of the protein charged N- and C- termini. Further, glycosylated phosvitin has shown to improve the viscoelastic layer (Khan et al., 1999).

## Livetin

Livetin is a globular water-soluble glycoprotein which makes up 30% of the total egg yolk plasma proteins. The protein is present in three forms, namely,  $\alpha$ -livetin,  $\beta$ -livetin, and  $\gamma$ -livetin (Sugino et al., 1997b).  $\gamma$ -livetin is primarily immunoglobulin Y (IgY) which is an ideal substitute for mammalian IgG (Laca et al., 2015). The reported molecular weights of  $\alpha$ -livetin,  $\beta$ -livetin, and  $\gamma$ -livetin are 80,000, 45,000, and 170,000 respectively.

$\alpha$ -livetin has been reported to be the primary allergen responsible for the bird egg syndrome, and the protein is partially heat-labile inhalant. The reactivity of IgE towards  $\alpha$ -livetin was reported to reduce by almost 90% when it was heated for 30 minutes at 90 °C. Only a partial cross-reactivity was observed between  $\alpha$ -livetin and conalbumin (Quirce et al., 2001). Martin et al. (1957) reported that although the molecular weights and tyrosine: tryptophan ratios of  $\alpha$ -livetin and serum albumin were similar, they were not identical proteins because of the solubility. However, newer studies reported that although there was some precipitation of  $\alpha$ -livetin at lower concentrations of  $(\text{NH}_4)_2\text{SO}_4$ , most of it was not precipitated by 50% saturation. Moreover, the peptide patterns and immunological results suggested that both  $\alpha$ -livetin and serum albumin were the same protein.

$\beta$ -livetin contains 7% hexose. This protein is distinct from ovalbumin, although the molecular weights of both the proteins are very similar. Because the immunological patterns of  $\beta$ -livetin were identical to serum protein, it was considered an  $\alpha$ 2-glycoprotein, from its carbohydrate content and electrophoretic mobility. The sedimentation coefficient of 3S of  $\beta$ -livetin was similar to human serum, although the sialic content was lower in  $\beta$ -livetin as compared to human serum proteins (Schmid and Burgi, 1961; Burgi and Schmid, 1961).

The  $\gamma$ -livetin or IgY is derived from IgG of hen's serum, although it differs in from mammalian IgG in many of its chemical and structural properties. Yolk IgY consists of Asn-linked oligosaccharides like IgG. However, the oligosaccharide composition is different in both the immunoglobulins. The molecular weight of the heavy chains of IgY is greater than mammalian IgG (Kovacs-Nolan and Mine, 2004). Along with compositional differences, IgG and IgY also have functional differences. For instance, the isoelectric point of IgY is lower, and it is incapable of association with the mammalian complement, Protein G, Protein A, or rheumatoid factors. IgY also shows lesser binding capabilities with bacterial and human Fc receptors (Kovacs-Nolan and Mine, 2004).

## Conclusion

Hen's egg has been considered as one of the most nutritious source of food as it can sustain both life and growth. The proteins present in the egg are nutritionally complete with a great balance of essential amino acids. Although the egg proteins are present in all parts of the eggs, but the major concentration lies in the egg white (50%) and egg yolk (40%), while the remaining proteins are distributed in the egg shell and egg shell membrane. Each protein component of the egg white and egg yolk is responsible for imparting a specific physical and chemical characteristic towards the entire functionality of an egg. Moreover, environmental conditions such as ionic strength, pH, and temperature treatments can modulate the functional properties of these proteins. Therefore, a greater understanding of the egg proteins could help in the development of functional foods, as egg proteins, particularly egg white proteins, have gained a lot of research interest in the recent years. Apart from academic research, food industries have also shown a lot of interest in egg proteins to explore the various functional properties of eggs, which could provide them many commercial benefits.

## Glossary

**Active packaging** Not only segregating the foods from environment, active packaging aims to selectively induce certain events in the food contents. The events include oxygen elimination, pH indication, and microbial decontamination.

**BAP** Bioactive peptides. During digestion of milk, meat, and plant proteins, smaller oligopeptides (10 to 15 amino acid units) are yielded. Some of them have positive effects on our health, such as lowering blood pressure, reducing the risk of blood clotting, and preventing microbe growth. The studies to intentionally enrich BAP in foods are recently focused in functional food research.

**Catalysis** Acceleration of chemical reactions by a catalyst that is involved in the reaction without changing its chemical structure before and after the reaction. Thus the catalyst can catalyze the reaction multiple times.

**Cellulose** A major poly-sugar in plant. Basic chemical component is glucose that is also the basic unit of starch. While starch is a storage compound in plant, cellulose is form physical structure of plant body. It is a plant fibre in foods.

**Esters** Chemical compounds where an acid (typically  $R-COOH$ ) is condensed with an alcohol ( $R'-OH$ ) forming  $R-COO-R'$ .

**Fatty acids** Acids made of a carboxyl group with an alkyl group, i.e., generally expressed as  $R-COOH$ . They are found in triglycerides in the form of esters. Small fatty acids can evaporate and we can smell them. Some larger fatty acids are essential nutrients.

**Fermentation** It is scientifically defined as metabolic activities where their metabolites are used as final accepters of electron in the metabolic reactions. If electrons are accepted by external compounds, such as molecular oxygen, it is called respiration. Meanwhile, in the food industry, fermentation is commonly defined as processing of food materials with the activities of microbes. Typical example is alcohol beverage, cheese, and pickles.

**Free radicals** Electrons occupy an electron orbit as a pair. But occasionally only one electron occupies an electron orbit. This unpaired electron is extremely reactive. It does not diminish until it meets another radical, so that a free radical can create a chain reactions in many molecules.

**HFCS (high fructose corn syrup)** A common sweetening agent utilized in foods. Unlike sugar (sucrose), it is a chemically processed product through hydrolysis of starch. Through glucose isomerase activity, glucose in hydrolyzed starch is converted into fructose. Fructose is much sweeter than sucrose or glucose, thus high fructose substances can show the same sweetness with smaller amounts.

**$K_m$  value (Michaelis Constant)** It is a parameter to define the affinity of a compound to an enzyme in catalytic reactions. Small  $K_m$  value represents better affinity, leading faster reactions.

**Lactose** The major carbohydrate in mammal milk. It is almost exclusively found in milk in nature. Chemically it is a conjugated molecule of glucose and galactose.

**Maillard Reaction** Reaction between amine group and hydroxyl group. Proteins contain multiple amine groups, and sugar molecules contain multiple hydroxyl group. Thus Maillard Reaction is a common reaction in foods, leading brown colour in foods. A typical example is colour formation of bread crust.

**Oligosaccharides** Sugar molecule polymers made with less than 10 to 15 sugar molecule units. In recent years, their biological activities are studied as functional food ingredients. GOS (galactose oligosaccharide) is one of the examples.

**Pectins (pectic substances)** Poly-sugar compounds found in plant body. It is a major compound in the plant cell wall to give physical strength in plant body. In nutritional view, it is considered as a plant fibre.

**Peroxides** Compounds that have  $-O-O-$  groups. This two oxygen structure is very reactive. It can oxidize another compound or form a free radical.

**Poly-phenols** Typical bitter compounds found in plant products. In recent years, its biological activities draw attentions of food industry for their health benefits.

**Prebiotics** Compounds that assist the growth and maintenance of probiotic microbes in our intestine.

**Probiotics** Gastro-intestinal microbes that show positive effects to our health.

**Proteins** polymers of amino acids. They are a main nutrients in foods, and also major functional compounds found in living organisms.

**Saccharification** Degradation of polymer of sugars, such as starch, into smaller units of sugar. For example, starch is degraded into maltose (two-glucose unit) and glucose.

**Starch** Polymer of glucose. It is a storage material in plant and human can use it for energy generation through hydrolysis into glucose and metabolizing glucose.

**Triglycerides** A major compound found in fats (lipids, oils). They are ester compounds between a glycerol and three fatty acids. Glycerol has three hydroxyl ( $-\text{OH}$ ) groups and each of them is condensed with a fatty acid. If only one or two hydroxyl group is esterified, the compound is called monoglyceride or diglyceride.

## Introduction

A majority of foods are processed from their raw materials before they are in grocery stores. The processing can occur at various stages in the food supply chain, and it utilizes many different means to achieve required/desired modifications in food materials. The processing is considered as controlled chemical and/or physical modifications of raw materials in order to change the properties of materials. In the chemical modifications, enzymes can play important roles to determine the direction of modifications and, therefore, the products. Moreover, the chemical modifications can lead to physical changes. The utilization of enzymes varies from traditional uses, modern applications to experimental approaches in developing stages.

## What Is the Enzyme?

Majority, if not all, of reactions associated with the living activities are mediated by enzymes. One of the advantages of enzymes is that they 'catalyze' the reactions to accelerate them. There is another big advantage of enzyme: the enzymes can distinguish specific molecules, allowing specific reaction and specific products. These two advantages (catalysis and substrate-product specificity) make the enzymes essential in the metabolism of living organisms.

## What Is Catalysis?

Many chemical substances are reasonably stable under the physiological conditions, and generally require a large energy input to convert them into others. This energy is called activation energy ( $\Delta G^\ddagger$ ) to bring the energy level of substance up to go over the energy barrier between substances (Fig. 1). Enzymes can bring this activation energy level low so that the energy available under physiological conditions is sufficient to go over the barrier to produce products. This lower activation energy also accelerates the rate of reaction drastically. Some enzymes can accelerate the reaction by  $10^{20}$ -times, and typically acceleration rates are  $10^6$ – $10^8$ -times

**Figure 1 Free Energy Profiles of Enzyme Reactions.** The enzymes stabilize the transition state of their reactions, lowering the free energy of transition state, i.e., low activation energy ( $\Delta G^\ddagger$ ). It allows the reaction from substrate to product easy to occur with a low energy input. It should be noted that the enzymes do not change the free energy of substrate or product, thus free energy difference ( $\Delta G^0$ ) remain the same, keeping the equilibrium between substrate and product.

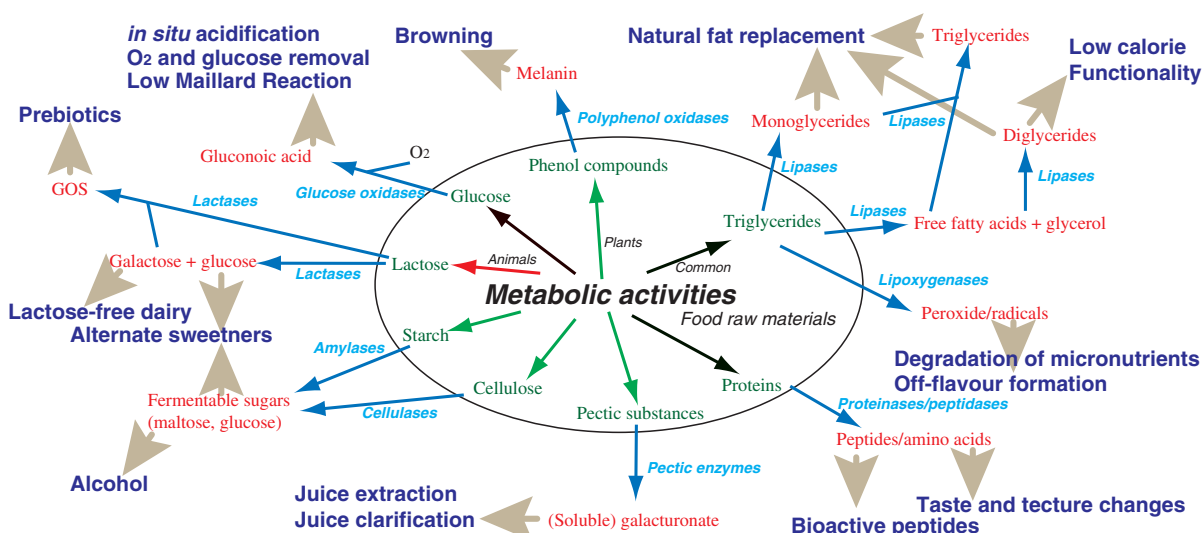

of spontaneous reaction under given conditions. This acceleration can be reproduced with cell-free systems as far as the available conditions are similar to physiological conditions, making enzyme ideal to accelerate reactions in many processing systems.

## Traditional Utilization of Enzymes in Foods

Enzymes were found and defined in 19th century as mediators in biological activities. They might not had been defined until that time, but the utilization of enzyme itself has a long history in food processing. In this section, such applications and their extensions are briefly summarized (Fig. 2).

### Amylases

One of traditional utilizations of enzyme is to use amylase (EC. 3.2.1.1 and EC.3.2.1.2) in cereal processing, especially cereal-based alcohol beverages (Fig. 3). Cereals are plant seeds, and are rich in starch. The seeds use their starch to provide the initial energy for germination and shoot/root formation until the plants can start photosynthesis. Metabolism in plant use glycolysis system to generate ATP as the energy source. A common starting material for this energy production is glucose, and starch provides glucose through their hydrolysis in the germination stage. Amylases are enzymes that catalyze this hydrolysis and are activated and synthesized in the event of germination when water, oxygen, light and temperature conditions meet the requirements (Georg-Kraemer et al., 2001; MacGregor, 1977).

**Figure 2** Enzyme Influences and Applications in Food Processing. Blue arrows indicate the enzyme reactions by indigenous enzymes and that we utilize. They give the influences on foods as shown by gray arrows. Green, black and red arrows indicate plants-specific, common and animal specific activities in general metabolisms.

**Figure 3** Enzyme Reactions of Plant Carbohydrate Processing. Plant carbohydrates (starch, sugar, and cellulose) are processed using enzymes to produce value-added food products.

From an ancient time, human have utilized amylases to saccharify the seed starch, notably to produce alcohol beverages from cereals (Damerow, 2012; Legras et al., 2007). Archaeologists speculate that beer was brewed in Mesopotamia where cultivation of wheat was first adapted as early as 10,000 BCE, and written evidences are found in Sumer/Mesopotamia and Egypt that are dated back at least 4000 years ago. As in many other traditional enzyme utilizations, they obviously did not know why cereals could be converted into alcohol beverages, but they knew that the malting process followed by a boiling step can ferment cereal extracts to beer.

In the traditional brewing, all amylase activities come from the cereal itself. Soaking seeds in water can stimulate the amylase activity in cereals and start to convert starch into maltose (glucose disaccharide). Fortunate coincidence for human being is the fact that amylase enzymes in cereal are fairly heat stable (Bush et al., 1989). This property allows us to extract converted sugars and residual starch from cereals in hot water (65 °C), yet keep the activity of amylase to process more starch into fermentable sugars during and after extraction of soluble materials in cereals. Quality of beer also heavily depends on the water quality. It is partly because amylase is activated and stabilized in the presence of calcium cation (Bush et al., 1989).

While traditional brewing only uses amylases in cereal, contemporary brewing may use exogenous amylases to ensure the saccharification of starch to maintain the consistency of beer quality among batches (Guerra et al., 2009). A major source of exogenous enzyme is aspergillus mould. This mould is traditionally used in brewing rice wine. The rice wine is made from rice, but unlike beer, raw materials are polished to remove kernel and germ, i.e., enzymes are removed. So that the soaking does not stimulate the saccharification. Instead *Aspergillus oryzae* is inoculated on the steamed rice to saccharify starch (Teramoto et al., 1993). Aspergillus amylases are commercially available for industrial applications and are used as exogenous enzymes in the process of beer making as adjunct materials for brewing (Guerra et al., 2009). In addition to aspergillus mould, *Bacillus amyloliquefaciens* and *B. licheniformis* are used to provide thermo-stable amylases (Guerra et al., 2009).

In addition to amylase enzymes, hemicellulases, cellulases, and proteinases are often used to increase the efficiency of saccharification and filtration and to allow the use of adjunct starchy materials (such as other cereals and low-quality barley malt) (Briggs et al., 2004). The addition of these enzymes can degrade cellulose/hemicellulose matrix to expose more starch to amylase activities.

### Proteinases

Proteinases (EC. 3.4.x.x) are often found in the traditional food processing. A representative proteinase application is the cheese-making process. Cheese is a product made of aged milk protein coagulum. Main milk proteins are grouped into two: caseins and whey proteins (Walstra et al., 2005). Casein proteins are found as micelles (colloidal particles) in milk, where hydrophobic  $\alpha$ - and  $\beta$ -caseins form the core and hydrophilic  $\kappa$ -casein is concentrated on the surface of micelles (Walstra et al., 2005). This structure allows water-insoluble  $\alpha$ - and  $\beta$ -caseins to be suspended in milk. Chymosin proteinase hydrolyzes  $\kappa$ -casein into hydrophobic para- $\kappa$ -casein, making micelles instable in the water phase (Walstra et al., 2005). This results in the coagulation of casein micelles to form cheese curds. Chymosin is the enzyme found in calf's stomach juice, and has a high activity to coagulate milk casein proteins to assist the digestion of the protein. Chymosin is collected from stomach juice of young cow after slaughter. Thus, the supply of chymosin depends on supply of calf meat. In 70's to 80's, the demands for beef and cheese went up. Since the cows were raised to fully-grown cows to yield more meat to meet these demands, the number of calf stomach supply was not sufficient to cover the required amount of chymosin for cheese making (Harris et al., 1982; Flamm, 1991). The hunt for alternative enzymes were extensively conducted, but none of them could produce the cheese as high in quality as using calf chymosin. Today chymosin are produced from cloned bacteria, and it makes the supply and price of chymosin more stable (Flamm, 1991).

Another traditional utilization of proteinases is found in meat tenderization. Meats are aged for 5 days to 2 weeks after the animals are slaughtered (Huff Lonergan et al., 2010; Ouali, 1990). During this stage, muscle is ripened into meat with the indigenous enzyme activities. In muscle, many different proteinases are present, and their specificities towards different meat proteins and their working pH ranges vary (Huff Lonergan et al., 2010; Ouali, 1990). As the ageing proceeds, remaining metabolic activities in meat produce lactic acids and the pH is gradually lowered. During this process, indigenous proteinases work on a variety of meat proteins, developing texture and flavour changes in meat. This process can be enhanced by injecting exogenous enzymes into meat during ageing (Huff Lonergan et al., 2010; Ouali, 1990).

Furthermore, many fermented foods develop their distinctive flavour due to protein hydrolysis by proteinases secreted by microbes. For example, Asian fermented soybean products (natto, tempeh, soy sauce, miso, and so on) and many types of cheese use *Bacillus subtilis*, *Aspergillus* spp., *Rhizopus* spp., *Penicillium* spp., and lactic acid bacteria as fermenting microbes (Rhee et al., 2011; Batra and Millner, 1974; Aidoo et al., 2006; Mine et al., 2005). These microbes yield proteinases in the fermentation, and hydrolyze proteins in the materials. While proteins are generally tasteless and odour-less, their hydrolysate shows a variety of taste based on the peptide profile generated by the microbial proteinases.

### Lipases

Lipases (EC. 3.1.1.3) are another group of enzymes that influences many types of fermented products. During fermentation, lipases secreted from microbes to hydrolyze triglycerides (Seitz, 1974). While triglycerides are odour-less, their hydrolysis products (free fatty acids) have distinctive smell because of liberated short-chain, volatile fatty acids. A small amount of hydrolysis can generate the smell in food products. In fermented foods, the developed smell is considered as their aroma, and can stimulate our appetite. Aroma of cheese is one of such examples and cheese is loved for their aroma as well as taste. Meanwhile, the excess smell development in fresh fluid milk and butter are called as rancidity and are considered as food spoilage by most.

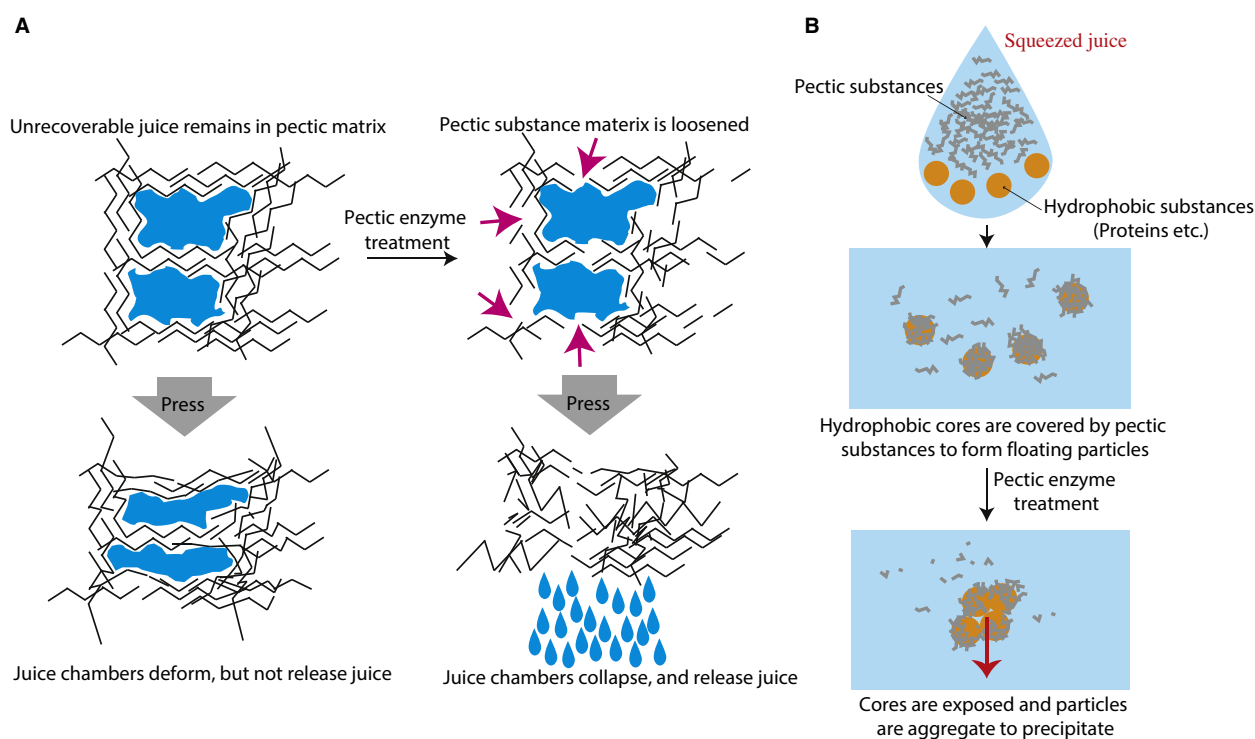

## Modern Enzyme Utilization in Foods

In addition to the traditional utilizations of enzymes, we now use enzymes intentionally to achieve certain effects in food products. The advancement of science allows us to rationally introduce enzymes in the food system and give a desired result within a short time and with a reasonable efficiency and costs. In this section, some of such applications are summarized.

### Pectinases

Fruit juice is a common commodity in the food supply and have been consumed for many centuries. As far as the juice produced at home, many people do not mind about the moderate yields and cloudiness after the squeezing of fruits. However, the juice industry needs high yields from fruits and crystal-clear juice for some juice (such as apple cider). The influential factor in these issues is the presence of pectin (Pinelo et al., 2010; McLellan et al., 1985). Pectin (pectic substances) is polymers of saccharides including galacturonans, rhamnogalacturonans, arabinans, galactans, and arabinogalactans (Thakur et al., 1997). These polymers are made of galacturonic acid, L-rhamnose, arabinose, and galactose. Among them, galacturonic acid consists of >97% of pectic substances, i.e., mostly galacturonan or rhamnogalacturonan (Thakur et al., 1997). Galacturonic acid has a carboxyl group on its sugar ring (i.e., 2,3,4,5-tetrahydroxy-6-oxo-hexanoic acid), and 75% of carboxyl group are esterified with methanol. The degree of methoxylation is a determinant of hydrophobicity of pectic substances (Thakur et al., 1997). Pectin forms skeletal matrix of fruit body. The matrix entraps the juice and often resists to the pressure (Fig. 4A). The other issue, juice cloudiness, is caused by liberated pectic substances (Pinelo et al., 2010; McLellan et al., 1985; Ceci and Lozano, 1998). The juice press squeezes the fruits and a part of pectic substances are liberated from fruits flesh. Due to their hydrophobicity, liberated methoxy-galacturonan can aggregate with other galacturonan and hydrophobic substances, and form colloidal particles. These particles give the cloudy looking in the juice (Fig. 4B) (Pinelo et al., 2010; McLellan et al., 1985; Ceci and Lozano, 1998).

To address these issues, pectic enzymes have been utilized in the juice industry (Fig. 4) (Pinelo et al., 2010; McLellan et al., 1985; Ceci and Lozano, 1998). Pectic enzymes are a family of three enzyme groups that are classified according to their substrate specificity and reaction mechanisms. The three groups are polygalacturonases, pectin esterases, and pectate lyases (Jayani et al., 2005; Kashyap et al., 2001). Pectin esterase (EC. 3.1.1.11) is a hydrolase that cleaves off a methoxy group from a methoxylgalacturonate unit in galacturonan, and polygalacturonase (EC. 3.2.1.15) hydrolyzes galacturonan (poly-(methoxy)galacturonic acid) into smaller

**Figure 4 Pectic Enzyme Utilization.** (A) When fruits are squeezed, pectin/cellulose flesh matrix are distorted without allowing the entrapped juice sipping out. When fruit flesh is treated with pectic enzymes, the wall of juice chambers is disintegrated to allow juice squeezed out from the chamber upon pressure application. (B) Pectic substances tend to aggregate around hydrophobic substances, such as denatured proteins, once pectin are liberated from plant flesh matrix. The aggregation particles of pectin are small enough to be suspended in the juice as colloids, showing cloudiness in juice. Pectic enzymes can increase the solubility of pectic substances through removal of methoxy group and fragmentation of long chains. These degradations allow the colloid particles aggregating between them through exposure of hydrophobic core of particles.

pieces. Non-methoxy galacturonan is hydrophilic; whereas methoxy groups give galacturonate hydrophobicity, leading to aggregation of pectin in fruits juice processing. A combination of two enzymes allows floating particles of pectin aggregate (cloudiness of juice) becoming soluble (Pinelo et al., 2010; McLellan et al., 1985; Ceci and Lozano, 1998), which clarify juice (Fig. 4B). The third pectic enzyme (pectate lyase; EC 4.2.2.2) also truncates the galactronan with a non-hydrolysis mechanism. These pectic enzymes can be utilized to loosen the structure of pectic skeleton of fruits fresh. The pectic skeleton of these fruits often restricts the recovery of juice from the fruits (Fig. 4A). It was shown that even pulp parts of fruits, which usually yield little juice by simple pressing, can yield 82% of weight as juice after treatment with pectic enzymes (Chauhan et al., 2001).

### Cellulases

For juice extraction, there is another substance that affects the fruits flesh matrix: cellulose. The hydrolysis of cellulose is shown to increase the yields of fruit juice (Kashyap et al., 2001). When using cellulases (EC. 3.2.1.4) in the combination with pectic enzymes, the enzyme mixture can totally liquefy the fruits. The process can be utilized to make juice without producing pomace (Kashyap et al., 2001).

Cellulase is also an important enzyme for sustainability of Earth's resources. As everyone now realizes, fossil energy emits carbon dioxide. One of the countermeasures for the excess CO<sub>2</sub> emission is to use biofuels. Bioethanol is one of the most common biofuels in today's technology basis. Cellulase enzyme is utilized to provide fermentable sugar from inedible materials, and this second-generation bioethanol is becoming an industrial choice for bioethanol production systems (Sun and Cheng, 2002; Cannella and Jørgensen, 2014; Tabka et al., 2006).

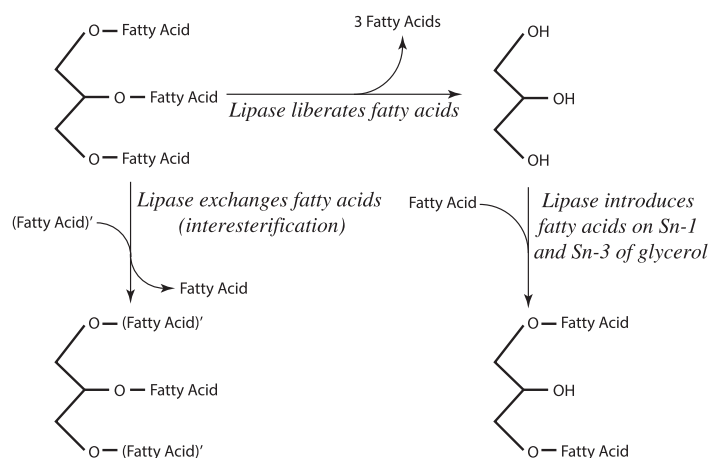

### β-Galactosidases

Dairy products are one of the largest sectors in the food industry in many developed countries. Milk is a 'perfect' food that contains all required nutrients to support infant growth; while many adults have issues with consuming dairy products. Two major issues of dairy products are food allergy and lactose intolerance (Prentice, 2014; Bordoni et al., 2017). Lactose is the major carbohydrate found in milk, and virtually it is exclusively produced as a milk ingredient in nature. Once children are weaned off from mother's milk and start to eat other foods, they lower the production of enzyme to hydrolyze lactose. How low this enzyme production becomes in adults depends on ethnic (genetic) groups and food consumption customs. If an individual does not produce enough of this enzyme, ingested lactose (in dairy products) reaches his large intestine. The assimilation of disaccharides is slower than monosaccharides, and therefore the remaining lactose is rapidly consumed by intestinal bacteria, producing carbon dioxide gas and lactic acid that stimulate the bowl movement to cause diarrhea (Deng et al., 2015).

β-galactosidase (aka lactase; E.C.3.2.1.35) is the enzyme that hydrolyzes lactose into galactose and glucose. To address the lactose intolerance issue, this enzyme is used in two ways: as a processing agent and as digestion assisting pills. By addition of β-galactosidase in the milk processing, lactose can be hydrolyzed in the milk (Deng et al., 2015; Corgneau et al., 2017). Resulted monosaccharides are easy to assimilate in our intestinal system and cause no diarrhea. Further this enzyme can be used to produce sweetening agents from a byproduct of dairy processing (i.e., whey) (Li et al., 2015).

### Lipases

As mentioned in an earlier section, lipase (E.C.3.1.1.3) catalyzes the hydrolysis of triglycerides to yield three fatty acids and glycerol. In the recent decades, the utilization of lipase has been developed to produce foods with less obesity issues (Fig. 5). One of such

**Figure 5 Interesterification and Esterification by Lipases.** We can manipulate the fatty acid moieties on triglycerides through lipase activities. Depending on the free fatty acid availability, lipase can replace or introduce fatty acids on glycerides (glycerol). Utilization of these reactions can yield specific-triglycerides and diglycerides with desired fatty acids.

applications is to form diglycerides (Singh and Mukhopadhyay, 2016; Berger et al., 1992). Many lipases have preferences in the position on triglycerides; while the length of fatty acid does not affect the hydrolysis much. The most preferred position is Sn-1 and Sn-3 positions (Xu, 2000). Since enzymes catalyze chemical reaction, but does not change the equilibrium between substances, most of enzymes can catalyze reverse reactions. Mixture of glycerol and fatty acids can yield diglycerides which have fatty acids on Sn-1 and Sn-3 positions when catalyzed by lipase. Diglycerides have similar properties to triglycerides as food ingredients, but ingestion of diglycerides produce less energy.

Lipases are also utilized for interesterification to replace fatty acids of triglycerides with different fatty acids (Fig. 5) (Macrae, 1983). This reaction can be achieved by chemical catalyst ( $\text{NaOCH}_3$ ) or by lipase enzymes. Chemical interesterification is a random reaction and is not suitable for position specific interesterification; whereas the position-specific interesterification by lipases is useful to mimic natural triglycerides from less expensive triglycerides. For example, lipase is utilized to produce cocoa butter alternatives. Cocoa butter triglycerides are mostly made of three fatty acids: oleic acid, stearic acid, and palmitic acid, and their simple compositions make the melting temperature range of cocoa butter narrow: at body temperatures, cocoa butter melts. A substitute of cocoa butter was developed using lipase on sunflower oil. Sunflower oil is an inexpensive oil and is widely available (the fourth common plant oil product). A sunflower cultivar has 50% ~ 60% oleic acid contents in its oil. Using lipases, interesterification of sunflower oil is processed with excess stearic acid. This interesterification introduces stearic acid on Sn-1 and Sn-3 position (i.e., 1,3-stearic acid-2-oleic acid). This chemical structure is the same found in cocoa butter, and thus this interesterified sunflower oil product shows the similar properties to cocoa butter (Chang et al., 1990). Another example of interesterification is found in human milk fat simulated oil. Baby formula is formulated to include all necessary nutrients for baby, and is made of commonly available materials, such as milk ingredient. Since milk fat is an expensive fat and milk is known to cause allergy, development of substitute from vegetable oil was desired. Vegetable oil often contains high amount of saturated fatty acids, meanwhile human needs higher amount of unsaturated fatty acids. Using oleic acid, linoleic acid, and linolenic acid, palm oil is interesterified. The resulted oil has unsaturated fatty acids on Sn-1 and Sn-3 position and palmitic acid on Sn-2 position. This composition is similar to human milk fat (Lai et al., 2000; Quinlan et al., 1995; Ghazali et al., 1995).

### Lipoxygenases

While the unsaturated fatty acids are beneficial and essential for our health, they can act negatively on the preservation of certain foods, leading to formation of off-flavour and discolouration. This is especially critical for vegetables and legume since they have high activities of lipoxygenase (EC 1.13.11.12) (Hsieh, 1994; Eskin et al., 1977). Lipoxygenase is an enzyme to catalyze the addition of molecular oxygen on to a double bond in the fatty acid. Resulted peroxide molecular species are a powerful oxidative agent in vegetables and legume (Brecht, 1995; Rolle and Chism, 1987). The peroxides also cleave themselves and yield an alcohol and a shorter fatty acid (for example, linoleic acid becomes hexanol and 12-oxo-*trans*-10-dodecanoic acid, yielding different smell from the original material). But more critical factors in off-flavour formation and discolouration are that lipoxygenase can yield radicals (Donnelly and Robinson, 1995). The radical reaction does not diminish radical; it passes the free radical to another molecule until it reacts with another radical. Thus, one radical affects many molecules including vitamins and proteins. It results in low vitamins and high volatile compounds such as sulfur compounds. Lipoxygenase is not only found at high activities in vegetables and legumes, it is also a hardy enzyme that can survive in many different treatments and they can even work at a very low temperature, i.e., frozen vegetables can develop off flavour during the frozen preservation (Sheu and Chen, 1991; Güneş and Bayindirli, 1993; Rodriguez-Saona et al., 1995; Velasco et al., 1989). The removal of lipoxygenase can be achieved by exposure to ethanol, mechanical milling, deblanching and alkali-heat treatment.

### Glucose Oxidases

While oxidation is considered as food deterioration, some oxidases are utilized in the food processing for the positive effects. Glucose oxidase (E.C.1.1.3.4.) is utilized for elimination of molecular oxygen, *in situ* production of hydrogen peroxide, and *in situ* production of a weak acid (Fig. 3).

Molecular oxygen is one of the most common oxidative agents abundant in the processing and storage. While we can pack foods in air-tight packages (such as cans) to prevent the oxygen exposure, the existing oxygen in the package and materials can be enough to cause oxidation of foods during the storage. The removal of molecular oxygen in the packages is a critical factor to attain a long shelf life. Glucose oxidase can use glucose to capture oxygen. A small dose of glucose oxidase can use glucose in foods to deplete molecular oxygen completely from air-tight packages (Dondero et al., 1993; Field et al., 1986). Moreover, the products of this enzyme is gluconolactone (spontaneously becomes gluconic acid) and hydrogen peroxide, thus we can use the reaction of glucose oxidase positively for *in situ* production of acid (Fox and Stepaniak, 1993) and hydrogen peroxide (Dobbenie et al., 1995). An issue of food processing is browning through Maillard reactions that is accelerated with heat (even at Pasteurization temperature), leaving brown colour in the food products. Glucose oxidase can be utilized to remove glucose to suppress the Maillard Reaction (Sankaran et al., 1989; Low et al., 1989).

Glucose oxidase is also used for glucose quantification (Wilson and Turner, 1992). This enzyme can be immobilized without sacrificing much of its activities (Wilson and Turner, 1992). The immobilized glucose oxidase is set with platinum, then hydrogen peroxide generated from glucose oxidase can be reduced into water and oxygen with the platinum catalyst. This reduction releases an electron that can be detected as an electric signal. The system is widely used as glucose electrodes in the processing and research.

### Glucose Isomerase

Another industrial enzyme that takes glucose as the substrate is glucose isomerase (E.C. 5.3.1.5) (Fig. 3). This enzyme is physiologically found as xylose isomerase (Bhosale et al., 1996). The difference between xylose and glucose is the presence of 6'-carbon and hydroxyl group in glucose. Xylose isomerase does not severely recognize the presence of 6'-carbon, and can take glucose as the substrate at a lower reaction rate. While  $K_m$  value (Michaelis Constant) for xylose is reported as 5 ~ 93 mM, the  $K_m$  value for glucose is 86 ~ 920 mM (Chen, 1980). In physiological settings, a high  $K_m$  towards glucose suppresses the glucose reaction and rather xylose is selectively isomerized. However, if xylose does not exist and glucose is abundant, this enzyme can isomerize glucose to fructose, and *vice versa*. The importance of this enzyme in industrial settings is in processing of high fructose corn syrup (HFCS) (Bhosale et al., 1996). Hydrolysis of starch, as discussed earlier in the amylase section, can generate glucose. Starch hydrolysate has been known as a sweetener for a long time. However, glucose is not as sweet as sugar (sucrose). Meanwhile, fructose is about 1.5-times sweeter than sucrose. When applying glucose isomerase on a glucose solution, the conversion of glucose to fructose proceeds and eventually reaches an equilibrium at 45:55 between fructose and glucose. This product is commonly referred as HFCS45 (using corn starch as the starting material). Theoretically this mixture shows sweetness about 10% to 20% above the same weight of sucrose. In the last few decades, more individuals pay attentions to calorie intake, and HFCS45 are utilized as an alternative sweetener. It is also inexpensive and supply is stable, compared to sucrose. Thus, certain foods (such as soda pops) use HFCS45 (or its higher-fructose derivative, HFCS55) as a substitute of sugar to achieve the same sweetness at a lower cost and calories.

### Polyphenol Oxidases

Browning of fresh plant products is a critical issue for food supply (Lee and Whitaker, 1995). Consumers tend to choose the products with the appearance, and brown vegetables are not their preferred choices. The browning of fresh products is due to the enzyme within the plant and molecular oxygen in the atmosphere. The enzyme is polyphenol oxidases (PPO; E.C.1.10.3.1 and E.C.1.14.18.1) (Yoruk and Marshall, 2003; Mayer, 2006; Queiroz et al., 2008). There are two enzymes that are referred as PPO: catechol oxidase and tyrosinase. The former enzyme catalyzes oxidation of catechol and *o*-diphenol to a corresponding quinone (Yoruk and Marshall, 2003), whereas tyrosinase catalyzes phenol to *o*-diphenol as well as further oxidation to quinone (Mayer, 2006). The resulted quinone substances spontaneously polymerize into polyphenol, i.e., melanin. This tannic substance shows brown colour in the food products. Prevention of PPO-browning can be achieved in two ways: elimination of oxygen and reduction of enzyme activities (Yoruk and Marshall, 2003; Sapers and Miller, 1998). The elimination of oxygen is achieved by physical separation of the fresh products from molecular oxygen. For enzyme inhibition, addition of salt is known as an effective measure. The browning also has an issue in the browning during fruit juice processing. We can add antioxidants to prevent the browning, but there is a limited effect with a limited dose of inhibitory compounds. Thus for the juice making, another countermeasure is often considered. PPO is mostly found as in the form associating with pulp portion of fruits. Therefore, the removal of pulp as much as possible can make the PPO activities low, and combined use of inhibitors can reduce the browning defects drastically (Yoruk and Marshall, 2003; Sapers and Miller, 1998).

### Recent Developments of Food Enzyme Applications

The above section has discussed the development/utilization of enzymes in the past decades, and they are currently employed in the food processing practice. In this section, we look into more recent R&D to use enzymes in food processing.

### Prebiotics and Lactases

Prebiotics promote probiotic microbes' activities. There are many prebiotics that have been reported, including resistant starch, pectin, and  $\beta$ -glucans (Lomax and Calder, 2008; Andersson et al., 2001). Majority of prebiotics are so-called dietary fibre, but there are other smaller prebiotics compounds. Such example is oligo-saccharides. Many of oligosaccharides are found in nature and by synthesis, and they can be taken as purified preparations, synthetic additives, and natural ingredients in food materials. For synthesis of oligosaccharides, enzyme activities can be utilized. Sialidases (E.C.3.2.1.18),  $\alpha$ -1-fucosidases (E.C.3.2.1.51) and  $\beta$ -galactosidases (E.C.3.2.1.23) are studied for their ability to synthesize oligosaccharide prebiotics (Zeuner et al., 2014). Human milk oligosaccharides made through transsaccharification by sialidases and fucosidases have been extensively reviewed (Bode, 2015). While transsialylation and transfucosylation naturally occurs in human milk,  $\beta$ -galactosidase mediated oligosaccharides are studied to produce oligosaccharides *in vitro* (Vera et al., 2012; Yu and O'Sullivan, 2014; Rodriguez-Colinas et al., 2012). As discussed earlier,  $\beta$ -galactosidases (lactases) are the enzymes which hydrolyze lactose into galactose and glucose. When lactose concentration is high,  $\beta$ -galactosidase can catalyze the transgalactosidation to produce a prebiotic compound, galactooligosaccharides (GOS), where galactose of lactose is transferred onto another galactose moiety of lactose and GOS. This reaction produces a trisaccharide Gal- $\beta$ -(1 $\rightarrow$ 4)-Gal- $\beta$ -(1 $\rightarrow$ 4)-Glc and a tetrasaccharide Gal- $\beta$ -(1 $\rightarrow$ 4)-Gal- $\beta$ -(1 $\rightarrow$ 4)-Gal- $\beta$ -(1 $\rightarrow$ 4)-Glc (Fig. 6).  $\beta$ -galactosidase studied in the production of GOS are from *Bifidobacterium longum* (Hsu et al., 2007), *Kluyveromyces lactis* (Rodriguez-Colinas et al., 2011), *Aspergillus oryzae* (Vera et al., 2012; Albayrak and Yang, 2002), *Lactobacillus pentosus* (Maischberger et al., 2010), *Lactococcus lactis* (Yu and O'Sullivan, 2014), and *Bacillus circulans* (Rodriguez-Colinas et al., 2012). The conversion of lactose has reached GOS at ~50% of total

**Figure 6 Galactooligosaccharides.** The galactose moiety in lactose is transsaccharified onto another lactose, and tri-saccharides (and another transsaccharification onto tri-saccharides for tetra-saccharides) are produced through  $\beta$ -galactosidase activities.

carbohydrates (Vera et al., 2012; Yu and O'Sullivan, 2014; Rodriguez-Colinas et al., 2012) with initial lactose concentrations at 40% ~60%. When lactose concentration is within the order observed in skimmed milk (4.6%), the conversion rates of lactose can reach 50% (Rodriguez-Colinas et al., 2012) to 72% (Yu and O'Sullivan, 2014).

### Bioactive Peptides and Proteinases/Peptidases

In the last twenty years, proteolysis of food proteins is found to have additional potential health benefits. The proteolysis yields smaller peptides and some of these peptides can have physiological activities: such as antihypertensive, antioxidative, calmodulin-modulating, anticancer, immunoregulatory, anti-inflammatory, and antithrombotic activities. These peptides are now classified as "bioactive peptides (BAP)". It was first observed in the milk proteins, and then expanded to egg, beef, fish meat, sea shell proteins, legume protein and so on (Udenigwe and Aluko, 2012). Many proteinases are artificially employed to hydrolyze these proteins, and the peptides in hydrolysate are examined for physiological activities. In order to increase the yields of BAP, many efforts have been conducted including denaturation of proteins (Le Maux et al., 2016; Korhonen et al., 1998) and prediction of potential BAP activities (Gu et al., 2011). A critical issue in the production of BAP is how to separate it from the hydrolysate. Most products claiming BAP activities use hydrolysates as the ingredients, and the effects per protein amount is still limited (Agvei and Danquah, 2011).

### Active Packaging

Another recent development is active packaging of foods. The packaging materials have been inert by nature. It is effective to protect foods from mechanical damages, dirt contamination, distribution ease, and so on. Meanwhile, they may not prevent growth of already-contaminated microbes, oxidation by atmospheric oxygen, and influences from ethylene for plant produces. Active packaging materials address these issues. For example, ethylene, which is a phyto-hormone to ripen fruits, can be scavenged by the presence of potassium permanganate in the packaging materials (Vermeiren et al., 2003), extending the shelf life of fruits. There are many materials and methods proposed for active packaging: two types of active packaging use enzyme activities for their actual active factors. One of them is oxygen scavenging and the other is antimicrobial packaging (Vermeiren et al., 1999). Oxygen scavenging packaging uses oxidases, such as glucose oxidases (Fortier and Bélanger, 1991; Wong et al., 2008), as the active ingredient and consume available oxygen in the package. It is, however, less cost effective than to use inorganic materials such as ferrous cations. For the antimicrobial packaging, enzymes such as lactoperoxidase (Min and Krochta, 2005), lysozyme (Padgett et al., 1998), glucose oxidase (Fortier and Bélanger, 1991; Wong et al., 2008) and lactoferrin (Min et al., 2005) are shown for their positive results. An issue of enzyme usage in the package is their stability towards temperature, moisture, and pH. It is still underdevelopment, but in future, more enzyme utilization in the active packaging is expected.

### Food Wastes and Enzymes

Lastly, the enzyme utilization in the food waste treatment should be mentioned. Foods are organic materials, and their production has certain impacts on the environment. Meanwhile, about 30% of foods are reportedly wasted. A majority of food waste is carbohydrates, and its utilization can contribute to the sustainable food supply and environmental protection. Many enzymes are available to hydrolyze carbohydrates, such as amylases, pectinases and cellulases. Along with hydrolases of other food waste components, such as proteinase and lipases, enzyme reactions can be utilized to degrade food waste to provide the feedstock for other purposes, including biofuel production (Uçkun Kiran and Liu, 2015; Uçkun Kiran et al., 2014).

## Conclusion

Enzymes are considered as efficient tools to decrease food processing costs, to reduce the waste and to provide more safe and healthy foods. Many of applications have been utilized and are being developed. In next decades, we expect to see more enzyme utilizations in the processing of foods, in the analyses of foods and in the reduction of impacts on the natural environment.

## Glossary

**Fat extender** used to reduce the concentration of fats by replacing them with a standard lipid combined with other ingredients.

**Fat mimetic** used to replace fat however it requires a high-water content for to attain its desired functionality.

**Fat Substitute** used to replace fat on a weight-by-weight basis but is resistant to hydrolysis by digestive enzymes.

**Low-calorie fat** used to substitute fat with a synthetic fat with one or more of the fatty acids on the glycerol backbone being replaced with something other than a fatty acid.

## Introduction

Reduced fat products are common place in the food landscape of today; consumers often choose these products to control or restrict caloric intake or to reduce the perceived threat of coronary heart disease (CHD). Messages centering on lipids, especially around saturated and *trans* unsaturated, has led a large cohort of consumers to shift their diet towards consuming more low-fat options. However, the paradigm that all saturated and *trans* fats have deleterious biological consequences has shifted once again and it is now being suggested that saturated fat and *trans* fats from ruminants may not be implicated in CHD as once believed (Chavan et al., 2016; de-Souza et al., 2015). In practice, because of recommendations to limit saturated fats to no more than 10% and *trans* unsaturated fats to no more than 1% of a person's dietary energy, consumers often choose low-fat options. Although mandates exist to reduce hardstock fats from foods, a simple fat reduction is associated with undesirable changes to texture and sensory perception of fat products (Liu et al., 2016b). Up to now, there has been no single fat replacer identified that is able to mimicking the diverse functionalities of fat across a wide range of foods therefore fat replacers are targeted to specific applications (Table 1).

Replacement of the fat component of foods is often difficult because they have multi-functional roles in foods as they influence chemical, physical and sensory attributes of foods as well as their processing characteristics. Simply reducing the content of fat causes quality losses that decrease the acceptance of foods (Peng and Yao, 2017). Therefore, depending on the role that fat has in determining the quality of these product it will affect the complexity of the system that must be implemented to replace that lipid fraction (Jones, 1996). Fat replacer is a broad term to describe any technology used to reduce or eliminate fat and can be subdivided into the following categories (Jones, 1996):

Fat Substitute: used to replace fat on a weight-by-weight basis but is resistant to hydrolysis by digestive enzymes;

Fat mimetic: used to replace fat however it requires a high-water content for to attain its desired functionality;

Low-calorie fat: used to substitute fat with a synthetic fat with one or more of the fatty acids on the glycerol backbone being replaced with something other than a fatty acid.

Fat extender: used to reduce the concentration of fats by replacing them with a standard lipid combined with other ingredients.

Fat replacers can also be sub-divided based on the primary reason for the removal of fat. Caloric reducers replace a fraction of all lipids, while hardstock fat replacers only replace a fraction of the *trans* unsaturated and saturated fats (Fig. 1) (Akoh and Decker, 1995; Rogers, 2011). Caloric reducers include olestra (Bergholz, 1992), non-digestible carbohydrates (Peng and Yau, 2017), proteins (Singer, 1996), while *trans* unsaturated and saturated fat replacers are often small molecules such as sorbitan tristearate, phospholipids, monoglycerides, and modified fatty acids (Rogers et al., 2014, 2009; Wang and Rogers, 2015).

## Carbohydrate-Derived Fat Replacers

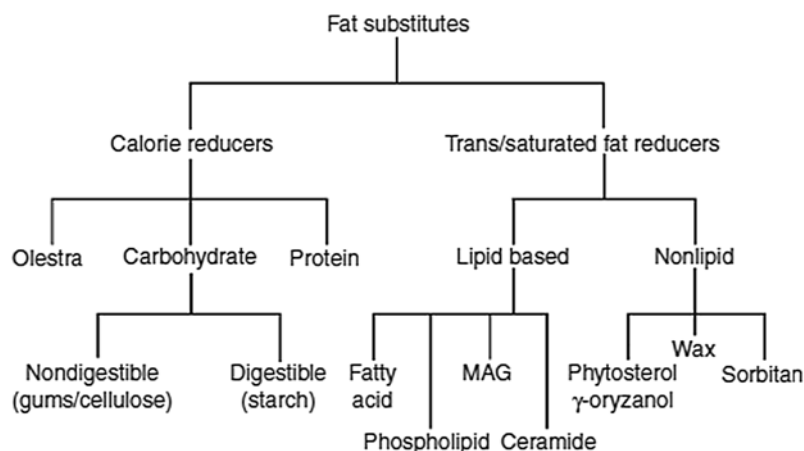

The molecular diversity of carbohydrates gives rise to various structural and physicochemical properties allowing formulation chemists to tailor the physical attributes that need replaced upon the removal of fat (de Souza et al., 2015; Peng and Yau, 2017). Furthermore, methods are available to modify carbohydrates; for example, substituted starch using octenyl succinate or cross-linked starches are commonly used as a fat replacer because of the indigestibility and further caloric reduction. When a fraction of fat is removed, it is most commonly replaced with carbohydrates such as starch, maltodextrin, gums, or dietary fiber with or without additional water.

Starch is typically used in its non-gelatinized form because the starch granules are on the same order of magnitude as fat crystals or fat emulsion droplets which emulates the mouthfeel imparted by lipid droplets (McClements et al., 2017). Because of the size and physical attributes of starch granules, they are commonly cross linked to prevent swelling and leaching of the amylose and in numerous cases amylopectin is debranched (Klaohanpong et al., 2017). Starch based gels have been proven capable of replacing

**Table 1** Classification of fat replacers by nutrient source and function properties

Type of fat substitute	Nutrient source (energy density)	Functional properties	Use in food
Derived from carbohydrate Polydextrose	Water-soluble polymer of dextrose (1 cal g <sup>-1</sup> )	Bulking and retaining moisture	A wide range of foods, including baked goods, confections, and frozen desserts
Modified food starch	A variety of starch sources (1–4 cal g <sup>-1</sup> )	Modifying texture, gelling, thickening, and stabilizing	Processed meats, salad dressing, baked goods, frozen desserts, etc.
Dextrin and maltodextrins	A variety of starch sources (4 cal g <sup>-1</sup> )	Modifying texture and bulking	Baked goods, dairy products, salad dressing, sauces, and spreads
Gums and pectin	Xanthan, guar, locust bean, carrageenan, alginates and fruit	Retaining moisture, mouthfeel and modifying texture	Wide range of products, including baked goods, sauces, and salad dressings
13-Glucan	Various plant sources (virtually noncaloric)	Modifying mouthfeel, texture, and pourability	Dairy products
Derived from protein	Soluble fiber extracted from oats (1–4 cal g <sup>-1</sup> )	Adding body and texture	Baked goods and a variety of other food products
Microparticulated protein and modified whey	Denatured or microparticulated protein from egg/milk (1–4 cal g <sup>-1</sup> )	Modifying mouthfeel	Dairy products, spreads, and bakery products
Derived from fat Olestra	Sucrose polyester with triglycerides (noncaloric)	Modifying texture and mouthfeel	Savory snacks (stable for fried foods)
Caprenin and salatrim	Caprylic, capric, behenic acid, and glycerine, or triglyceride of short- and long-chain fatty acids (5 cal g <sup>-1</sup> )	Simulating properties of cocoa butter	Confections, baked goods, and dairy foods
Mono- or diglycerides	Derived from vegetable oil and emulsified with water (9 cal g <sup>-1</sup> )	Adding moisture and modifying texture and mouthfeel	Baked goods, vegetable dairy replacers

**Figure 1** Primary strategies to substitute fats in edible food applications. Reproduced from Rogers, M.A., 2011. Novel lipid substitutes. In Moo-Young, M. (Ed.), Comprehensive Biotechnology, second ed., vol. 4. Elsevier, pp. 603–616. Reproduced with permission from Elsevier.

numerous attributes which fats contribute including: increased water-holding capacity, gel firmness and viscosity and these changes are often perceived as an increase in creaminess in liquid formulation such as low fat salad dressing (Peng and Yau, 2017).

Starch can also be partially hydrolyzed using enzymes or acid to form maltodextrin. Maltodextrins with dextrose equivalents (DE) between 2 and 4 are most commonly used as fat replacers between 1 and 5 wt% because of their ability to gel and thicken (McPherson and Seib, 1997). At 1 to 5 wt% maltodextrin, 25 to 35 wt% of the fat can be replaced in cookies while maintaining a full-bodied texture and desirable mouthfeel (Chavan et al., 2016). By selecting the appropriate DE the melting point of the maltodextrin gel can be tailored to simulate the oral melt down properties of fat (Peng and Yau, 2017). Not only does the DE effect the ability to mimic the physical properties of fats, but so does the source of the maltodextrin (Peng and Yau, 2017). Maltodextrin fat replacers are commonly employed in dairy products, confectionary, frozen desserts, cereal baked goods, and meat products because they form soft, spreadable, thermo-reversible gels with melt-in-the-mouth properties. However, maltodextrins increase

the glycemic load of the food and post meal glycemia, which are less desirable for health (Hofman et al., 2016). There are also physical limitations in its application due to the amylopectin which has a tendency to retrograde, causing setback in low-fat salad dressings and their poor freeze-thaw stability and unreliable heat and acid stability (Chavan et al., 2016).

Non-digestible polysaccharides may also be utilized as fat replacers. Microcrystalline cellulose (MCC) is partially depolymerized cellulose synthesized from  $\alpha$ -cellulose precursor. MCC is a modified form of cellulose that is composed mainly of anhydroglucose units with  $\beta(1-4)$  glycosidic bonds (Chavan et al., 2016). The majority of colloidal grades have microcrystals less than 0.2  $\mu\text{m}$  in length, that when added to an aqueous medium disperse rather than hydrate (Lucca and Tepper, 1994). MCC is typically processed with adjuvants such as guar gum which act as a 'glue' to hold the insoluble cellulose crystals in a 3D network that is thixotropic mimicking the body and mouthfeel of lipids. Other non-digestible polysaccharides such as pectin,  $\beta$ -glucan, inulin, locust bean gum have all shown promise to be used as fat replacers.

Pectin is composed of a galacturonan backbone which may be methyl-esterified giving rise to low and high-methoxy pectin. Pectin is able to gel and thicken foods; however, because it forms strong gels, there are challenges in incorporating high concentrations of pectin into foods (Min et al., 2010). The functionality of pectin is influenced by the source, which gives rise to variations in molecular weight and degree of methyl esterification. High methoxy pectin gels in the presence of high sugar concentrations in acidic conditions, while low methoxy pectin requires the addition of divalent ions such as calcium in basic conditions (Durand et al., 1990). Slendid is a citrus pectin that when combined with calcium is able to replace up to 100% of the fats in a variety of processed foods ("Low-calorie fat replacer is based on pectin," 1991). Recent work with pectin fat replacers has focused on reducing the amount of fat in processed meats, salad dressings and ice cream (Maneerat et al., 2017; Tekin et al., 2017).

Inulin is a fructosyl-fructose-linked oligomeric carbohydrate with a polymerization degree  $\approx 10$ . Inulin is a fructosyl-fructose-linked oligomeric carbohydrate with a polymerization degree  $\approx 10$ , inulin is a moderately water soluble fructosyl-fructose-linked oligomeric carbohydrate with a polymerization degree  $>10$  that is resistant to human digestion (Zahn et al., 2010). Inulin forms a short spreadable gel network, when added at high concentrations, that acts as fat replacer in spreads and fillings, dairy products, desserts and dressings (Franck, 2007; Guven et al., 2005). In the case of adding inulin to muffins, only 50% of the fat could be replaced with similar crumb firmness as the full fat counterpart (Zahn et al., 2010).

### Protein-Derived Fat Replacers

The ability to mimic fat functionality by microparticulated proteins is attributed to their spherical shape and small size that are comparable in size to oil droplets found in food emulsions. There are numerous microparticulated protein based fat replacers that are derived from whey, egg, and zein proteins (Cheftel and Dumay, 1993). Often, the microparticulated protein is applied in combination with a stabilizing polysaccharide such as carboxymethylcellulose with zein protein and xanthan with egg white protein (Liu et al., 2016b). Specifically, microparticulated proteins effectively replace the sensory perception of oil droplets in liquid and semi-solid food matrices (Liu et al., 2016a). Microparticulated whey protein has numerous applications in dairy-based products where it has been shown to provide a smooth, creamy mouthfeel in low-fat applications such as low fat cheeses, yoghurts, ice creams (Cheftel and Dumay, 1993; Liu et al., 2016a, 2016b). In the case of microparticulated whey protein, the attributes of these ingredients are dependent on the size of the particles. Small particles, contribute to the creaminess, while large particles impart a roughness which suppresses creaminess (Liu et al., 2016a).

Microparticulated proteins induce a creamy oral sensation when they are dispersed into an aqueous phase because of the 'ball-bearing' lubrication properties of microparticulated whey proteins in liquid and semi-solid food matrices (Liu et al., 2016a). The 'ball-bearing' lubrication model suggests that creaminess arises when the microparticulated protein is dispersed in the aqueous phase allowing them to roll freely over one another under an applied shear. Although microparticulated proteins increase the creaminess by reducing the friction via the 'ball-bearing' model, the underlying mechanism differs considerably from how oil droplets impart creaminess. These differences may induce changes in sensory perception of creaminess.

### Lipid-Derived Fat Replacers

The most commonly thought of lipid-derived fat replacer is olestra, which is a mixture of hexa-, hepta- and octa-esters of sucrose. Six to eight long-chain fatty acids are covalently linked to sucrose by chemical transesterification. Gastric lipases and the bacterial lipases produced in the colon are incapable of cleaving the fatty acids from the sucrose ester and as such the fatty acids are not absorbed by the microvilli but instead are excreted in the stool (Jandacek, 1982). Since olestra is lipophilic, nondigestible, nonabsorbable, it can interfere with the absorption of other lipophilic components in the diet, consumed at the same time as olestra. An advantage of olestra over other fat replacers is that the physical properties can be tailored depending on the fatty acids esterified to sucrose. For example, if highly unsaturated fatty acids are esterified to sucrose then the resulting olestra will be fluid, conversely, if long chain saturated fatty acids are used then it will be solid (Ognean et al., 2006). Olestra has very similar organoleptic and thermal properties compared to triglycerides with similar fatty acids.

Caprenin is a triglyceride that contains glycerol esterified to two medium chain fatty acids (caprylic and capric) and a long chain fatty acid, behenic acid. The reduction in calories occurs because behenic acid is only partially absorbed, while capric and caprylic acids are readily metabolized and as such caprenin provides only 5 kcal/g (Akoh, 1998). Because of the fatty acid composition, the functional properties are similar to cocoa butter allowing it to be used in soft candy and confectionary coatings. Salatrim also relies on the fact that short chain fatty acids provide fewer calories per unit weight and that long chain fatty acid, stearic acid, is only partly

absorbed resulting in 55% fewer calories than traditional fats (Akoh, 1998). Salatrim is a generic name for triglycerides that contain at least one short chain fatty acid and at least one long chain fatty acid, typically stearic acid. The physical properties of salatrim can be manipulated by chaining the amounts of short chain and long chain fatty acids allowing the melting points and hardness to be manipulated. It is sold as Benefat 1. Its primary application is as a replacer for cocoa butter.

### Small Molecule Fat Replacers

Small molecule fat replacers are used to replace the hardstock fats, i.e. *trans* and saturated fats, while maintaining the concentration of unsaturated oils and the original physical properties of the fat blend. These liquid oil gels, termed oleogels, molecular gels and/or organogels, are similar to fats in that they can undergo the sol–gel transition numerous times simply by reheating and recooling the system (Weiss, 2014). Highly effective oleogelators form gels in vegetable oils, at concentrations as low as 0.5 wt% (Rogers, 2017). Oleogels self-assemble, in vegetable oils, via non-covalent interactions (i.e. hydrogen bonding,  $\pi$ - $\pi$  stacking, electrostatic and van der Waals interactions) forming fibrillar or platelet crystals (Patel and Dewettinck, 2016; Rogers et al., 2009). These intermolecular interactions favor 1-dimensional (1D) fibrillar growth leading to the formation of a 3 dimensional (3D) networks that is capable of entrapping the liquid oil phase. Few applications of oleogels in foods exist because it is difficult to identify new food grade, inexpensive gelators; however, research in this area is increasing exponentially. Although there is a plethora of reported small molecular gelators, here we will focus only on two systems – the waxes and the phytosterol/ $\gamma$ -oryzanol system.

Although numerous waxes have been studied as potential oleogelators to replace hardstock fats, candelilla wax (CDW), carnauba wax (CBW), rice bran wax (RBW) and beeswax (BW) are of the greatest interest as food-grade waxes for use as edible oleogels (Rogers et al., 2014). Oleogels comprised of wax and vegetable oils have varying fractions of n-alkanes, fatty alcohols, and fatty acids. Wax esters have a tendency to form platelet-like or needle-like crystals in edible oils at low concentrations that are very effective at gelling vegetable oil (Toro-Vazquez et al., 2013, 2010). CDW is obtained from the leaves of *Euphorbia cerifera* and comprises n-alkanes, between 29 and 33 carbons and structures safflower and canola oil at concentrations less than 2 wt% (Blake et al., 2014). CDW forms the most elastic gel (i.e., highest hardness value) while BW is the lowest (Lim et al., 2016).

$\beta$ -Sitosterol and  $\gamma$ -oryzanol are unable to gel vegetable oil when added individually, however they are able to self-assemble efficiently enough to entrain oil when combined at a 60:40 wt%  $\gamma$ -oryzanol/ $\beta$ -sitosterol ratio. At a 1:1 M ratio they self-assembled into hollow tubules, that have a diameter between 67 and 80 Å, are between 8 and 12 Å thick and have a length which can exceed 1000 Å, at concentrations as low as 2% (Bot et al., 2012). The ratio of  $\gamma$ -oryzanol to  $\beta$ -sitosterol and vegetable oil effects the self-assembled structures which in turn alters their ability to entrain liquid oil. For this system to gel it requires the molecules to form synergistic hydrogen bonding, they must contain a ring system, and alkyl residue (Bot and Agterof, 2006). Not only does  $\beta$ -sitosterol form effective gels with  $\gamma$ -oryzanol but so do other plant sterols such as ergosterol, stigmasterol, cholesterol, cholestenol (Bot et al., 2012). In sunflower oil, the gels are transparent and by changing the concentration, the mechanical and rheological properties can be fine-tuned to mimic saturated fats. These oleogels are food grade and phytosterols lower blood cholesterol levels making these attractive alternatives to colloidal fat crystal networks.

### Conclusions

The physical attributes that fats impart to foods are very diverse. In emulsions they provide enhanced viscosity, mouthfeel, and body to the food, while in solid fat matrices they provide an elastic network essential for the food structure. Depending on the type of food, which fat is being removed from, there are numerous fat replacers that can be used depending on the physical attributes that need replaced. Fat replacers that work well in emulsions, such as microparticulated whey proteins, will not work as a hardstock fat replacers, therefore it is important to identify a suitable fat replacer for the specific application or food that is being formulated. Although numerous fat replacers exist to create low-fat options, there are very few oleogelators that are allowed in foods that can effectively structure unsaturated oils. However, this is a rapidly growing area of research as there is a constant desire by manufactures to eliminate *trans* fats while also reducing the concentration of saturated fats and maintaining unsaturated oil concentration.

# Flavor Enhancers and Modifiers

Nicole J Gaudette, Food Processing Development Centre, Government of Alberta, Leduc, AB, Canada

## Introduction

Within the context of sensory science, flavor can be described as a combination of taste, odor and chemesthetic sensations. Generally speaking, there are five basic tastes, including sweetness, sourness, saltiness, bitterness and umami (recent and ongoing research indicates fat may also elicit taste; [Running et al., 2015](#)). Odor includes sensations experienced through the ortho- and retronasal routes, for example, vanilla and lemon aromas. Chemesthetic sensations activate the trigeminal nerve, such as the burn of capsaicin from hot peppers, or the coolness of menthol from mint. While the sensory perception from each of these sensory modalities may occur alone, they are more often experienced together during food and beverage consumption.

Flavor perception is dynamic and may be influenced, and thus, altered through the addition and/or removal of various ingredients. From a food product development standpoint, continuous pressure to remain market relevant is placed due to evolving consumer trends, including sugar, salt and fat reduction, clean labeling and incorporation of health-promoting, functional ingredients. Formulation strategies to satisfy these objectives can negatively impact flavor, and thus, the incorporation of ingredients that will optimize flavor to better align with consumer expectation and product liking are necessary. For example, sugar, salt and fat reduction may lead to a less flavorful product, while the addition of functional ingredients can introduce off-aromas and less desirable tastes (e.g., bitterness).

Flavor optimization during food product formulation may focus on the incorporation of flavor enhancers or flavor modifiers. Generally, enhancers are used to increase the overall palatability, richness, pleasantness and hedonics of savory foods ([Kemp and Beauchamp, 1994](#); [McCabe and Rolls, 2007](#)). Modifiers may be used to target the suppression or enhancement of basic tastes and odors within a food matrix, and thus, vary in their impact on overall flavor perception.

## Flavor Enhancers

Ready-to-eat meats, cheeses, sauces and condiments, ready meals and various snack items represent categories of savory foods that may be targeted for the application of flavor enhancing ingredients. In particular, new products or re-formulations that target lowered amounts of sodium in order to meet regulatory guidelines and consumer expectation may require the use of flavor enhancers to counterbalance the loss of sensory palatability from the removal or replacement of salt. Strategies include the use of umami-eliciting compounds that aim to elevate the overall palatability of savory foods.

Monosodium glutamate (MSG) elicits umami or savoriness, a basic taste sensation ([Zhao et al., 2003](#)). By itself, taste from MSG has not been characterized as 'delicious', nor does it provide flavor enhancing capacity ([Halpern, 2002](#)). However, when combined with additional compounds, including purine nucleotides - 5'-adenosyl monophosphate (AMP), inosine 5'-monophosphate (IMP), 5'-guanosine monophosphate (GMP) - and some amino acids, a flavor enhancing effect can result ([Halpern, 2002](#); [Chandrashekar et al., 2006](#)).

Enhancing capabilities for these compounds have been demonstrated in food model systems. For example, when paired with a congruent savory vegetable odor, the sensory impact of glutamate (MSG + inosine 5' monophosphate) has been found to elevate 'pleasantness' compared to glutamate or vegetable odor presented alone ([McCabe and Rolls, 2007](#)). Elevated pleasantness from glutamate + vegetable odor was also significantly higher compared to sodium chloride + vegetable odor, demonstrating the advantageous flavor enhancing capacity for glutamate over sodium chloride. In real food applications, the use of nucleotides and amino acids to enhance flavor has been demonstrated in reduced sodium processed meats ([dos Santos et al., 2014](#); [Campagnol et al., 2012](#)) and Cheddar cheese ([Khetra et al., 2016](#); [Grummer et al., 2012](#)).

Flavor enhancing compounds may successfully be used to elevate the palatability of various savory foods. However, the use of some ingredients may be less desirable if they are unfamiliar to consumers. A clean labeling approach - which may in part be defined as a back of the package ingredient list that is short and simple, containing 'kitchen cupboard ingredients' that are not 'chemical-sounding' ([Asioli et al., 2017](#)) - will target the use of umami-eliciting ingredients that may be perceived as more 'natural' by the consumer in order to better align with the product category. Here, umami-eliciting ingredients derived from more familiar sources may be applied to food formulations to enhance flavor. For example, the addition of mushrooms has been used to compensate for flavor loss and enhance overall flavor and umami taste in a reduced sodium ground beef taco blend ([Miller et al., 2014](#)). Modified soy sauce has been utilized to successfully increase the overall taste intensity, meat taste, and salty taste of reduced sodium frankfurters ([McGough et al., 2012](#)). In reduced sodium ham and turkey sausage, a milk protein and cultured milk based flavor enhancer was used to mitigate flavor loss ([Pietrasik and Gaudette, 2014, 2015](#)). Commercial yeast extracts have also been found to compensate for the potential flavor loss from salt removal in reduced sodium ready meals ([Mitchell et al., 2009](#)).

## Flavor Modifiers

In order to improve or optimize the sensory properties of foods and beverages, ingredients may be used to modify overall perceived flavor. Approaches include the use of ingredients to suppress or enhance basic taste and/or odor sensations within foods and beverages. Similar to the need for flavor enhancers in sodium reduced savory foods, flavor modifiers may be required in re-formulations where salt and sugar are reduced. While the addition of sodium chloride and sucrose are used, respectively, to deliver salty and sweet taste, their purpose in formulations may also be to suppress the bitterness elicited by other ingredients. Thus, sodium chloride and sucrose may have multiple functions within a food product regarding their direct or indirect impact on taste and odor sensations. For example, the bitterness of caffeine is decreased through the addition of sucrose, with increasing sucrose concentration leading to decreasing bitterness (Calviño et al., 1990). Sodium chloride can suppress the taste from bitter eliciting compounds, primarily due to the influence of the sodium cation (Breslin and Beauchamp, 1995); although the mechanism for this remains unclear (Gaudette and Pickering, 2011).

As mentioned previously, current food trends include the reduction of salt and sugar to satisfy health-conscious consumers. This remains challenging for industries that rely heavily on these ingredients (e.g., confectionary, meat, cheese, and bakery items), for they contribute to the functionality, safety and sensory properties of foods. Since salt and sugar reduction can negatively affect sensory properties, including decreased overall flavor intensity and increased intensity of less desirable tastes (bitterness, sourness), options for flavor modification are needed.

Flavor modifying strategies are more challenging for functional foods - where fortification with health-promoting ingredients elevates the nutritional profile of foods and beverages. For these products, functional ingredients (e.g., grape and green tea-derived polyphenols, glucosinolates, soy isoflavones) can negatively impact the flavor profile of foods by introducing off-flavors, including elevated bitterness, which may lead to decreased consumer acceptability. While bitterness suppression can be successful through the addition of sodium chloride and sucrose, this approach is not ideal in functional food formulations which are positioned for health conscious consumers. Thus, alternative approaches and ingredients should be considered. For example, the use of alternative sweeteners (e.g., agave, Rebaudioside A or stevia leaf, honey, monk fruit) may provide an option for some product formulations. However, due to the potential for the elicitation of off-flavors and bitterness, the successful use of some plant-based sweeteners for providing a pleasant aftertaste while masking the bitterness of other ingredients may be concentration dependent (Li et al., 2015).

The impact of odor on taste perception; a cross-modal, sensory interaction, is substantial (Delwiche, 2004; Prescott, 1999) and may provide a viable strategy towards flavor modification in salt and sugar reduced foods. Due to learned taste-odor associations experienced through everyday food and beverage consumption, congruent mixtures of tastes and odors can have an enhancing effect on taste intensity. For example, when compared to sucrose alone, the sweetness of sucrose can be elevated when paired with the addition of strawberry but not peanut butter odor (Frank and Byram, 1988). In simple aqueous solutions, the saltiness of sodium chloride can be enhanced through the addition of sardine but not carrot odor (Lawrence et al., 2009) - demonstrating the importance of taste-odor congruency on the impact of flavor. While odor-induced taste enhancing effects have been shown in simple matrices, their capacity in foods with more complex flavor profiles remains relatively unclear. Overall, the effect is likely dependent on the complexity of the food matrix, with increased complexity associated with a decreased effect.

## Other Considerations

Additional approaches towards flavor modification may target the use of ingredients that provide textural properties to foods and beverages. In particular, hydrocolloids used as thickeners or gelling agents can modify flavor by trapping compounds and thus, limiting interaction between tastants and odorants and sensory receptors. For example, several hydrocolloids have been demonstrated to reduce bitterness, including cellulose gum, low-viscosity carboxymethyl cellulose, and sodium alginate (Moskowitz and Arabie, 1970; Pangborn et al., 1973).

The binding of taste eliciting compounds is also of value for functional food formulations, especially towards bitterness suppression (Coupland and Hayes, 2014). Here, the use of cyclodextrins, polymers, surfactants, lipids and emulsions may provide an alternative strategy towards the incorporation of bitter tasting, health promoting functional ingredients into food and beverage formulations.

## Conclusion

The use of flavor enhancers and modifiers represents a valuable approach towards improving the overall sensory properties and consumer acceptability of foods and beverages. For simple matrices, it is possible that a single flavor enhancing or modifying strategy may be successful. However, it is likely that a multi-strategy approach that incorporates various concentrations of one or more ingredients is more impactful.

It is important to note that the impact of any particular flavor enhancing or modifying strategy on overall flavor perception is highly dependent on the presence of various within- (taste-taste) and cross-modal (taste-odor) sensory interactions. Suppressing

and additive effects on flavor will occur due to oral peripheral physiological interactions or a central cognitive effect. Therefore, it is important to understand that the sensory impact of enhancing and modifying ingredients within a matrix may not be straightforward.

In addition to various sensory interactions, the flavor response to an added ingredient is based on its dose - a relationship that is not always linear and easily predictable. Finally, chemical and/or physical interactions can occur within the food matrix, providing even more complexity towards the prediction of ingredient impact on overall flavor perception. Therefore, prior to the use of flavor enhancing and modifying ingredients in food and beverage formulations, testing at several concentrations should occur in order to understand, verify and optimize their impact on overall flavor.

# Flavors (Bittering Agents, Astringent Flavors, Pungency, Menthol)

Paul Hughes, Oregon State University, Corvallis, OR, United States

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Bitterness, astringency, pungency and menthol are primarily perceived in the buccal cavity. Whilst the former is regarded as a taste, the three latter are generally considered to be responsible for specific chemesthetic experiences, *ie* those sensory experiences that activate receptors not generally considered to fit the classical categories of aroma and taste, often known as somatosensation. As a group these taste qualities can have dramatic effects on the flavor perception of many foods and beverages, as well as other orally administered substances, such as pharmaceuticals and oral hygiene products. As such these tastes often need to be considered when these qualities are to be included in such products. The focus of this article is primarily on positive sensory responses so consideration of other related aspects, such as taste modulation and suppression are not discussed here.

The perception of bitterness, pungency and menthol requires interaction between the active compounds and their associated G-protein coupled receptors (Table 1). Additionally, certain pungent compounds, such as acrolein and ethanol, also interact with G-protein coupled olfactory receptors in the olfactory epithelium to give a retronasal sensory response (*ie* an “aroma”). These additional perceptions complicate the sensory appraisal of such compounds.

As we will discuss below, the mechanism of astringency perception is currently disputed, but to date there do not seem to be any astringency receptors identified. A commonly- but not universally-held view is that astringency perception is due to the non-covalent binding of astringent species with salivary proteins that results in the precipitation of the resulting complex. This chemistry is analogous to the initial stages of leather tanning and the formation of particulates in ageing red wines and beers.

## Chemical Entities and Their Occurrence

The range of compounds that can induce perceptions of bitterness, pungency and astringency is generally broad (Tables 2–4), whilst the flavor and cooling properties of menthol can also be substantially replicated in other menthol derivatives. Many of these compounds have commercial significance, either as pure substances or as part of food or beverage products. Whilst we recognize that some of the compounds discussed below have broad applications, for the purposes of this article we will not consider applications beyond the food and beverage sectors.

## Future Aspects

The scientific exploration of flavour perception is highly active at present, exemplified by the recent reports of putative oil- and starchy-related tastes reported since 2015. With the plethora of sensory stimuli and rapid developments in the physiological and sensory approaches to both chemesthetic and flavour perceptions, it is not beyond the bounds of expectation that more targeted design of chemical entities with specific bitter attributes will be more accessible. Where bitterness is undesirable, bitterness could be attenuated, either by tailoring the chemical entities themselves or by design of bitter antagonists or “masking agents”. Clarification of the mechanism(s) of astringency perception and its apparent association with bitterness will help to rationalize the sensory properties those foods and, especially, drinks, where astringency plays a key role in flavour perception, such as wood-aged drinks, wines and ciders.

## Bitterness

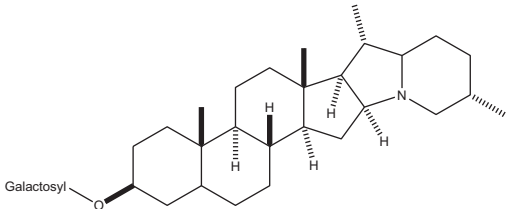

Humans can detect bitterness in many foods and beverages, including fruits, vegetables, drinks such as beer, cocoa, coffee and tea as well as in animal products such as dairy, fish and chicken. Generally bitterness is often considered to be an undesirable sensory quality, although this is not the case for certain foods and beverages. Additionally other substances, such as orally-administered pharmaceuticals can convey bitterness. Bitter compounds are structurally diverse and work carried out since the late 1990s has identified around 25 distinct G-protein-coupled bitterness receptors (Table 2). As of January 2018 the bitterness database BitterDB ([bitterdb.agri.huji.ac.il](http://bitterdb.agri.huji.ac.il)) listed more than 680 distinct bitter substances, either as pure compounds (*eg* quinine, 1) or as mixtures,

**Table 1** Receptors responsible for the perception of bitterness, astringency and menthol

<i>Taste quality</i>	<i>Receptors</i>	<i>Localization</i>	<i>Taste descriptors</i>
Bitterness	TAS2R (1,3-5,7-10, 13,14,16,38-50,60)	Oral taste receptor cells, larynx, upper esophagus	Bitterness, metallic
Pungency	TRPV1, TRPA1	Skin, mucous membranes	Hot, burning
Menthol	TRPM8	Skin, mucous membranes	Cooling, (pepper)mint

**Table 2** Example bitter compounds and their occurrences in nature

Bitter compound	TAS2R receptor(s)	Occurrence/sources
Alkaloids (1–3)	Include 4,10,39,46	Widespread in plant kingdom
Caffeine (3)	7,10,14,43,46	Many plants, including coffee beans, tea leaves and cacao pods
Saponins (4)	?	Various plants, including aubergine and maple
 <p>(α-solanine, 4)</p>		
Pyrazines (5–7)	38	Thermal degradation of free amino nitrogen
Hop-derived bitterness	1,40 (α-acids); 1,14 (iso-α-acids)	The cultivated hop, <i>Humulus lupulus</i>
Diketopiperazines (8,9)	?	Thermal degradation of free amino nitrogen
Bitter peptides	?	Thermal degradation of free amino nitrogen
PROP, PTC (10,11)	38	Synthetic
Sucrose octa-acetate	?	Synthetic
Glucosinolates	38	Cruciferous vegetables
Goitrin (12)	38	Cruciferous vegetables, canola
Cucurbitacins (13)	10	
Bitter tannins	Include 14,39	Widespread in the plant kingdom

**Table 3** Example pungency compounds and their occurrences in nature

Pungency compound	Receptor(s)	Occurrence/sources
Ethanol	Nasal?	Adult beverages
Formaldehyde	Nasal?	Synthetic chemical
Acetaldehyde	Nasal?	Fermentation by-product
CO <sub>2</sub>	Nasal?	Carbonated beverages
Capsaicin (14) and derivatives	TRPV1	<i>Capsicum</i> species
Piperine (15)	TRPV1	Long, black and white peppers
Gingerol (16), shogaol (17) and analogues	TRPV1	Members of the Zingiberaceae (ginger) family
Acrolein, other lachrymators	TRPA1	Various, including thermal degradation
Nicotine	TRPA1	Tobacco
Allyl isothiocyanate	TRPA1, TRPV1	Mustard, radishes, horseradish, wasabi
Allicin	TRPA1, TRPV1	Raw garlic and onions
Syn-Propanethial S-oxide	TRPA1, TRPV1	Onions
Oleocanthal	TRPA1	Olive oil

**Table 4** Principal astringent compounds and their occurrences in nature

Astringent compound	Occurrence/sources
Tannins (18–20)	Widespread in the plant kingdom
Alums	Baking powders

such as fennel oil. The diversity of receptors and the structural diversity of bitter compounds has led to speculation that human perception of bitterness is in fact a defense mechanism to protect against toxic substances that also happen to be bitter, such as plant alkaloids. A corollary of this thesis is that human appreciation of bitterness is learned. Indeed Henry VIII of England attempted to ban bitter hops (“the pernicious weed”) because of their alleged ability to induce hangovers.

With the exception of the generally undesirable protein-derived bitterness, commercially sought bitter compounds are derived primarily from plant sources. Thus beer bitterness is derived from the a low-yielding isomerization reaction of the hop-borne

**Figure 1** Isomerization of hop-derived  $\alpha$ -acids into their bitter iso- $\alpha$ -acid counterparts. R = 2-methylpropyl-, 2-methylbutyl- and 3-methylbutyl-.

**Figure 2** Example alkaloid structures. (1) quinine, (2) gentianine, (3) caffeine.

$\alpha$ -acids (or humulones) to iso- $\alpha$ -acids (Fig. 1), traditionally brought about by a boiling stage during the beer production process, but now also commonly a reaction performed by hop product manufacturers outside of the brewery.

Alkaloids are nitrogen-containing compounds that are derived from plants and have significant effects on humans, specifically either as drugs (eg morphine) and toxins (eg strychnine; see Fig. 2 for some examples). Indeed, given the impact that alkaloids can have on humans, it is perhaps unsurprising that many are bitter, arguably a selection pressure for early humans as they sought to forage for foodstuffs that were both nutritious and safe. Today caffeine is the most commonly consumed alkaloid, with the top 50 caffeine-consuming countries ingesting 1.2–9.6 kg per capita per year. Being both water- and lipid-soluble it easily crosses the blood-brain barrier and acts as a stimulant in sufficiently high doses. Other alkaloids such as strychnine, atropine, brucine and curare are almost legendary in terms of their toxicity and are often described as bitter but of course have little use in the food and beverage industries.

### Pungency

Pungency is associated with the perception of spiciness and heat, based on the non-covalent binding of trigger molecules with the TRPV1 and/or the TRPA1 receptors (Table 3). A further term, piquancy, is often ascribed to a milder experience of pungency. As mentioned previously, pungency can also be attributed to an olfactory response, as in the case an acrid aroma. Indeed the trivial name for the pungent and lachrymatory propenal (acrolein), is a contraction of “acrid oil”, and is a common artefact of the thermal degradation of glycerol. Acetaldehyde and ethanol have also been associated with pungency. Clearly in these cases, pungency is also perceived *via* (retro)nasal detection by the olfactory epithelium, in addition to TRP-based mechanisms. While it is not clear what the mechanism of nasal perception of pungency is, presumably it is mediated at least to some extent by interaction with nociceptors.

The major natural sources of pungency are derived from the plant kingdom: the *Capsicum* genus (eg bell peppers), white/green/black peppers (*Piper nigrum*), *Allium* spp. (eg onion, garlic), tobacco and olive oil. Other sources of pungency can arise from thermal processing or from industrial activities such as carbohydrate fermentations to produce ethanol and related compounds such as acetaldehyde. Whilst the perception of pungency is often a positive sensory experience, the causative agents do find applications in other areas, especially healthcare and pharmaceuticals.

Industrially the principal capsaicinoid, capsaicin (14), is the most important pungency agent, with applications beyond the food industry, including pharmaceutical applications and as a repellent for animals and humans (“pepper spray”). Global production of the various *Capsicum* species is in excess of 30 million metric tons and is dominated by China. Other major sources of commercially-available pungent agents are black pepper and ginger. Black pepper is one of the most popular spices worldwide, with production volumes of around 500,000 metric tons per annum. Half of this production is in Vietnam and Indonesia, with India, Brazil and China also being major black pepper producing countries. The annual ginger harvest is more than 2.5 million metric tons, with India, China and Indonesia accounting for more than half of global production.

**Figure 3** Example tannin structures. (18) catechin (19) procyanidin B3 (20) castalagin.

The measurement of the pungency intensity of capsaicinoids and other pungent substances was traditionally based on sensory evaluation to derive the Scoville Heat Units (SHU's) of a sample. The methodology is based on ethanolic extraction of capsaicinoids and then dilution in a sucrose solution. The higher the dilution of the sample that gave a positive heat detection, the higher the number of SHU's. Pure capsaicin itself may register 15–16 million SHU's, whilst pepper spray is typically < 1 million. Some other naturally-occurring capsaicinoids (eg resiniferatoxin) can register as much as  $16 \times 10^9$  SHU's, three orders of magnitude more than pure capsaicin. By way of comparison, pure piperine (15) is estimated to register at 100,000 SHU's and 6-gingerol at around 60,000 SHU's. Today this sensory-based methodology has largely been superseded by high-performance liquid chromatography (HPLC) analysis, although this latter is still multiplied by a factor in an attempt to bring intensities on to a similar scale to the more traditional SHU's.

### Astringency

As mentioned earlier, no astringency receptors have yet been reported, although quite how astringency is perceived is, as yet, not fully resolved. The major astringent species in the diet are polyphenolic- or tannin-based, although alums and other inorganic salts (eg potassium permanganate, zinc oxide, silver nitrate) can also elicit the characteristic drying and mouth-puckering experience of astringency. For the purposes of this article we will focus exclusively on tannins. The term tannin is used here to denote the broad array of polyphenolic secondary metabolites of higher plants. We recognize the limitations of this definition but further elaboration is beyond the scope of this article (see Fig. 3 for example structures).

Studies *in vitro* have shown that astringent tannin species can reversibly bind to many proteins and, especially, to proteins with proline-rich domains (proline-rich proteins, PRP's). These interactions tend to be non-covalent, but result in precipitation of the protein-tannin adduct, an action that is, in principle, reversible. Irreversibility of complexation is thought to be due to the oxidation of tannins to, for instance, more reactive 1,2-quinones that can subsequently react to form covalent complexes with proteins.

The unambiguous perception of astringency is not always straight-forward, and can be erroneously conflated with bitterness, despite the apparent difference in perceptual mechanisms. There appears to be a complementarity between astringency and bitterness. It is interesting to speculate on the reasons for this. Certainly there will be some steric constraints on significant interactions between bitter TAS2R receptors and substances perceived as bitter, in comparison with the protein-binding model of astringency which can be expected to be much less dependent on steric factors. Work carried out on the sensory characteristics of tannins from apples in cider suggest that as molecular size increases, tannins tend to demonstrate more astringency and less bitterness.

In dietary terms, the occurrence of tannins is widespread. They are found in various woods, fruits, berries, nuts, herbs, spices, legumes and chocolate, as well as beverages such as tea, coffee, cocoa, beer, cider and wines. There are also detectable levels of tannins found in alcoholic beverages that are exposed to wood during their production process (eg whisky, brandy, wood-aged beers). Tannins also have uses beyond the diet, especially where favorable protein interactions are required. Thus oak tannins ("tannic acid") can effectively reduce the levels of potentially haze-forming proteins in beers, although much of the industrial use of tannins is to "tan" leather, which makes the leather more durable, less susceptible to degradation and even modifying its color.

## Menthol

Menthol or, more precisely (–)-menthol, L-menthol or (1R,2S,5S)-menthol (21) is a naturally-occurring cyclic monoterpene alcohol. Whilst there are eight possible stereoisomers (21) is the preferred one due to its low cooling threshold. Of compounds related to L-menthol, only L-menthone (22) and L-isomenthone (23) show more potent minty and cooling characteristics. Because of these characteristics L-menthol is considered, along with vanilla and citrus, to be one of the most important flavoring additives, with annual consumption probably in excess of 30,000 metric tons. The applications of menthol are diverse, and include: use to relieve sore throats, anti-itching, topical analgesics, decongestants, oral hygiene products, chewing gums and candies. One controversial use is as a tobacco additive, where some authors suggest that menthol can improve the sensory acceptability of cigarette smoke, arguably enhancing addiction.

Menthol occurs naturally almost always as the essentially pure L-menthol and is primarily sourced from wild mint (*Mentha arvensis*). It also occurs in peppermint oil, together with other cooling compounds such as menthone and menthyl acetate, and peppermint (*Mentha x piperita*), a hybrid of watermint and spearmint. Oil from spearmint itself also contains menthol, but is generally cultivated less extensively than peppermint or wild mint. Naturally-occurring mint oil is generally prepared by steam- or hydro-distillation. The leaves may be cured, allowing the mint plants to dry once cut to reduce their moisture content. In some cases the proportion of L-menthol exceeds 70% and can be crystallized out of mint oils and, if further purity is required, recrystallized from low boiling solvents.

The demand for L-menthol outstrips global supply, so various efforts have been made to produce it synthetically. Indeed Noyori won the 2001 Nobel Prize for chemistry based on his elegant asymmetric synthesis of L-menthol from the inexpensive monoterpene myrcene. Other approaches, such as the Haarmann-Reimer process, synthesize racemic menthol, and then separate the required stereoisomer by chiral resolution of the menthyl benzoate esters before hydrolysis of the ester. More recently, BASF have developed a number of synthetic routes to L-menthol, one of which requires the stereospecific production of (+)-R-citronellal, also an intermediate in the Noyori synthesis.

The cooling property of menthol is due to its ability to trigger the cold-sensitive TRPM8 (Transient Receptor Potential cation channel subfamily M member 8) receptor, also known as the Cold and Menthol Receptor 1 (CMR1). This channel is the main molecular transducer of cold somatosensation in humans. A range of menthol analogs have demonstrable cooling properties, many, but not all, based on the L-menthol skeleton.

# Galactomannans (Guar, Locust Bean, Fenugreek, Tara)

## Introduction

Seed polysaccharides have attracted research attention due to a spectrum of diverse applications in food, pharmaceutical, and chemical industries. A class of seeds where the endosperm is present (i.e., endospermic seeds) are of industrial importance and include corn, wheat or rice. These polysaccharides are formed in the seed with ultimate goal to deliver carbohydrates to the developing seedling. The advantage of polysaccharides from endospermic seeds, as seen from industrial point of view, is that they are isolated easily in pure form and after suitable physical or chemical treatments are used as food or formulation ingredients. The major cell wall storage polysaccharides are most commonly divided into three polysaccharide groups, that is, mannans, xyloglucans, and galactans (Meier and Reid, 1982) with galactomannans falling in the mannan group. The distribution of galactomannans in the plant kingdom is limited and are mostly found in the endospermic seeds of four economically important plants that belong to the same family i.e., *Fabaceae* or *Leguminosae*. The focus of the present article are the galactomannans from guar (*Cyamopsis tetragonoloba*), carob or locust bean (*Ceratonia siliqua*), tara (*Tara spinosa*) and fenugreek (*Trigonella foenum-graecum*) that are the major sources of industrial galactomannans. As it will be discussed in the following sections, flour is obtained from the seeds of these plants, which is either used directly in food formulations or it is further processed to obtain special ingredients (Fig. 1).

## Structure-Extraction

Galactomannans are heteropolysaccharides (i.e., they consist of more than one carbohydrate residue) composed of D-mannose, which is the residue that makes up the backbone of the chain, and D-galactose that forms single branches along the mannan chain. Mannose units are linked with each other via  $\beta$ -(1 $\rightarrow$ 4) glycosidic linkages whereas galactose is attached at the C-6 of mannose with  $\alpha$ -(1 $\rightarrow$ 6) bonds. Galactomannans are neutral polysaccharides, which means that they do not carry uronic acid residues or other charged groups (e.g., sulfo groups) on the backbone. They are distinguished from each other based on the mannose-to-galactose ratio (M/G), which is characteristic for each source. The ratio ranges approximately between 1:1, 2:1, 3:1 or 4:1 for fenugreek, guar, tara or locust bean gum, respectively (Figure 2) (Prajapati et al., 2013; Srivastava and Kapoor, 2005). For instance, an M/G ratio of 1:3 indicates that a galactose residue is found in every three mannose units. It should be noted that the experimentally determined ratios may vary anywhere between 1 and 5 depending on the source and extraction conditions.

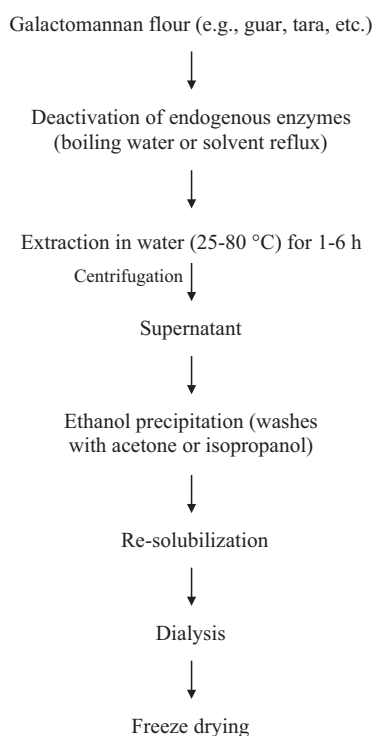

Generally, galactomannans are extracted from the endosperm of the seeds after milling, husk removal, and sieving steps. The flour (Fig. 1) usually contains impurities, most commonly protein and insoluble cellulosic polymers that are co-extracted during the milling process. Further purification usually involves dissolution in water at various temperatures followed by ethanol precipitation, dialysis and freeze drying (Fig. 3) (Sébastien et al., 2014; Salvalaggio et al., 2015). The first stage is usually a deactivation step of the endogenous enzymes that are naturally found in galactomannan flour and can potentially degrade the polysaccharide (e.g.,  $\beta$ -D-mannanases) during the extraction step. This step is carried out with thermal deactivation of enzymes in boiling water or

**Figure 2** Idealised structures of repeating units of the four major galactomannans. Mannose residues are linked with  $\beta$ -(1 $\rightarrow$ 4) whereas galactose via  $\alpha$ -(1 $\rightarrow$ 6) glycosidic bonds.

**Figure 3** Generalised extraction strategy for galactomannan purification.

use of solvents (e.g., PET-ether or hexane reflux) that may also serve as a means for removal of polar contaminants (e.g., lipids). Extraction is then carried out for several hours after reduction of temperature to the required temperature that is usually higher for poorly soluble galactomannans (e.g., locust bean). A proteolytic enzyme may be added at this stage if protein contamination creates problems for the purity of the sample. After solubilisation, the polysaccharide is recovered with an ethanol precipitation step usually using twice as much volume of ethanol as that of the extraction medium. At this stage the polysaccharide is recovered but if further purity is required a dialysis or ultrafiltration step can be carried out. This step removes low molecular weight contaminants (depending on the molecular weight cut-off of the membrane that has been selected) that may have been co-precipitated. Contaminants may include, amino acids (if an enzymatic treatment was employed), monosaccharides, small peptides, and oligosaccharides. The final stage involves a freeze-drying step while further precipitation with alcohol and oven-drying should be preferably avoided, as it normally results in lower yields and potentially lower molecular weight.

## Physical Properties

Hydroxyl groups of mannose in carbons 2, 3 and of galactose in 3, 4 are in *cis*-configuration. These groups are responsible for extensive intra- and inter-chain hydrogen bond formation resulting in differences in solubility between galactomannans (Rinaudo, 2008). Galactose substitution provides steric hindrance to chain associations, thus improving solubility. As a result, highly substituted galactomannans such as those from fenugreek (Fig. 2) are highly soluble even in cold water (Mathur and Mathur, 2005). On the other end of the spectrum, locust bean gum has the least degree of substitution making the polysaccharide soluble only in hot water (Wielinga, 2009). As a result, the solubility follows the order (from more to least soluble): fenugreek > guar > tara > locust bean.

Fundamental and applied research interest for galactomannans stems primarily from their ability to enhance viscosity of aqueous media (Bresolin et al., 1997; Robinson et al., 1982). The solutions are Newtonian at low concentrations (<~0.5% w/v) whereas at higher (~1% w/v) they exhibit shear thinning behaviour. Due to particularly high viscosity build up galactomannans are rarely used at concentrations greater than 1% w/v in food applications. Complex foods contain several ingredients with remarkably disparate chemical structures that create challenges to formulations. For instance, protein-polysaccharide mixtures (e.g., ice cream mix or milkshakes) are incompatible at certain concentrations resulting in phase separation. This technological difficulty is commonly avoided by working at low polysaccharide concentrations normally in the range of 0.1%–0.6% w/v. It should be noted that because galactomannans do not carry charge, pH and ionic strength do not particularly influence the viscosity of their solutions. Additionally, to achieve maximum viscosity, dissolution should be carried out under specific conditions depending on the source. For instance, guar gum may generate highly viscous solutions after mild heating (20–40 °C) for ~2 h whereas locust bean gum with similar molecular characteristics (e.g., molecular weight) cannot be fully dispersed if it is not heated to at least 80 °C, and consequently, it will result in solutions of low viscosity (Srivastava and Kapoor, 2005; Barak and Mudgil, 2014; Brummer et al., 2003).

Galactomannans may also influence the rheology of the aqueous systems due to intermolecular synergistic chain associations with helix forming polysaccharides (Bresolin et al., 1997; Dea and Morrison, 1975), and a remarkable increase in viscosity (Pinheiro et al., 2011) or even gel formation (Barak and Mudgil, 2014; Miles et al., 1984; Dunstan et al., 2001; Lazaridou et al., 2001) may be achieved. The tendency of galactomannans to modulate the rheological characteristics depends on the degree of galactose substitution. Galactomannans with higher galactose content (e.g., fenugreek) show little tendency to form gels and generally exhibit lower viscosity than their counterparts with lower degree of substitution (e.g., locust bean gum) due to the steric hindrance posed by galactose residues (Mathur, 2012). Generally, unsubstituted regions in galactomannan backbone interact *via* multiple hydrogen interactions with certain polysaccharides (e.g., xanthan or  $\kappa$ -carrageenan) (Dea and Morrison, 1975). For example, locust bean gum interacts readily with xanthan leading up to formation of a stable three-dimensional structure. Although the exact mechanism of the synergism is still a matter of debate (Grisel et al., 2015) the most acceptable model is that interactions occur between disordered segments of xanthan chains and unsubstituted regions of galactomannan (Grisel et al., 2015; Cairns et al., 1986) (Fig. 4). Similar mechanisms of synergy exist between galactomannans and  $\kappa$ -carrageenan or agar.

Polysaccharides are frequently modified to meet certain industrial needs e.g., improve water solubility, enhance viscosity or modify the interfacial properties of the biopolymer. Physical modification usually involves changes to the raw material without affecting the chemical structure of the polysaccharide such as particle size reduction, instantinization or certain heat treatments (e.g., pregelatinisation in starches). In chemical modification, a functional group (e.g., methyl or carboxymethyl) is attached and the chemical structure changes along with the functional properties. Galactomannans are modified with reactions that include etherification, esterification, or crosslinking of hydroxyl groups (Warkar and Gupta, 2015; Savitha Prashanth et al., 2006). Galactomannan derivatives that are produced after modification have improved functional properties (e.g., improved solubility in water or enhanced hydrophobicity) (Maier et al., 1993; Zhang et al., 2005, 2007).

## Food Applications

Galactomannans are commonly used in the food industry, particularly those from guar and locust bean gum (Table 1). Tara and fenugreek gums are not widely used due to the availability and cost although they are steadily increasing their market share.

**Figure 4** Schematic diagram showing the predominant mechanism of interaction between xanthan and galactomannans. The interaction proceeds with formation of junction zone associations between the disordered segments of xanthan and the unsubstituted regions of galactomannan.

In most of the cases tara gum can be replaced by mixtures of locust bean gum and guar gum. Since the M/G ratio is in between that of guar and locust bean gum its physical properties are approximated by mixtures of guar and locust bean flours. Guar and locust bean gums are common ingredients in ice cream formulations where they modulate ice crystal formation and recrystallization, and prevent lactose crystallization, during frozen storage of the product. They also find applications in other dairy products such as cheese spreads to improve spreading or yoghurts where they are used in fat reduction to structure water and improve texture (Thombare et al., 2016). They are also used in salad dressings, sauces, soups and in a range of liquid formulations where they control viscosity, mouthfeel, and stability of the dispersions. For instance, in low fat mayonnaise they provide viscosity and prevent creaming of the emulsion. In sauces (e.g., salad dressings or stock condiments) they provide a way to control syneresis and phase separation of the solids which is particularly important considering the long shelf-life of these products. In processed meats (e.g., sausages, frankfurters etc.) they are used to bind meat pieces together, provide a uniform texture, increase yield through water management and prevent phase separation during heat treatments (Nussinovitch, 1997; Mudgil et al., 2014). Commercial galactomannans have been also shown to have surface active properties (Garti et al., 1997; Wu et al., 2009) that could be exploited in the encapsulation of flavour oils of beverages (Mikkonen et al., 2009). As mentioned earlier, the ability of locust bean gum to control rheology of aqueous media in synergism with other polysaccharides (e.g.,  $\kappa$ -carrageenan or xanthan) allows formation of gels with diverse rheological characteristics. This makes it possible to replace gelatin for certain applications (e.g., for religious or vegetarian diets) and permits manipulation of texture and stability in a range of products (e.g., bakery formulations, fruit based desserts etc.) (Gidley and Grant Reid, 2006). Additionally, galactomannans are also used in gluten-free bakery products where they improve volume and moisture content of the crumb, among other important technological characteristics (Anton and Artfield, 2008). Apart from the self-association due to hydrogen bond formation, galactomannans may interact with each other (inter-chain interactions) and alter the rheological properties of the food matrix, as a result of sub-zero temperatures. For instance, the freezing step in ice cream manufacturing results in formation of a freeze concentrated matrix where the effective concentration of all the soluble ingredients increases significantly. As a result of the increased concentration, cryogelation of galactomannans may occur with potentially detrimental results for the sensory characteristics of the product (Doyle et al., 2006; Lozinsky et al., 2000; Patmore et al., 2003).

Galactomannans also provide a sustainable source of biopolymers for edible film applications. These materials require tuning of their gas (mainly CO<sub>2</sub> and O<sub>2</sub>) and moisture permeability, mechanical, and optical properties. Generally, galactomannans with lower galactose content produce films with higher elongation at break and tensile strength thus presenting an opportunity to tune the film properties by varying the molecular structure of the biopolymer (Mikkonen et al., 2007). Galactomannan films are also used in conjunction with waxes, lipids, antimicrobials or antioxidants in order to modify their physical properties and extend their functionality to foods with a diverse range of physical properties (e.g., moisture or fat content) (Cerqueira et al., 2011). It should be, mentioned that in addition to the industrially relevant functional properties galactomannans may also exert *bio*-activity to a certain degree, as it has been reported to show immunomodulating and radical-scavenging activities (Liu et al., 2015). In addition, galactomannans that have been derivatised may have anticoagulant and antithrombotic properties or may be used as bioactives delivery-vehicles in drug and pharmaceutical formulations (Prabaharan, 2011).

## Conclusions

Galactomannans particularly those from guar and locust bean gum are widely utilized in the food industry and are of particular technological importance with those extracted from tara and fenugreek being less exploited at present. This is due to their suitable

**Table 1** Outline of food applications and functionality of galactomannans (Thombare et al., 2016; Mudgil et al., 2014; Gidley and Grant Reid, 2006)

<i>Applications</i>	<i>Functionality</i>
Dairy	Cream and milk desserts (e.g., milkshakes), yoghurts, ice creams (thickener, stabiliser), processed cheese (control syneresis and texture modification)
Bakery products	Icings, cake mixes, gluten-free (soften texture, improve loaf volume)
Gels	Fruit-based desserts (water structuring with the aid of other polysaccharides e.g., xanthan)
Beverages	Soft drinks (thickener, flavour oil encapsulation)
Seasonings	Sauces, salad dressings, mayonnaise and syrups (control of phase separation and texture, fat reduction)
Meat products	Sausages, frozen and tinned meats (consistency improvement, control syneresis)
Films	Biodegradable film formation for packaging. Inclusion of actives in the film, such as antibiotics, antioxidants, colour indicators.

functional properties, which include thickening of aqueous solutions, stabilizing and controlling phase separation, binding formulation ingredients to improve processing ability, and control sensory properties of the final product. The functional properties are tunable by controlling the galactose substitution of the chains and additionally by derivatisation of the polysaccharide to improve functionality (e.g., solubility or interfacial behaviour). As the use of galactomannans in food industry is well established future technologies should focus on the potential of these materials in biomedical, pharmaceutical and advanced nutrition applications with an overall aim to create advanced biomaterials with tailored functionality for food and non-food industries.

## Gases and Vapors Used in Food

Loong-Tak Lim, University of Guelph, Guelph, ON, Canada

### Overview

In the context of food, a vapor is a gaseous phase substance at a temperature where it can co-exist with its liquid or solid phase. The release of vapor from a liquid or solid does not necessarily involve boiling, i.e., through evaporation. On the other hand, a permanent gas does not form liquid or solid at typical atmospheric and temperature conditions. Many gases and vapours possess properties useful for food preservation, e.g., antimicrobial, anti-oxidative, anti-enzymatic and so on. Other gases and vapors are being exploited during processing to impart desirable physicochemical and sensorial characteristics in food products. In this section, selected gases and vapors commonly used in the food industry are discussed.

### Gases and Vapours for Modified and Controlled Atmosphere Applications

Modified atmosphere packaging (MAP) is common for protecting processed products from the deleterious ambient factors, in particular  $O_2$  and moisture, to prevent/delay deteriorative phenomena, such as rancidity, browning, microbial growth, loss of crispness, and so on. Typical MAP approach involves flushing the package headspace with an inert gas (e.g.,  $N_2$ , Ar and other noble gases) before package closure (Fellows, 2009; Robertson, 2013). To maintain the modified atmosphere, the use of package materials of adequate barrier properties is essential. Among the MAP gases,  $CO_2$  is the most important for extending the shelf-life of perishable products, due to its effectiveness against Gram-negative and aerobic bacteria. For example, the injection of  $CO_2$  in dairy products (e.g., cottage cheese, sour cream, ice-cream mix, and pasteurized milk) can result in up to 400% increase in shelf-life via improving the microbial stability (Singh et al., 2012). However, solubilization of  $CO_2$  in the aqueous phase of the product can produce carbonic acid which dissociates into bicarbonate and  $H^+$  ions, imparting acidity to the product. Also,  $CO_2$  is highly soluble in both water and oil. At  $0^\circ C$ , the Henry law constants for  $CO_2$  in water and oil are  $1.33 \times 10^6$  and  $2.3 \times 10^6$  Pa.m<sup>3</sup>/kmol, respectively. To put this in perspective, at atmospheric pressure, 1 L of water and oil can absorb approximately 1.7 and 1 L of  $CO_2$ , respectively (Lencki, 2005). Therefore, in MAP involving  $CO_2$ , its solubility in water and oil phases of the product should be taken into consideration. To prevent the unwanted package distortion,  $N_2$  is often used as a filler gas.

MAP of fresh perishable products (e.g., fruits, vegetables, meats) requires careful manipulation of headspace gas composition to prevent physiological damages of the live tissues, while suppressing the respiratory and microbial activities to extend product shelf-life. In red meats,  $O_2$  (35% to 80%  $O_2$ ; blended with 20%–60%  $CO_2$ , balanced with  $N_2$ ) is often used to maintain the myoglobin in oxygenated state (i.e., oxymyoglobin), inducing red coloration which is often being associated with freshness by consumers. For fruits and vegetables, concentration of  $O_2$  is typically reduced while  $CO_2$  elevated to tolerable levels to maximize storage stability (Fig. 1). The target  $O_2$  and  $CO_2$  concentrations can be established through the use of thermoplastic films with optimal permselectivity (i.e., ratio of  $CO_2$  permeability to  $O_2$  permeability) that matches the respiration rate of the live products (Mahajan et al., 2007; Robertson, 2013). Temperature abuse during transportation can result in dramatic increase in the respiration rate, creating anoxic condition which can be detrimental to the product. To compensate for the increase in respiration rate, side chain crystallizable polymers may be used to allow for proportional increases in  $O_2$  and  $CO_2$  transmission rates of the packaging structure. Other strategies for MAP of fresh produce include the use of plastic films perforated with holes (several micron in size) using a focused laser beam, and microporous film dispersed with porous fillers during the extrusion process (Clarke, 2011; Goswami and Mangaraj, 2011; Hussein et al., 2015; Mangaraj et al., 2009; Robertson, 2013; Zhang et al., 2016).

In general, the goal of controlled atmosphere storage (CAS) is to delay the senescence of fresh produce during storage through manipulating  $CO_2$  and  $O_2$  concentrations in the air. Here, fruits and vegetables are stored in large insulated and gas-tight rooms/containers equipped with sophisticated  $CO_2/O_2$ , humidity, and temperature control systems (Dilley, 2010; Thompson, 2010). During the ripening process, climacteric fruits (e.g., avocado, banana, nectarine, mango, pear, peach, apple) tend to produce ethylene vapor (1) – a naturally-occurring hormone that promotes the respiration and accelerates the development of aroma, color changes, and softening of tissues. On the other hand, non-climacteric fruits do not exhibit burst release of ethylene production during ripening, although exposing them to ethylene can increase their respiration and hasten the ripening process (Bapat et al., 2010). Scrubbing of ethylene in controlled storage atmosphere delays the ripening of fruits, which can be achieved via adsorption/absorption, high-temperature catalytic oxidation, photocatalytic oxidation, and chemical oxidation (Keller et al., 2013; Pathak et al., 2017). In addition to scrubbing, the food industry also applies various strategies to mitigate the effect of ethylene at a cellular level. Of particular importance is 1-methylcyclopropene (1-MCP) (2), which is a potent ethylene receptor blocker capable of delaying the ripening of fruits (Blankenship and Dole, 2003; Lee et al., 2006; Pepera et al., 2003; Watkins, 2006). Because climacteric fruits deteriorate rapidly once when the ripening process begins, they are often harvested at “commercially maturity” stage, i.e., hard green before ripening to provide adequate time for distribution. At the point of sales, the ripening of these fruits is then initiated in a temperature- and relative humidity-controlled ripening room injected with ethylene gas.

Senescence and wounding in fruits result in degradation of phospholipids in the cell membrane through the lipoxygenase pathway, leading to the production of hexanal (3) and other six carbon aldehydes important for defending the plant from microbial

**Figure 1** Optimal  $O_2$  and  $CO_2$  concentrations for MAP of selected fruits and vegetables. Plots are re-created based on the data from Fellows (2009).

**Figure 2** Selected volatile compounds used for food preservation.

proliferation and further tissue damages (Casey et al., 1999; Lanciotti et al., 1999; Patrignani et al., 2008). Besides being a potent antimicrobial, hexanal also elicits enzymatic inhibition properties to delay discoloration, softening, ripening, and generation of off-flavors in fruits (Paliyath and Murr, 2007; Paliyath et al., 2003). It inhibits the activity and expression of phospholipase-D, which is responsible for catalyzing the hydrolysis of phospholipids (e.g., phosphatidylethanolamine, phosphatidylcholine, and phosphatidylglycerol) into phosphatidic acid and their corresponding head-groups (Exton, 1997). Hexanal has been exploited to preserve the cell membrane, substantially delaying the ripening and senescence of fruits. Being a GRAS (generally regarded as safe) substance frequently uses as a flavour additive, hexanal can be very useful to reduce fruit spoilage during storage and distribution (Cheema et al., 2018; El-Kereamy et al., 2009; Paliyath and Murr, 2007; Paliyath et al., 1999; Paliyath et al., 2003; Tiwari and Paliyath, 2011).

### Antimicrobial Volatiles

The antimicrobial properties of hexanal are well documented in the literature, which are mainly due to its interaction with microbial cytoplasmic membrane, causing increased membrane permeability and cell death (Corbo et al., 2000; Gardini et al., 1997; Kubo et al., 2004; Kubo et al., 1999; Lanciotti et al., 2004; Lanciotti et al., 1999; Simons et al., 2000). Other aldehydes, many of which are naturally-occurring in spices and their essential oils, are also known to elicit antimicrobial activities useful for food preservation. For example, benzaldehyde (4), an aromatic aldehyde consisting a formyl substituted phenyl ring with a characteristic almond odour, is

a major constituent of the essential oil from the kernels of almonds (*Prunus amygdalus*) and other seeds (e.g., peaches, cherries, plums, and apricots) (Butzenlechner et al., 1989; Remaud et al., 1997; Sanchez-Perez et al., 2008). Its antimicrobial properties have been attributed to covalent attachment of the aldehyde's carbonyl group to the sulfhydryl groups of cysteine in microbial cell, disrupting active transport and oxidative phosphorylation in microbial cells (Hugo, 1967; Morris et al., 1984; Ramos-Nino et al., 1996; Ramos-Nino et al., 1998). Benzaldehyde is potent against pathogens responsible for fruit spoilage, such as *Bacillus subtilis*, *Serratia marcescens*, *Acinetobacter calcoaceticus*, *Erwinia carotovora*, *Escherichia coli*, *Flavobacterium suaveolens*, *Monilinia fructicola*, *Botrytis cinerea*, and *Tyrophagus putrescentiae* (Wilson et al., 1987; Deans and Ritchie, 1987; Sung et al., 2006).

Cinnamaldehyde (5) is extracted from the bark of *Cinnamomum zeylanicum* with an unique aroma of cinnamon spice (Burt, 2004). The aldehyde vapor exhibits broad-spectrum antimicrobial properties against mold, fungi, Gram-positive and -negative bacteria (López et al., 2005, 2007a,b; Rodríguez et al., 2008), including food-borne pathogens, such as *Bacillus cereus*, *B. subtilis*, *E. coli*, *Listeria monocytogenes* and *Campylobacter jejuni* (Tajkarimi et al., 2010). It interacts with microbial cell membrane to disperse the proton motive force, causing the leakage of small ions and the inhibition of glucose transport and glycolysis (Gill and Holley, 2004; Helander et al., 1998). Researchers have investigated the antimicrobial effects of cinnamaldehyde in various food products, such as *Salmonella tennessee* on peanut paste (Chen et al., 2015a), *E. coli* O157:H7 and *Salmonella typhi* in ground beef (Turgis et al., 2008), microflora in carp (Mahmoud et al., 2004), *Salmonella typhimurium*, *Staphylococcus aureus* and *Yersinia enterocolitica* in apple juice (Yuste and Fung, 2003), and spoilage microbes in melon juice (Mosqueda-Melgar et al., 2008). Solid matrices investigated as carriers for cinnamaldehyde include paper impregnated with paraffin (Echegoyen and Nerín, 2015), cast plastic films (Lopes et al., 2014; Qin et al., 2015), and edible films (Balaguer et al., 2013; Zhu et al., 2014).

Thymol (2-isopropyl-5-methylphenol) (6) is a major component in the essential oil of thyme (*Thymus capitatus*). The volatile can disrupt the phospholipid bilayers of the cell membranes, causing the leakage of cellular contents, as well as interacting with hydrophobic proteins in altering their structures (Chavan and Tupe, 2014; Nedorostova et al., 2009; Zheng et al., 2013). Researchers have shown that the application of thymol in MAP of sweet cherries and table grapes can reduce the growth of mesophilic aerobics, yeasts, and fungi during cold storage, in addition to decreasing weight loss, color changes, loss of firmness (Serrano et al., 2005; Valverde et al., 2005). In MAP of raw shrimp, thymol vapor has been shown to inhibit the growth of *Salmonella* spp., lowering the maximum growth rate by up to 71% and lag time by 100% (Zhou et al., 2013). An isomer of thymol, carvacrol (5-isopropyl-2-methylphenol) (7), found in the essential oil from oregano herb (*Origanum vulgare*) is another antimicrobial volatile potent against *Pseudomonas fluorescens*, *Erwinia amylovora*, and *Candida albicans* (Zheng et al., 2013). Carvacrol can delay the spoilage of table grapes, kiwifruits, and honeydew melon without substantially affecting their sensory properties (Martínez-Romero et al., 2007; Roller and Seedhar, 2002). Its mode of action is believed to be its interaction with cellular membrane proteins and periplasmic enzymes, disrupting the membrane proton motive force (Hyldgaard et al., 2012). Synergistic antimicrobial properties of thymol and carvacrol have been reported against a number of microorganisms. For examples, minimum inhibitory concentration (MIC) values of thymol and carvacrol against *P. fluorescens* inoculated in tryptic soy broth (incubated at 37 °C for 24 h) are reported to be 648 and 167 µg/mL, respectively, while the minimum bactericidal concentration (MBC) values are 1932 and 555 µg/mL, respectively. By combining both thymol and carvacrol, the MIC and MBC values decreased substantially to 78 and 156 µg/mL, respectively (Zheng et al., 2013). Similarly, other researchers reported synergistic antimicrobial effect of thymol and carvacrol against *Salmonella typhimurium* (Zhou et al., 2013) and *Listeria innocua* (García-García et al., 2011). In view of their strong flavour attributes, synergistic antimicrobial properties of thymol and carvacrol, as well as other potential essential oil volatiles, can be beneficial to minimize the possible undesirable sensory attributes via lowering the dosage required to exert the antimicrobial effects.

Diacetyl (2,3-butanedione) (8) is a metabolic by-product of lactic acid bacteria, such as the species from *Lactococcus*, *Leuconostoc*, *Lactobacillus* and *Pediococcus* (Šuškočić et al., 2010). It is naturally present in fruits, milk, dairy products, beer, wines, coffee, and other fermented food (Papagianni, 2012; Shibamoto, 2014). It is commonly used as a food additive to impart buttery flavor (Lanciotti et al., 2003). The dione has a wide antimicrobial spectrum against yeast, as well as Gram-positive and -negative bacteria due to the reaction of its dicarbonyl group (—CO—CO—) with arginine in enzymes, which weakens the microbial cells (Papagianni, 2012; Ray and Bhunia, 2014). It is more potent in acidic than in neutral pH conditions (Jay, 1982; Jay and Rivers, 1984). Jay (1982) reported antagonistic effects of several additives on the antimicrobial efficacy of diacetyl, that 1% (w/v) acetate exhibited the strongest inhibitory effect to diacetyl, followed by 5% glucose and 1% Tween 80. On the other hand, Lanciotti et al. (2003) reported that NaCl enhances the efficacy of diacetyl by increasing its vapor pressure through "salting out" effect. These factors should be taken in account when applying diacetyl in complex food systems.

Allyl isothiocyanate (AITC) (9) is a volatile compound produced by plants from the Cruciferae family (e.g., horseradish, mustard, cabbage) when their tissues are disrupted. In its natural state, AITC is glycosinolated as sinigrin. When the plant tissues are disrupted, the glucosinolate is hydrolyzed by the cell wall bound myrosinase, releasing AITC, along with D-glucose and sulfate ion (Mari et al., 1993). The antimicrobial properties of AITC have been well demonstrated in the literature (Delaquis and Mazza, 1995; Delaquis and Sholberg, 1997; Kim et al., 2002; Lin et al., 2000a,b; Nadarajah et al., 2005; Nielsen and Rios, 2000; Park et al., 2000). In vapor phase, its MIC values against bacteria, yeasts, and molds are reported to be 34–110, 13–37, and 16–62 ng/mL, respectively (Isshiki et al., 1992). Tsunoda reported that the toxic limits of AITC against five fungi on wood ranged from 3.8 to 118 ppm (Tsunoda, 2000). In view of its broad spectrum antimicrobial potency, AITC continues to gain research and development interests (Mari et al., 1993; Kim et al., 2002; Shofran et al., 2006; Winther and Nielsen, 2006; Shin et al., 2010; Wang et al., 2010; Ko et al., 2012; Ugolini et al., 2014; Dai and Lim, 2015; Chen et al., 2015b). Both synthetic and naturally-derived AITC are used for food preservation. In the latter approach, dried mustard seed meal powders have been used as a naturally source of AITC, the release of which is activated by water via the myrosinase-mediated hydrolysis of sinigrin (Dai and Lim, 2014, 2015).

Chlorine dioxide ( $\text{ClO}_2$ ) (10) vapor is a broad-spectrum oxidizing/antimicrobial agent potent against bacterial, viral and protozoan pathogens. Its efficacy is generally considered to be equivalent or stronger than chlorine, but less than that of ozone on a mass-dose basis (Erickson and Ortega, 2006; Gómez-López et al., 2009). The main mode of disinfection action can be attributed to its interaction with nucleic acid and/or peripheral cell structures, leading to a disruption of protein synthesis. The destruction of outer membrane proteins that alters the permeability of the cell membrane is also believed to be a possible mode of action (Aieta and Berg, 1986; Benarde et al., 1967; US EPA, 1999).  $\text{ClO}_2$  has been used for treating fresh produce (Garcia et al., 2003; Gil et al., 2009; Gómez-López et al., 2009; Sapers et al., 2003; Sy et al., 2005). It is often used as a sanitizing agent of packaging, food processing equipment, factory tools, potable water treatment, and so on.

## Fumigants

Methyl bromide (11), a very effective fumigant for quarantine purposes, has been used for decades during the pre-shipment treatment of horticultural products to destroy insect pests. However, its use as a fumigant has been prohibited in most countries due to its ozone-depleting properties (Benschoter, 1988; Fields and White, 2002; Tebbets et al., 1983). Various alternative fumigants have been explored. For example, ethyl formate (EF) (12), a volatile compound naturally present in many products (e.g., rice, beef, grapes, wine, beer, and cheese), is a FDA approved GRAS food-flavouring agent that exhibits potent fumigant activities against insects in various crops. EF at concentrations ranging from 0.8% to 4.7% are shown to be effective in inducing various degrees of mortality in flower thrip, two-spotted spider mite, mealybugs, and leafroller on strawberries and grapes (Simpson et al., 2007; Simpson et al., 2004). Ren and Mahon (2006) reported a 85 g/t for 4 h followed by the second 85 g/t treatment, which resulted in a high level of control of insects in wheat, split faba beans, and sorghum. Unlike other fumigants, EF degrades rapidly and do not pose long-term environmental residual concerns (Desmarchelier et al., 1999). The hydrolytic by-products formed, formic acid and ethanol, are both naturally-occurring and exhibit antimicrobial properties. Synergistic effects have also been reported when EF vapour is mixed with  $\text{CO}_2$  in compressed gas cylinder, at 16.7% wt. level, for the fumigation of fruits, vegetables, and grains. The product is commercially available as Vapormate® by Linde Group. EF also acts synergistically with AITC, menthone (13), carvone (14) and other essential oils in the destruction of pests (Dancevski et al., 2010; Lee et al., 2007; Ren et al., 2008; Ren et al., 2012; Simpson et al., 2007).

## Gases as Integral Product Constituents and Processing Aid

Gases are incorporated in food to impart desirable physicochemical and sensorial properties. Methods to incorporate gases into products are many, including injection, fermentation, whipping, missing, pressurization, steam generation, decompression, vacuum expansion, and so on. The gas incorporated can remain dissolved in the aqueous or lipid phases of the products if it is under-saturated. When supersaturated, the gas will nucleate and grow into bubbles and trapped within the product matrix or ascend to the product surface. The solubility of gases is strongly dependent on temperature and pressure, as well as product compositions.

In carbonated soft drinks (CSD), products are pressurized with  $\text{CO}_2$  gas to provide the characteristic effervescence and fizziness to the palate. In bottled/canned CSD, carbonation level is typically expressed in volume of  $\text{CO}_2$ , where one volume of  $\text{CO}_2$  produces about 1 atm of internal pressure at room temperature, equivalent to about 2 g/L of dissolved  $\text{CO}_2$ . Typical bottled CSD ranges from 1.5 vol for carbonated fruit juices, 4 vol for cola drinks, and up to 5 vol for club soda and ginger ale (Robertson, 2013). By contrast, carbonation in alcoholic beverages such as champagnes, sparkling wine, and beers are due to the  $\text{CO}_2$  produced during the fermentation of sugar by yeast. The level of carbonation in CSD are affected by beverage formulation; sugar reduces  $\text{CO}_2$  solubility in water, while free amino-acid and protein increase  $\text{CO}_2$  concentration (Descoins et al., 2006). The presence of surface-active agents can affect the hydrodynamics of bubbles. For example, the drag force of bubbles in beers as they ascend to the surface is greater than that exerted on bubbles in champagnes, due to higher adsorption of surfactant species (e.g., protein) onto the gas-liquid interface in beer. Also, because the dissolved  $\text{CO}_2$  content is three times lower in beer than champagne, the growth rate of beer bubbles is slower than that of champagne (Liger-Belair et al., 2000). The methods by which the carbonated beverages are poured into the glass and serving temperature will affect the magnitude of dissolved  $\text{CO}_2$  (Liger-Belair et al., 2010).

To reduce product acidity, stout beers are pressurized with a mixture of  $\text{CO}_2$  and  $\text{N}_2$  (instead of pure  $\text{CO}_2$ ) at approximately 0.80 and 3.00 bar (11.6 to 43.5 psi) partial pressures, respectively. The use of  $\text{N}_2$  here also results in smaller bubbles and creamier foam head texture than the use of  $\text{CO}_2$  alone, when the stout beer is poured into a glass (Lee et al., 2011; Vega-Martínez et al., 2017). Similarly, in nitrogen-infused cold brew coffee, also known as “nitro coffee”, coffee is pressurized with  $\text{N}_2$  (typically 30–50 psi) alone, rather than  $\text{CO}_2$ , to avoid the development excessive product acidity and to achieve fine bubbles in the foam head (Gerstner, 2011; Jarvis and Morrison, 2015). When these beverages undergo decompression (e.g., existing from a tap, uncapping a bottle), the dissolved  $\text{N}_2$  becomes over-saturated, forming small bubbles that rise to the top of the drinking glass to form a thick foam head. Concomitantly, a cascade of sinking bubbles appear near the glass wall due to the circulatory flow induced by the rising bubbles in the center of the beverage, as well as the geometry of the glass (Benilov et al., 2013). The infusion of  $\text{N}_2$  also imparts “sweetness” perception in cold brew coffee (Jarvis and Morrison, 2015).

Gases are incorporated in solid and semi-solid products to develop the desirable physical and sensory properties (Campbell and Mougeot, 1999). For example, ice-cream is an air foam in which the air cells are stabilizes by ice crystals. The smaller the size of ice crystals, the greater the proportion of air can be incorporated (Sofjan and Hartel, 2004). In aerated chocolate, air is infused into the molten chocolate mass, dissolving mainly in the lipid phase to provide the light and creamy mouth feel. To create a more creamier

texture, gases with low solubility (e.g., N<sub>2</sub> and Ar) are used instead to form smaller bubbles (Niranjan and Silva, 2008). In whipped cream, N<sub>2</sub>O is being introduced (often blended with N<sub>2</sub> and CO<sub>2</sub> to reduce cost) during mechanical agitation to give overrun properties better than the typical air-aerated cream (Adhikari et al., 2017). In pressurized aerosol whipped cream products, foaming is achieved by rapid expansion of the dissolved N<sub>2</sub>O as the cream emulsion exits the discharge valve of the aerosol can. The foam is stabilized by rapid adsorption of fat to the air cell interfaces, giving a typical overrun of 400% to 600% (Goff and Vega, 2007). Other gases explored in dairy manufacturing include H<sub>2</sub>, Ar, Xe and He (Adhikari et al., 2017), with limited commercial applications.

## Introduction

Gelatin is derived from collagenous materials via thermal denaturation. Practically, gelatin is extracted with hot water at temperature higher than its mother collagen's thermal transition temperature. It has been widely applied in food, pharmaceutical, biomedical, cosmetic and photographic industries. The global demands of gelatin for food and non-food products have been increased. [Grand View Research \(2016\)](#) reported that the global gelatin market size was 412,700 tons in 2015 and the increasing demand for food and beverage and pharmaceutical applications, based on its excellent stabilizing characteristics and good binding features, is expected for the continuous market growth. Gelatin is produced from the collagenous materials, mainly from porcine and bovine skin and bone. Due to the their limitation as well as increasing demand of halal and kosher gelatins, alternative sources for gelatin production, such as fish, poultry, and other mammals (camel and goat), etc have gained more attention ([Abedinia et al., 2017](#); [Almeida and Lannes, 2013](#); [Al-Kahtani et al., 2017](#); [Mad-Ali et al., 2016](#)). The novel sources, e.g. amphibians have been also used for gelatin production ([Karnjanapratum and Benjakul, 2014](#)). Yield and properties of different gelatins are varying. Manufacturing processes involving pretreatment and extraction conditions, filtration and drying are considered to impact the final quality of gelatin. Owing to the varying molecular and functional properties, different gelatins are employed for the particular applications with different purposes, in which the full benefit can be gained.

## Sources

Most of raw materials for gelation production are from animal slaughtering or animal source food processing. The major raw materials of gelatin production are generally from bovine and porcine bone or skin, which are approximately 46% and 52% of the global demand, respectively ([Karim and Bhat, 2009](#)). Raw materials from other mammals such as goat skin and camel bone have been proved to be the promising sources for gelatin production ([Al-Kahtani et al., 2017](#); [Mad-Ali et al., 2016](#)).

Fish skin, bone and scale, etc., generated as the leftover from fish processing, are widely used for production of gelatin and its derivatives. Those raw materials are abundant and cheap ([Benjakul et al., 2012](#)). Moreover, gelatin can be also extracted from the other parts of fish, such as fish head and swim bladder ([Sinthusamran et al., 2016b](#); [Elavarasan et al., 2017](#)). Nevertheless, fish gelatin, especially from skin, has fishy odor, thereby limiting its applications. Fishy odor in fish gelatin could be diminished by several techniques, such as pretreatment, defatting and spray-drying under the appropriate condition ([Sae-Leaw et al., 2015](#), [2016](#)). In contrast, gelatin from fish scale has less fishy odor, but its yield is quite low ([Tu et al., 2015](#)).

Apart from porcine, bovine and fish collagenous materials, avian and amphibian processing leftover are also used for gelatin production. Chicken and duck feet and chicken and turkey heads obtained from slaughtering or dressing could be used as the alternative raw material for gelatin production without BSE transmission, but bird flu is still of concern. Gelling property of gelatin from these materials was comparable to that of mammalian counterparts ([Kuan et al., 2017](#); [Du et al., 2013](#)). However, their yield was quite low (7.01%–7.83%) when compared with those from other sources ([Abedinia et al., 2017](#); [Du et al., 2013](#); [Kuan et al., 2017](#)). Furthermore, frog skin, a byproduct from deskinning process, was also used for gelatin production ([Karnjanapratum et al., 2017](#)).

## Production

Gelatin production can be divided into 3 major steps, including pretreatments (non-collagenous material removal and swelling processes), extraction with water at high temperature and clarification/drying (hot air drying or spray drying or freeze-drying) ([Benjakul et al., 2012](#)). Evaporation, clarification, deodorization (only for fish gelatin) and sterilization can be implemented prior to drying as optional steps. This is dependent on the type of material and specification of final products. The removal of non-collagenous materials, including non-collagenous protein, fat and minerals, aims to increase extraction efficiency and purity of gelatin. Non-collagenous proteins are generally removed by alkaline solution such as sodium hydroxide, while fat and minerals are eliminated by non-polar solvent and EDTA/HCl, respectively. For swelling process, it is applied to disrupt noncovalent bond in collagen molecule, thus promoting the swelling of collagenous material. This can favor the subsequent extraction or solubilization of gelatin ([Stainby, 1987](#)). The swelling process is carried out by acidic or alkaline processes, based on the complexity of raw material. The acid and alkaline processes are used for material with low and high degree of crosslinking, respectively. The gelatin obtained by the acidic process is called type A gelatin, whereas the gelatin manufactured from the alkaline-treated raw material is named type B gelatin ([Karayannakidis and Zotos, 2016](#)). Acid introduced for acid pretreatment is generally organic acid, especially acetic acid, while the alkali used are sodium hydroxide or calcium hydroxide.

Extraction of gelatin is performed from pretreated material, in which hot water is used to destroy the hydrogen bonds stabilizing triple helix of mother collagen. During the transition of collagen to gelatin, non-covalent bonds are broken along with some

covalent inter and intramolecular bonds and a few peptide bonds are cleaved (Benjakul et al., 2012). Temperature has the profound impact on molecular property. Excessive heat negatively affects the gelation of gelatin by reducing the chain length of gelatin (Sinthusamran et al., 2016b). Thus, the appropriate temperature and time are recommended, in which the high quality gelatin can be manufactured (Sinthusamran et al., 2014). To augment the extraction efficacy, especially from animal bone or fish scale, demineralization should be implemented (Herpandi et al., 2011). Additionally, ultrasonication or pulsed electric field can be employed to increase the yield (Tu et al., 2015). These techniques can disrupt or loosen the matrix of those compact materials. As a consequence, gelatin can be more released from the starting material (Chemat et al., 2011).

Filtration and clarification are required to bring about the gelatin with desired clarity. Gelatin solution is treated with diatomaceous earth or activated carbon (Benjakul et al., 2012). Subsequently, the gelatin solution is subjected to drying. In general, drying method and condition used have the impact on characteristics and properties of resulting gelatin (Mad-Ali et al., 2016). Spray drying is a promising means to lower fishy odor of fish gelatin via evaporation of volatiles contributing to the offensive smell (Sae-Leaw et al., 2015).

## Characteristics of Gelatin

Characteristics of gelatin are influenced by both intrinsic and extrinsic factors. Those include isoelectric point, amino acid compositions and molecular weight distribution, etc. and are considered as the factors determining the functional properties and applications of gelatin.

### Isoelectric Point (pI)

According to pretreatment process (swelling step), gelatins possess different pIs. Type A gelatin has pI with the range of 6–9, while pI of type B gelatin ranges from 4.8 to 5.2 (Gelatin Manufacturers Institute of America, 2012). The higher pI of type A gelatin is due to the limited hydrolysis of the side chains of asparagine and glutamine, whereas the side chains of these amino acids are easily hydrolyzed to aspartic and glutamic acids, resulting in the lower pI of type B gelatin (Alfaro et al., 2015).

### Amino Acid Compositions

Amino acid compositions of gelatin vary with animal species, pretreatment and extraction processes. The amount of aspartic acid and glutamic acid in type B gelatin is higher than that of type A gelatin (Duconseille et al., 2015). Overall, gelatin shows the similar amino acid composition to collagen. Gelatin contains glycine (~33%), proline (~12%), alanine (~11%) and hydroxyproline (10%) as the major amino acids but has the low contents of histidine, methionine and tyrosine (Karayannakidis and Zotos, 2016). Proline and hydroxyproline, which are so called imino acid, play an essential role in gelling properties, especially rheological property and gel strength. Imino acid content of gelatin among animal species is different, depending on their normal habitat. Gelatins from tropical animal, both land or aquatic animals, had higher imino acid content (194–225 residues/1000 residues) than those from temperate animals (150–173 residues/1000 residues) (Abedinia et al., 2017; Karnjanapratum et al., 2017; Kittiphattanabawon et al., 2016; Benjakul et al., 2012).

### Molecular Weight Distribution

Gelatin is a heterogeneous polypeptide mixture of  $\alpha$ -chain (single chain),  $\beta$ -chain (two  $\alpha$ -chains covalently cross-linked) and  $\gamma$ -chain (three covalently cross-linked  $\alpha$ -chains) (Ramos et al., 2016). Hydrolysis of those components may occur as induced by the harsh extraction condition, in which peptides with molecular weight ranging from 15 to 400 kDa are formed. The adequate swelling and rupture of intra- and intermolecular bonds can favor the degradation of those components, particularly when extraction is performed at high temperature (Gómez-Guillén et al., 2002; Alfaro et al., 2015). The degradation of those components, especially  $\alpha$ -component, negatively affects gelling property of resulting gelatin. Therefore,  $\alpha$ -component should be maintained as much as possible (Muyonga et al., 2004; Gómez-Guillén et al., 2002). Generally, gelatin extracted at higher temperature with shorter chain length has the higher yield but lower gelling property, when compared to that obtained from milder process.

## Functionalities

Functional property of gelatin can be divided into two groups. The first group is the functionality associated with surface or interfacial behavior, such as the formation of emulsion, foam and film. The latter group is functionality related with gelling properties (Schrieber and Gareis, 2007). Gelatin can be used as gelling agent or provide elasticity, consistency and stability of food products. Gelatin can be also served as coating or edible/biodegradable packaging due to its film forming ability, where transmission of light and oxygen into agricultural produces or foods during storage can be prevented (Benjakul et al., 2012; Ramos et al., 2016).

## Gelling Properties

Gelling properties of gelatin, including gel strength and setting/melting temperatures as measured by texture analyzer and rheometer, respectively, are the indices determining its application. Gel strength or Bloom value, which is determined according to the standard method (BSI, 1975), is the most important property for grading the quality of gelatin (Alfaro et al., 2015; Gelatin Manufacturers Institute of America, 2012). Commercial gelatins have Bloom values from 50 to 300 g, classified as low Bloom (<150 g), medium Bloom (150–200 g) and high Bloom (>220 g) types (Meng and Cloutier, 2014). High Bloom gelatin generally requires lower amount of gelatin to reach the desired gel strength in the final product, when compared with low Bloom gelatin (Gelatin Manufacturers Institute of America, 2012; Schrieber and Gareis, 2007). Setting and melting temperatures are the temperature required for phase transition from liquid to solid and solid to liquid of gelatin, respectively. Gelatin gel is mainly stabilized by hydrogen bond. Hydrophobic and ionic interactions are also involved in gelation (Benjakul et al., 2012). The properties are governed by source, pretreatment, extraction conditions and endogenous protease present in raw material. Also, gelatin concentration and temperature and time for making gel affect the property of gelatin. Gelatin having more degradation of  $\alpha$ -,  $\beta$ - and  $\gamma$ -chains has poor gelling property (Kittiphattanabawon et al., 2016). Generally, fish gelatin, especially from cold water fish, had poorer gelling property than mammalian gelatin because it contains lower amount of imino acids (Hyp + Pro) (Karim and Bhat, 2009). Gelatin from some warm water fish had gelling property comparable to mammalian counterpart (Kittiphattanabawon et al., 2016; Sinthusamran et al., 2014). The property of fish gelatin depends on molecular weight distribution, which is governed by pretreatment and extraction conditions (Kittiphattanabawon et al., 2016; Niu et al., 2013).

The presence of endogenous protease in fish skin is associated with the decrease in gelling property. Endogenous serine protease, which is activated at 50–70 °C, is able to hydrolyze collagen molecules during extraction of gelatin from some fish species (Intarasirisawat et al., 2007; Ahmad et al., 2011).

To improve or strengthen gelatin gel, some substances or enzyme including protein crosslinkers (phenolic compounds, aldehydes, genipin, transglutaminase) are incorporated into fish gelatin during gel preparation, especially gelatin from cold water fish containing low imino acid content (Sinthusamran et al., 2016a; Benjakul et al., 2012). Hydrocolloids such as gellan or  $\kappa$ -carrageenan have been used for modification of gel property of fish gelatin (Sinthusamran et al., 2016a; Petcharat and Benjakul, 2017).

## Film Formation

Gelatin is a protein, which has been used to make the edible coating and film. Gelatin film generally has good mechanical property with an excellent oxygen barrier property, but still has high water absorbability. Gelatin based film is prone to swell, partially dissolve or disintegrate upon the contact with wet surface (Nilsuwan et al., 2016). To tackle the problem, gelatin based film has been modified by incorporation with different substances, such as phenolic compound as a protein crosslinker, etc. Hydrophobic plasticizer and the selected surfactant are employed to improve water resistance property via increasing hydrophobic characteristic of gelatin molecules (Nilsuwan et al., 2016; Ramos et al., 2016). Gelatin film from warm water fish had the comparable stress and elongation at break to bovine and porcine gelatin films (Muyonga et al., 2004). However, water vapor permeability of gelatin film from fish gelatin, especially from cold water fish, was lower than that from porcine and bovine because of much higher hydrophobicity of fish gelatin (Karim and Bhat, 2009). Bilayer films, emulsified film/fish gelatin film, has been developed to improve water vapor barrier property (Nilsuwan et al., 2017).

## Interfacial Properties

Gelatin is a surface-active agent, which is able to act as emulsifying and foaming agents in food and non-food applications. An emulsion is a dispersion or suspension of two immiscible liquids, while a foam is a gas phase dispersed in liquid (Hill, 1998). The hydrophobic domains or residues on the peptide chain are responsible for giving gelatin its emulsifying and foaming properties (Cole, 2000). Gelatin concentration has an impact on interfacial properties, but these properties are also governed by the source of gelatin, its molecular weight distribution and environment of emulsion (pH, temperature and salt) and foam preparation methods (Benjakul et al., 2012; Karayannakidis and Zotos, 2016). Increasing gelatin concentration results in the decrease in emulsifying ability but the increase in emulsion stability, foaming ability and stability (Nagarajan et al., 2012). Bovine gelatin had the better emulsifying ability and emulsion stability than duck feet gelatin. Gelatin from channel catfish had better emulsifying stability, but showed poorer emulsion stability (Kuan et al., 2017; Duan et al., 2018). Gelatin containing higher molecular weight peptides tends to have better emulsifying properties (Nagarajan et al., 2012). Modification of gelatin using oxidized tannic acid could enhance the stability of its emulsion (Aewsiri et al., 2010). In addition, gelatin modified with oxidized linoleic acid rendered the better emulsifying and foaming properties (Aewsiri et al., 2010).

## Applications

Gelatin has been widely used in both food and non-food products. For food applications, gelatin has been utilized as a food additive, such as stabilizer, thickener, gelling agent, film former, whipping agent, clarifying agent, etc. Also, gelatin can be employed in non-food applications, including the biomedical and pharmaceutical industries (hard and soft capsule manufacture, wound

dressings, adsorbent pads and health supplements), cosmetic industries (shampoos, conditioners, lipsticks and fingernail formulas) and the photographic industry (the unique combination of gelling agent and surface activity to suspend particles of silver chloride) (Persistence-Market-Research, 2017).

The unique characteristic of gelatin is the generation of melt-in-the-mouth characteristic and formation of thermo-reversible gel. Additionally, it has high solubility over a broad pH range (Gelatin Manufacturers Institute of America, 2012). The major applications of gelatin can be summarized into 5 groups, including confectionary and jelly desserts, dairy product, meat product, beverages and other applications, such as sauce, soup, frozen product, edible film and coating and hydrolyzed gelatin (Table 1). Gelatin from chicken feet with gel strength of 294 g was classified as high Bloom gelatin and was suggested to use for the production of gelatin gums, marshmallows, gelatin desserts and other products requiring high Bloom value (Almeida and Lannes, 2013). Low Bloom gelatin, obtained from cold water fish gelatin or gelatin extracted under improper condition, can be used in frozen or refrigerated products that are consumed after taking out from the fridge or defrosting to prevent syneresis (Karim and Bhat, 2009).

Confections such as gummy bears contain a relatively high percentage of gelatin. These candies dissolve more slowly, while smoothing the flavor. Gelatin is used in whipped confections such as marshmallows, where it can lower the surface tension of the syrup, stabilize the foam via the increased viscosity, set the foam via gelation, and prevent sugar crystallization (Gelatin Manufacturers Institute of America, 2012).

Gelatin is widely used in ice cream as a stabilizer by binding water, forming a gel network at low temperature and also decreasing ice crystallization (Duan et al., 2018). The addition of gelatin in yogurt can improve stability of yogurt by decreasing syneresis (Pancar et al., 2016). Addition of 0.4% (w/v) gelatin with Bloom value of 246 g in corn-milk yogurt gave the product with good acceptability. Syneresis of those gels can be reduced without causing the development of dense and compact structure (Supavititpatana et al., 2008).

Gelatin is used to gel aspics, head cheese, souse, chicken rolls, glazed and canned hams, and jellied meat products. Gelatin is able to absorb meat juice and acts as the binder. Normal usage level ranges from 1% to 5%, depending upon the type of meat, amount of broth, gelatin Bloom, and texture required in the final product (Gelatin Manufacturers Institute of America, 2012). Addition of cuttlefish gelatin in the octopus sausage could stabilize the emulsion and decrease cooking loss (Souissi et al., 2016). Also, the addition of 0.5% and 1.5% (w/w) porcine gelatin with Bloom value of 200 g in the pork sausage could decrease its cooking loss (Lee and Chin, 2016). In addition, low Bloom gelatin can be used as a stabilizer of emulsion produced at below room temperature, which allows the loading material encapsulated with the gelatin (Meng and Cloutier, 2014).

Gelatin can be used as a clarifying agent in beer and apple juice (Liu et al., 2009; Duan et al., 2018). Gelatin shows the binding ability with a floc, followed by binding the protein into jelly-like mass. Consequently, the aggregate can settle at the bottom of container, making the juice clear (Duan et al., 2018).

Gelatin in hydrolyzed form, which is commonly obtained from enzymatic hydrolysis, has gained an increasing attention from consumers. Gelatin hydrolysate, generally known as 'hydrolyzed collagen' has been fortified in several dietary foods and drinks. It

**Table 1** Application of gelatin with different Bloom values and functionalities in different foods

Product groups	Bloom value (g)	Product	Functionalities
Confectionaries	50–300	Gummy	Thickener
		Marshmallow	Whipping agent
		Nougats	Whipping agent
		Chiffons	Whipping agent
		Pudding	Thickener
		Frozen dessert	Protective colloid
Dairy products	150–250	Yogurt	Stabilizer
		Cream cheese	Stabilizer
		Whipped cream	Whipping agent, emulsifier
		Ice-cream	Protective colloid
		Cheese	Binding agent
Meat products	175–275	Meat roll	Binding agent
		Canned meat	Binding agent
		Sausage	Gel former, water holder
		Beer	Clarifying agent
Beverages	100–200	Wine	Clarifying agent
		Juice	Clarifying agent
		Power drink mix	Thickener
		Gravy, sauce, soup	Thickener
Others	–	Edible coating for fruit and meat	Film former
		Microencapsulation of color, flavor, oil, vitamin	Process aid/wall material

Modified from Gelatin Manufacturers Institute of America, 2012. Gelatin Handbook. Gelatin Manufacturers Institute of America, Inc, New York; Schrieber, R., Gareis, H., 2007. Gelatine Handbook. Wiley-VCH Verlag GmbH & Co. KGaA; Turner, W.A., 1988. Prepared foods. Dan Best, Chicago, USA.

has high digestibility and bioactivities, including antioxidant activity, ACE-inhibitory activity, human LDL-cholesterol oxidation inhibitory activity, dipeptidyl-peptidase IV (DPP-IV) inhibitory activity, antimicrobial activity, mineral binding capacity, the lipid-lowering effect and immunomodulatory activity (Gelatin Manufacturers Institute of America, 2012; Karayannakidis and Zotos, 2016). Those bioactivities depend on type and amount of enzyme used, imino acid composition and peptide sequence and size (Alemán et al., 2011). Hydrolyzed collagen can be used in several products with nutraceutical property such as protein drink and nutrition bars (Persistence-Market-Research, 2017). More importantly, the beneficial effects on skin nourishment have attracted the interest since it can induce the production of collagen as well as minimize the reduction of collagen via inhibiting metalloprotease. The daily ingestion of collagen hydrolysate on skin extracellular matrix proteins of male Wistar rats could increase their type I and IV collagen contents. Collagen hydrolysate uptake significantly decreased both proenzyme and active forms of matrix metalloproteinase 2 (MMP2) (Zague et al., 2011). Bone or joint health is also improved by intake of hydrolyzed collagen. From clinical studies in patients with degenerative hip or knee disease, administration of 10 g collagen hydrolysate daily for 2 months could reduce pain in patients with osteoarthritis of the knee or hip by increasing the synthesis of collagen in joint and cartilage as well as intake of collagen hydrolysate had a great effect in inhibiting bone collagen breakdown in osteoporosis patients (Moskowitz, 2000).

Apart from using gelatin as a food additive, gelatin can be used as an edible film and coating applied in meat and fishery products. Cold-smoked salmon wrapped with fish gelatin based film incorporated with 5.63% (w/w) olive leaf extract could reduce the growth of *L. monocytogenes* during storage at 23 °C, 58% RH for 6 days (Albertos et al., 2017). The application of gelatin based film and coating in pork meat and beef steak could reduce color changes. This was associated with an excellent oxygen barrier property of the film, leading to the retarded metmyoglobin formation (Davis and Lin, 2005; Cardoso et al., 2016).

In pharmaceutical and biomedical applications, gelatin is commonly used as an ingredient for wound dressing, drug delivery systems (soft and hard capsules), soft and hard-tissue engineering scaffolds and a cell-interactive coating or micro-carrier embedded in other biomaterials (Dubruel et al., 2007). Owing to gelling property, it can be used as a major ingredient for soft and hard capsule. Gelatin can melt in human digestive tract and the contained drugs can be released and function at the required target (Duconseille et al., 2015). Gelatin based scaffolds from various processing techniques exhibit excellent biocompatibility, biodegradability and porosity (Hoque et al., 2015). Gelatin has been used to produce biomedical materials, such as heart valve, cardiac tissue engineering, artificial skin, small intestine, liver, wound dressing, nerve regeneration, blood vessel, bone substitute, cartilage, contact lens, plasma substitutes, etc (Gorgieva and Kokol, 2011).

## Gelatin Speciation and Adulteration

Although gelatin is an ingredient commonly used in many applications, the major concern is drawn from some groups of consumers associated with religious practice and belief. The original materials and process used for gelatin must be approved or certified. For example, halal gelatin and its products need to be labeled on the package (Shabani et al., 2015). Additionally, some consumers have allergy to food containing mammalian and fish gelatin (Kuehn et al., 2009). Therefore, the adulteration of prohibited gelatin in the product is necessary to be determined. Many researchers have proposed the analytical methods for detection the presence and species origin of gelatins, such as chemical precipitation, Fourier transform infrared spectroscopy, NanoUPLC-ESI-Q-TOF-MS<sup>E</sup>, polymerase chain reaction (PCR), electrophoretic analysis, high-performance liquid chromatography, mass spectrometry, enzyme-linked immunosorbent assay (ELISA), etc (Cebi et al., 2016; Hidaka and Liu, 2003; Yilmaz et al., 2013; Venien and Leveux, 2005; Grundy et al., 2016; Hermanto and Fatimah, 2013; Shabani et al., 2015). These aforementioned methods have different advantages and limitations. To select any method for gelatin speciation and adulteration detection, specificity, sensitivity, accuracy, rapidity, simplicity and cost should be considered. Development of rapid method with precision to determine the origin of gelatin in food and pharmaceutical products is still required.

### Glossary

**CBE** cocoa butter equivalent

**CBR** cocoa butter replacer

**CBS** cocoa butter substitute

**FDA** US Food and Drug Administration

**GRAS** Generally Recognized As Safe

**H** C<sub>16</sub> – C<sub>24</sub> saturated fatty acids

**K** C<sub>16</sub> – C<sub>22</sub> fatty acids

**O** oleic fatty acid

**M** C<sub>12</sub> – C<sub>14</sub> fatty acids

**N** saturated fatty acids with C<sub>8</sub> – C<sub>14</sub>

**P** palmitic fatty acid

**PHO** Partially Hydrogenated Oils

**PUFA** poly-unsaturated fatty acids

**S** stearic fatty acid

**S<sub>ps</sub>** palmitic or stearic fatty acid

**S<sub>t</sub>** saturated fatty acids

**SFC** solid fat content

**U** unsaturated C<sub>18</sub> fatty acids

For food products with a high fat content, such as butter, margarine and shortening, sensory attributes are largely dependent on the structure and properties of their underlying solid fat crystal networks. The solid fat, denoted as hardstock fat, serves to structure the fat phase and prevent coalescence of the liquid phase, which is either water droplets for water-in-oil emulsion products like margarine, or liquid oil for various shortening products.

Fats and oils are mainly triacylglycerides, which are esters of glycerol and three fatty acids. The behavior and functionality of hardstock fat is determined by their fatty acid composition, arrangement of the fatty acids on the glycerol backbone, and the polymorphic crystal forms of the triglycerides. Melting points of common fatty acids and triglycerides in food products can be found in some literature (O'Brien, 1998a; Larsson, 1986). The most common fatty acids in hardstock fats are lauric, palmitic, oleic, and stearic fatty acids, which form triglycerides and are solid at ambient temperature. Depending on the packing patterns of the hydrocarbon chains of the fatty acids, the crystal polymorphic form of triglycerides can be any of the  $\alpha$ ,  $\beta'$ , or  $\beta$  form with melting point increasing from  $\alpha$  to  $\beta'$ , to  $\beta$ . Some fats may have sub-polymorphic forms. The most well-studied fat having sub-polymorphic forms is cocoa butter, which has six polymorphic forms with different melting temperatures ranged from 16 °C for sub- $\alpha$  form, 21 °C for  $\alpha$  form, 25.5 °C and 27 °C for  $\beta_2'$  and  $\beta_1'$  separately, and 34 °C and 36 °C for  $\beta_2$  and  $\beta_1$  separately (Talbot, 2009).

The crystallization habit of hardstock fats or oils is determined by one or more of four characteristics: 1) palmitic fatty acid content, 2) distribution and position of palmitic and stearic fatty acids on the triglyceride molecule, 3) degree of hydrogenation, and 4) the degree of randomization (O'Brien, 1998b). In general, hardstock fats with a diverse triglyceride structure tend to form  $\beta'$  fat crystals and hardstock fats with limited number of triglyceride structure tend to form  $\beta$  fat crystals. For example, hardstock fats with high palmitic acid content normally form  $\beta'$  fat crystals, but lard tends to form  $\beta$  fat crystals even though it contains around 27% palmitic acid. It is because lard has a predominately asymmetric triglyceride structure with palmitic acid in the sn-2 position. Crystallization behavior of some common fats and oils is well studied and readily available (O'Brien, 1998b).

For food products structured with hardstock fat, a specific melting or SFC (solid fat content) profile is often desired according to the application. For example, the melting point of cocoa butter in chocolate should be around body temperature, so it can have a sharp melting and cooling sensation. All-purpose shortening has a flat SFC curve over a wide range of temperatures, so it can maintain its workability at different temperatures. To have the desired SFC curve, it is often necessary to modify the natural fats and oils through various techniques including hydrogenation, interestification, and fractionation.

## Hydrogenation

Hydrogenation has been used to produce hardstocks from liquid oils since the beginning of the 20th century. It involves addition of molecular hydrogen to the double bonds of unsaturated fatty acid in the presence of a catalyst such as Nickel, which results in decreased unsaturation of the fatty acids, and thus gives elevated melting point and increased oxidation stability of the fatty acids. Many of the hydrogenated oils can serve as hardstock fat. Depending on the conditions used, the starting oils, and the degree of saturation or isomerization, fats and oils with wide range of functionalities can be produced through the hydrogenation process. Hydrogenation can be either partial hydrogenation or full hydrogenation. While full hydrogenation converts the vegetable oils into fully saturated fats, vegetable oils being partially hydrogenated are partially saturated so the melting point increases to the point where solid fat is present at room temperature. The degree of hydrogenation of unsaturated oils controls the final consistency of the product. The partial hydrogenation gives edible oil companies a great flexibility to make fats and oils with a wide range of physical properties and functionalities. However, geometric isomerization during partial hydrogenation process produces trans-fat, which was demonstrated to have cardiovascular health risk, FDA has concluded that PHO (Partially Hydrogenated Oils) are not GRAS (Generally Recognized As Safe) and asked all food manufacturers to make sure their products do not contain PHO from June 18, 2018 (FDA, 2017).

Fully hydrogenated fats and oils do not contain trans-fat, thus do not have the same health risk, but average consumers cannot distinguish the difference between fully hydrogenated fats and oils and partially hydrogenated fats and oils, so a lot of food manufacturers try to avoid all hydrogenated fats and oils on their labels. It raised new challenges to the edible oil industry to manipulate the consistency and functionality of fats and oils through other measures.

## Fractionation

Fractionation is the process which separates a natural fat or oil into several fractions with different melting points. The high-melting fraction serves as hardstock fat and can be blended with other fats and oils to obtain desired consistency. There are two methods of fractionation: dry fractionation and solvent fractionation. Under dry fractionation the oil is heated and then cooled to a given temperature under agitation such that the partially crystallized mass can be filtered off under vacuum to give the high-melting fraction. The remaining liquid fraction gives the low-melting fraction. Each fraction of the oil can be blended with other fats and oils for different applications.

The most popular oil being fractionated is palm oil, which can be fractionated into at least four fractions: palm stearin, palm mid fraction, palm olein, and palm super olein. The main reason for palm oil fractionation is the demand for clear liquid oil (palm olein). The high-melting palm stearin fraction has been used to produce cocoa butter equivalents/replacers, and as a hardstock for margarine and other fat continuous products.

## Interestification

Interestification is the process by which fatty acids are rearranged on the glycerol fragment of the triacylglyceride molecule. Interestification can be either random interestification (chemically catalyzed) or selective interestification (enzyme catalyzed). The most commonly used chemical catalysts are sodium methylate and sodium ethylate. Alkaline catalyzed interestification produce new triacylglyceride molecules with fatty acids randomly distributed on the three available positions; while lipase mainly catalyze rearrangement of the fatty acids on sn-1 and sn-3 position, leaving the fatty acids on the sn-2 position unchanged. Interestification of a designed fat blend can reduce the solid fat levels at high temperature and make a hardstock fat better suited for certain applications. Fig. 1 (Wassell and Young, 2007). shows the SFC of a blend of 60% palm stearin and 40% palm kernel oil before and after interestification. The interestification process significantly lowered SFC of the mixture, especially the SFC above 30 °C, which improved the sensory sensation of the product. In combination with oil fractionation, interestification can modify the SFC curve of fats and oils and improve their functionality without the formation of trans fatty acid, thus make it an ideal alternative to hydrogenation process.

So far, the chemical structure and physical properties of hardstock fats including their melting point and polymorphic forms and the techniques to modify hardstock physical properties have been discussed. In the next two sessions, the application of hardstock fats in margarine and confectionery products will be discussed.

## Trans Free Hardstocks for Margarine

Margarine is water-in-oil emulsion, where finely dispersed water droplets and liquid oil are immobilized by the hardstock fat crystal network. The melting behavior of the hardstock used in margarine is extremely important to the quality and sensory perception of the product, because margarine must remain firm at refrigerating temperature, spreadable at room temperature (10–20 °C), and melt completely at body temperature (>35 °C). In addition to the requirement of its melting profile,  $\beta'$  form of the hardstock fat crystals is preferred in margarine since the needle-like shape and smaller crystal size of  $\beta'$  fat crystals give margarine smooth texture. PHO has been widely used for margarine production; however, the recognized health risk of trans fatty acid and saturated fatty acids has led to active research and development work on trans-free and lower-saturated fatty acid hardstock for margarine.

**Figure 1** A blend of 60% palm stearin/40% palm kernel oil before and after interesterification. Adapted from Wassell, P., Young, N.W.G., 2007. Food application of trans fatty acid substitutes. *Int. Journal Food Science Technology* 42, 503–517, with permission.

Margarine manufacturers have suggested that triglycerides with “H–U–H” structure form stable  $\beta'$ - crystals thus give smooth texture to margarine (Elliott et al., 1999; Floeter et al., 2004), where H is  $C_{16}$  –  $C_{24}$  saturated fatty acids, U is unsaturated  $C_{18}$  fatty acids. Hardstock triglycerides with “K2M” structure have been reported to give desired texture to margarine as well, where K is  $C_{16}$  –  $C_{22}$  fatty acids and M is  $C_{12}$  –  $C_{14}$  fatty acids (Sahasranamam, 2005).

In order to achieve the desired triglyceride composition and nutritional composition of the hardstock, margarine manufacturers either blend natural, unmodified vegetable oils, or modify the chemical structure of hardstock fats through hydrogenation, fractionation, and interestification of a mixture of fats and oils containing high level of mono- and PUFA (poly-unsaturated fatty acids). Palm oil fractions are the most used oil in margarine production, especially palm stearin has been widely used in blending and interestification with other liquid oils to produce trans-free and high PUFA margarine oils. For example, a typical trans-free fat blend for a table margarine may contain palm stearin, palm kernel olein, and sunflower seed oil in the ratio of 60:20:20 (Yusoff and Dian, 1995), or alternatively palm oil, palm olein and canola oil in the ratio of 57:23:20 (Yusoff et al., 1998). Thanks to its short chain lauric acid content, palm kernel oil is excellent for industrial type margarines due to its enhanced creaming properties and preferred fat crystallization properties (Yusoff and Dian, 1995). In addition to palm oil, some specialty oils such as Allanblackia oil and Pentadesma oil have been used in margarine production as well. Allanblackia oil and Pentadesma oil contains 60% - 80%, and 48% SOS (stearin-olein-stearin) triglycerides separately (Arellano et al., 2015; Floeter et al., 2006). The high level of high melting SOS triglyceride makes both oils perfect hardstock for margarine production, where both oils are either fractionated or use as a natural oil, and blended with other liquid oil. The high content of similar mixed fatty acids triglycerides such as SOS also increases the intersolubility of triglycerides and formation of mixed fat crystals, thus give smaller fat crystal size, uniformly dispersed fat crystal networks, enhanced emulsion stability and a smooth texture.

### Hardstock Fats in Confectionery

In confectionery industry Cocoa butter is one of the most important fats and oils thanks to its sharp melting profile around body temperature. Cocoa butter contains mainly three fatty acids – palmitic, stearic and oleic, which mostly in one of the three triglycerides – POP, POS, and SOS, where P is palmitic acid, O is oleic acid, and S is stearic acid. Because of its specific triglycerides composition, especially its high level of SOS triglycerides, cocoa butter can form six polymorphic forms with different melting temperature, where form V ( $\beta_2$ ) is the desired form for chocolate production.

In confectionery products, cocoa butter and cocoa butter alternatives are important hardstock fats providing structure to chocolate, compound coatings, confectionery fillings and other confectionery products and prevent or slow down oil migration from center filling to the coating. There are three basic types of cocoa butter alternative: CBE (cocoa butter equivalent), CBR (cocoa butter replacer), and CBS (cocoa butter substitute).

CBEs are based on lauric fats rich in lauric acid ( $C_{12:0}$ ) specifically palm kernel oil and coconut oil and has limited compatibility with cocoa butter. CBRs used to be produced from partially hydrogenated vegetable oils, but now it is mainly produced from fractions of palm oil. CBEs are vegetable fats composed of similar symmetrical  $S_tOS_t$  triglycerides as cocoa butter ( $S_t$  is saturated fatty acids and O is oleic fatty acid), and it behaves similarly as cocoa butter such as crystallization and tempering. A typical triglyceride composition of cocoa butter and some CBE component fats are available in literature (Talbot, 2015). CBEs can be produced from blending of those component fats according to applications. Various oil modification techniques are often used to produce cocoa butter alternatives from vegetable oils. For example, a cocoa butter – like fats were prepared from interestification of a blend of palm oil and fully hydrogenated soy bean oil in a ratio of 1.6:1 followed by fractional crystallization from acetone (Abigor et al., 2003).

In addition to providing structure, some hardstock triglycerides have excellent anti-blooming properties in confectionery products. It was found that blends of triglycerides comprising a fat A containing  $> 40\%$   $S_{ps}OS_{ps}$  ( $S_{ps} = C_{16:0}$  or  $C_{18:0}$ ; O =  $C_{18:1}$ )

and a fat B containing an ( $H_2N + N_2H$ ) fat, where N is saturated fatty acids with  $C_8 - C_{14}$ , displays excellent anti-blooming properties in chocolate compositions (Frederick et al., 1995). Blends of SOS-rich Vietnamese mango fat and Indian mango fat with cocoa butter at a ratio of 70/30 has shown to increase the heat resistance and anti-blooming properties of the chocolate made with the fat blends (Tran et al., 2015).

## Summary

Hardstock triglycerides are solid fat at room temperature, which provides structure to food products with high fat content. The crystallization and melting behavior of hardstock triglycerides is determined by their chemical structure and physical polymorphic forms. Various modification techniques including hydrogenation, fractionation and interestification were employed to produce hardstock triglycerides with desired properties, especially trans-free and low-saturated hardstock triglycerides.

Hardstock triglycerides with “H–U–H” structure was shown to give the desired  $\beta'$  crystal form and smooth texture to margarine. In contrast,  $\beta$  crystal form is often desired in confectionery applications, which is formed mainly by the symmetric  $S_1OS_1$  triglycerides.

### Glossary

**GRAS** abbreviation for “generally recognized as safe” by the American Food and Drug Administration (FDA) and it indicates that the substance is considered safe by experts

**Triacylglyceride** lipid molecule containing a glycerol as backbone with three esters bonds of hydrocarbons hydrophobic chains

**Phospholipids** lipid molecule consisting of a hydrophilic phosphate group and two hydrophobic fatty acids. The head and tail groups give this molecules an amphiphilic characteristic that is used to form bilayers

**Glycolipids** lipid molecule comprised of a hydrophobic lipid tail and one or more hydrophilic sugar groups linked by a glycosidic bond

### Nomenclature

**TAG** triacylglyceride

**DAG** diacylglycerides

**MAG** monoglyceride

**FA** fatty acid

**MCT** medium chain triacylglyceride

**LCT** long chain triacylglyceride

**GRAS** generally recognized as safe

**CB** cocoa butter

**MCFA** medium chain fatty acid

**LCFA** medium chain fatty acid

**HC** hydrocarbon chain

### Introduction

Edible fats and oils comprise one of the three major classes of foods, the others being carbohydrates and proteins. Edible fats and oils can be obtained from terrestrial or aquatic animals, from the seeds or leaves of many plants, from the pulp, or from the nut/stone of many fruits. Edible fats and oils are used in many products not only to make food palatable but also to make them functional.

The terms “fat” and “oil” are used according to the physical state of the material at room temperature. Fats are in a semi solid state, but the appearance is of a solid, while oils are in a liquid state. Chemically, fats and oils are mixtures comprised of more than 95% triacylglyceride (TAGs) molecules mixed with minor components. Triacylglycerides can also be found in the literature with the name triglycerides or triacylglycerols. These minor components can include phospholipids, glycolipids, free fatty acids, monoglycerides (MAGs) or diacylglycerides (DAGs) (Swern and Bailey, 1964). When dealing with edible fats and oils for the manufacture of food products, one tends to refer to the TAGs molecular composition, avoiding all other components as they represent less than 5%. More over, it is common to refer to the fatty acid (FA) composition instead of the TAG composition. TAGs molecules are esters of a glycerol molecule with three FAs. The FA is a hydrocarbon chain with a methyl (CH<sub>3</sub>) group at one end and a carboxylic acid (COOH) group at the other. The COOH is the one reacting with the alcohol group of the glycerol to produce the ester linkage. FAs are characterised by the hydrocarbon chain (HC) length (number of carbon atoms), the saturation (number of hydrogen atoms per carbon atom), the presence of *trans*- or *cis*-bonds (straight or bended hydrocarbon chain) and the type of bonds (single, double or triple bond) between carbon atoms (Small, 1986).

The melting point is a physical property commonly used to characterize FAs. The melting point is related to the way the molecules packed. The temperature at which FAs with short HC lengths melt are lower that those with large HC. Also, the more double bonds or the higher the number of bonds between two carbons (moving from single to triple bonds) the lower the temperature of the melting point.

Un-saturated FA *cis*-bond with a single, double or triple bonds create a FA that is non-linear. This non-linearity in the FA originates a loose packing of the molecules, hence low melting points. The loose packing configuration is due to weak van der Waals interactions since the molecules are not close to each other. Hence, the amount of energy needed in the solid–liquid transition (melt) is less than that required for well packed molecules, as is the case for *trans* or saturated TAGs.

Fig. 1 shows two FA, represented by using the expanded structural formula name, the condensed structural formula, the common name and the symbols by which they are commonly identified.

Table 1 expands on the symbols and names following the IUPAC convention (<http://www.sbcs.qmul.ac.uk/iupac/lipid/>) for only some cases. The reader is encouraged to see Akoh (2017) or Lehninger (1970) books for more complete tables.

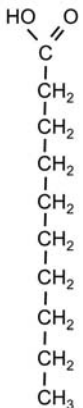

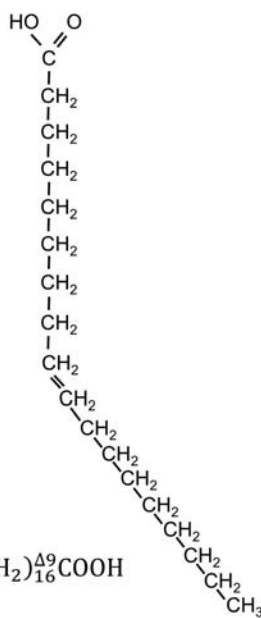

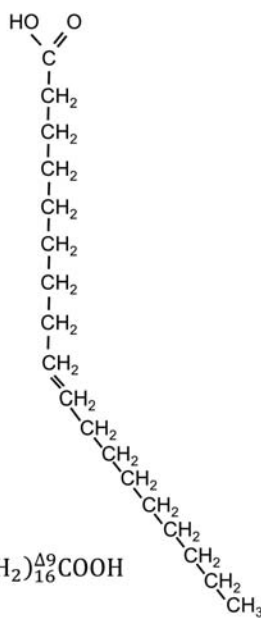

There is no “typical” TAG fat molecule in nature. The amount and type of TAGs that constitute a particular fat or oil varies not only with the cultivar or animal species, but also with the source of origin. For example, it is known that the environmental growing conditions notoriously affect the FA composition of cocoa butter, CB (Marty and Marangoni, 2009; Lehrina and Keeney, 1980; Chaiseri and Dimick, 1989). This “problem” of composition is not unique to CB, but other fats and oils obtained from animals or vegetables are also known to have different FA composition. Changes in the composition can lead to changes in some physical and chemical properties (Shukla, 1995; Schlichter-Aronhime and Garti, 1988; Foubert et al., 2004), hence, affecting the functionality of the product manufactured with that particular edible fat.

TAGs are named using the fatty acids that make them up. n-1, n-2 and n-3, or Sn-1, Sn-2 and Sn-3 are used to identify the FA position in the glycerol backbone. For example if stearic acid is in the Sn-1 position, oleic is in the Sn-2 position and stearic acid is in the Sn-3 position, then the TAG is referred as SOS and ways of naming it could be: stearic-oleic-stearic or 1,3-distearoyl-2-oleoylglycerol. One can anticipate that the number of possible combinations of similar or different FA that can be esterified to the glycerol back bone is very large. Fortunately, nature does not use all of those combinations. For example, unsaturated FA typically appear in the Sn-2 position in animal fats (Beppu et al., 2017), while oils originated from seed display a saturated FA in the Sn-2 position.

Examples of TAGs are given in Table 2, where the third column shows the FA position in relation to the backbone that make up that particular TAG.

Calling a TAG “saturated” or “unsaturated” is not a simple task because it contains 3 FA which can be saturated or unsaturated or a mix of them. For example calling PPP a saturated TAG is correct as it contains three fatty acids that are saturated, while OOO is an unsaturated TAG as it is made exclusively by unsaturated FA. The tendency has been to call a TAG molecule saturated if it contains 2 or 3 saturated FA and unsaturated if it contains 2 or 3 unsaturated FA.

FA analysis are easy to perform and the reader can find in the literature lists of FA compositions for many edible fats (Gunstone, 1970). On the other hand, the analysis to detect TAGs is expensive, as pure TAGs (usually synthesized ones) need to be used for

Expanded Structural formula		
		
	Condensed structural formula	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>8</sub> COOH
	Common name	Capric acid
	Symbol	8:0
		
	Condensed structural formula	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>16</sub> <sup>Δ</sup> COOH
	Common name	Oleic acid
	Symbol	18:1

**Figure 1** Example of two fatty acids and their naming based on different conventions. The expanded structural formula is a visual way of seeing the number of carbon and hydrogen atoms, which gets simplified in the condensed structural formula. In the condensed structural formula, double bonds are indicated using the  $\Delta$  symbol. COOH identifies the carboxyl group at one end of the fatty acid and the CH<sub>3</sub> identifies the methyl group at the other end of the hydrocarbon chain. The symbolic name contains two numbers separated by “:”; the first number indicates the number of carbon atoms in the FA and the second number indicates how many double bonds are present. Hence, when the second number is “0”, it indicates that the FA is saturated, as there is no double bonds.

**Table 1** Name and symbols for some common fatty acids

<i>Symbol</i>	<i>Common acid name and abbreviation</i>	<i>IUPAC name</i>
<b>Most common saturated</b>		
4:0	Butyric - B	Butanoic acid
6:0	Caproic - C	Hexanoic acid
8:0	Caprylic - C	Octanoic acid
10:0	Capric - C	Decanoic acid
12:0	Lauric - L	Dodecanoic acid
14:0	Myristic - M	Tetradecanoic acid
16:0	Palmitic - P	Hexadecanoic acid
18:0	Stearic - S	Octadecanoic acid
20:0	Arachidic - A	Icosanoic acid
22:0	Behenic - B	Docosanoic acid
24:0	Lignoceric - Lig	Tetracosanoic acid
<b>Some MONO- unsaturated</b>		
10:1	Caproleic acid	dec-9-enoic acid
12:1 n-3	Lauroleic acid	(Z)-dodec-9-enoic acid
14:1 n-5	Myristoleic acid	(Z)-tetradec-9-enoic acid
16:1 n-7	Palmitoleic acid	(Z)-hexadec-9-enoic acid
18:1 n-9	Oleic acid	(Z)-octadec-9-enoic acid
<b>Some POLY- unsaturated</b>		
18:2 n-9,12	Linoleic acid (LA)	(9Z,12Z)-octadeca-9,12-dienoic acid
18:3 n-9,12,15	alpha-Linolenic acid (ALA)	(9Z,12Z,15Z)-octadeca-9,12,15-trienoic acid
18:3 n-6,9,12	gamma-Linolenic acid (GLA)	(6Z,9Z,12Z)-octadeca-6,9,12-trienoic acid

**Table 2** TAG examples using the abbreviations used in Table 1

<i>Symbol</i>	<i>Common name</i>	<i>Fatty acid position and name</i>
PPP	Tri-palmitin	Sn-1 palmitic acid Sn-2 palmitic acid Sn-3 palmitic acid
POS	1-palmitic, 2-oleic, 3-stearic	Sn-1 palmitic acid Sn-2 oleic acid Sn-3 stearic acid
LA,LA,S	1, 2-linoleic, 3-stearic	Sn-1 linoleic acid Sn-2 linoleic acid Sn-3 stearic acid
OOO	Tri-olein	Sn-1 oleic acid Sn-2 oleic acid Sn-3 oleic acid

standards. Instead, many researchers report only the percentage of each hydrocarbon chain present in the oil, without being specific about the Sn-position of the FA in the glycerol backbone.

Medium-chain triacylglyceride, MCT, are particular TAGs that contain between 6 and 12 carbons in the FA. MCT can be found in milk, coconut oil and palm kernel oil. MCT can also be found in structured lipids, the man-made lipids created by using enzymes, esterification or hydrogenation. On the other hand, LCT refers to those “long chain triacylglyceride” that contain more than 14 carbons in the FA, mainly 16 and 18 and up to 21. Because of the shorter hydrocarbon chain, MCTs are smaller in molecular weight than LCT with a lower smoke and melting point than the LCT (Gunstone, 1970; Lehninger, 1970). The saturated FA that make up MCT are caproic acid, caprylic acid, capric acid, and lauric acid.

## Metabolic Path Way

MCTs have several unique nutritional and physiological properties that started being used in 1950 for dietary treatment of malabsorption syndromes (Seaton et al., 1986). MCT are nowadays used for parenteral nutrition (Bach et al., 1989) when rapid energy supply is desired or for enteral nutrition when digestion, absorption or transport of LCT is impaired (Megremis, 1991; Timmermann, 1993). MCT have been shown to be a good source of nourishment for patients that displayed malabsorption

syndromes caused by rapid absorption (Seaton et al., 1986). Another successful use of these triglycerides has been for rapid calorie supply on postsurgical patients, who run into acute loss of energy (Winawer et al., 1996). In 1994, MCT were recognized as GRAS (Traul et al., 2000) and it is known that they are well tolerated when the amount consumed in one meal does not exceed 30 g (Jeukendrup and Aldred, 2004).

The usefulness of MCT resides in the way they are metabolized, absorbed and oxidise in the body. MCT hydrolysis, starts partially with enzymes in the mouth, but more importantly in the stomach (Fernando-Warnakulasuriya et al., 1981; Staggers et al., 1981; Hamosh et al., 1989) where the hydrolyses is faster and more complete than for LCT (Greenberger et al., 1966; Borgstrom and Patton, 1991), and the gastric transient time is faster (Harkins et al., 1964; Hunt and Knox, 1968; Hopman et al., 1984). It is also said that the absorption of MCT is more efficient (Webb et al., 1991; Harkins and Sarett, 1968; Roy et al., 1975; Lau et al., 1979; Jensen et al., 1986; Sulkers et al., 1992) than for LCT. The shorter medium chain fatty acids, MCFA, compared with the longer chain fatty acids, LCFA, pass directly into the bloodstream (Bach and Babayan, 1982). The portal system transports the MCFA to the liver for hepatic metabolism before they are sent to the heart. The metabolism for the longer triacylglycerides is different. The entrance of LCTs into the duodenum stimulates the enteric secretion of the hormone cholecystokinin (CCK) together with the pancreatic enzymes. Also, bile is secreted from the gallbladder to help emulsify the triglycerides into fat droplets (Isaacs et al., 1987; Symersky et al., 2002). The pancreatic lipase hydrolyzed the LCT into FA and either mono (MONO)-acylglycerides or di (DI)-acylglycerides. The FA, MONO or DI enter the enterocyte cells lining the intestine via passive diffusion or via a protein transporter. TAGs get re-assemble in the enterocyte from their fragments and are packed together with cholesterol and proteins to form the chylomicrons (Tso and Balint, 1986). The chylomicrons are excreted from the cells and collected by the lymph system and transported to the subclavian vein to reach the bloodstream. LCT are used either for energy or they are deposited into the adipose tissue.

### Natural Sources of MCT: Fatty Acid and TAG Profiles

Natural sources of MCT are palm kernel oil, coconut oil and milk fat. Some literature mention that MCT can be obtained from palm oil (the flesh of the palm fruit) but in its natural state, the amount of fatty acid with less than 12 carbon is 0.2%, an insignificant amount.

MCT can be produced either through enzymatic (with 1,3 specific or nonspecific enzyme), chemical methods or by fractionation.

The coconut fruit consists of an external husk, a white "flesh or meat" and a nut or stone. The flesh is dried to obtain what is called copra. To achieve this, the fruit is cut in half, the stone remove and the halved coconuts are exposed to the sun for drying, a process that facilitates removing the husk from the flesh. The "dry method" of obtaining coconut oil involves pressing the copra first, and solvent may also be used after the press to obtain more oil. If the oil is not refined, then the oil is called virgin. Typically the oil goes through a refining process for direct human consumption. The processed product is called "RBD coconut oil" to indicate that it has been refined, bleached and deodorized as any other oil for human consumption (Block and Barrera-Arellano, 2009).

Palm kernel oil is obtained from the kernel of the stone in the palm fruit. Similar to coconut, the palm fruit consists of a husk, yellow flesh, and a stone or nut. After harvesting the fruit, the fruit is separated into its flesh and the stone. The flesh is used to obtain palm oil. The stones are extremely hard, allowing for safe transport for processing far from the harvesting region. The dried-stones are cracked to remove the husk and expose the kernels. The kernels are pressed to obtain palm kernel oil and similar to coconut oil, solvent extraction may also be used. The refining process may also be employed to guarantee a product safe (free of pathogens, and physical contaminants) for human consumption.

Milk fat's MCTs are obtained from milk fat but in less quantities than from coconut or palm kernel oil as shown in Table 3.

All three edible oils listed in Table 3 contain a percentage of unsaturated fatty acids as well as palmitic and stearic acid. If the end product is to have only MCT, then those fats/oils must be fractionated or separated in order to obtain the desired MCT triacylglycerides (hydrocarbon chains containing between 6 and 12 carbons) from the rest.

**Table 3** shows the fatty acid profile for milk fat, palm kernel oil and coconut oil

<i>Fatty acid</i>	<i>Milk fat<sup>a</sup></i>	<i>Palm kernel oil<sup>b</sup> (PKO)</i>	<i>Coconut oil<sup>c</sup> (CNO)</i>
4:00	2.6–6.3		
6:00	07.–3.0	0.2–0.4	
8:00	0.4–1.6	3.2–4.7	4.6–10
10:00	1.4–3.2	2.9–3.5	5.0–8.0
12:00	2.4–3.7	45.4–49.8	45.1–53.2
14:00	0.3	15.4–17.2	16.8–10.2
16:00	29.4–39.4	7.9–9.3	7.5–10.2
18:00	12.6–21.1	1.9–2.3	2.0–4.0
Unsaturated	16–26.7	15–21	6–13

<sup>a</sup>Ransom-Painter et al., 1997.

<sup>b</sup>Ibrahim et al., 2003.

<sup>c</sup>Pantzaris and Basiron, 2002.

Fractionation is a process in which the desired TAGs (either high, medium or low melting point) are separated using waterbath or incubators at the different temperatures. By placing the material at particular temperatures, the desired fat-fraction can be removed. This method is used when dealing with coconut and palm kernel oil. In the case of milk fat, different methods can be used to obtain the MCTs: two-stage dry fractionation (Dimick et al., 1996), continuous counter-current supercritical carbon dioxide (Bhaskar et al., 1993) or vacuum filtration (Black, 1975). The goal is to separate TAGs with a short hydrocarbon chain length, hence with low melting point as compared to LCT.

One can see from Table 3 that coconut oil contains more saturated FA than palm kernel oil. More saturated FA can also be seen in the iodine value, which is in the range from 6 to 10 in coconut and 14 to 21 in PKO (Ibrahim et al., 2003). Contrary to those two materials, milk fat contains a good percentage of short chain fatty acids 4:0 which oxidize easily and which can confer a buttery flavor.

## Future Trends

There is a continuous demand of functional foods associated with health benefits. Edible fats are only one kind of these foods. The search for an ideal food that can prevent heart disease, diabetes or help in losing weight is on going.

For the last 30 years, nutritionists had been categorizing edible dietary fats as either “good” or “bad” according to their ability to increase or decrease the amount of low density lipoprotein (LDL) cholesterol or high density lipoprotein (HDL). It has been shown that having high levels of HDL cholesterol in the blood correlates well with a reduction in cardiovascular disease, hence the aim is to consume those fats or oils that can achieve this. In particular, increase amount of saturated fats by humans had been linked to increases in LDL level, while unsaturated fats have been linked with increasing the level of HDL. This has lead the World Health organization to advice the public into restricting the amount of saturated fats that are consumed. However Mensink and co workers (Mensink et al., 2003) showed that saturated fats neither raise nor lower the ratio of total cholesterol to HDL cholesterol. Mensink findings support that lauric acid, the saturated fat present in high percentage in palm kernel oil and coconut oil should not be categorized as a bad “fatty acid”.

The work mention in this section favours many positive physiological and nutritional aspects concerning MCT. These aspects have lead to MCT gaining popularity among high performance athletes as the MCT had been shown to be fast source of nourishment. MCTs are also being used in oils, sports drinks, energy bars, meal replacements and some special baby foods. As more is learned about the health benefits of MCTs, new applications of MCT will be developed.

## Milk Proteins

Ryan Hazlett, Christiane Schmidmeier, and James A O'Mahony, University College Cork, Cork, Ireland

© 2019 Elsevier Inc. All rights reserved.

### Nomenclature

$\alpha$ -LA	Alpha-lactalbumin
AA	Amino acid
$\beta$ -LG	Beta-lactoglobulin
BSA	Bovine serum albumin
Ca	Calcium
CCP	Colloidal calcium phosphate
EtOH-HCl	Ethanol-hydrochloric acid
GMP	Glycomacropeptide
LF	Lactoferrin
MW	Molecular weight
pI	Isoelectric point
SH	Sulfhydryl group
(S-S)	Disulfide bond

### Introduction

Milk is a complex biological fluid secreted by the females of all mammalian species. It is produced to meet the nutritional requirements of the neonate such as delivering the energy, essential amino acids (AA) and micro-nutrients required for adequate growth and development. Depending on the mammalian species, the new-born will have very different nutritional requirements leading to large interspecies differences in gross composition and yield of milk (**Table 1**) (Fox et al., 2015b). Bovine milk (especially from the species *Bos taurus*) is the predominant raw material for dairy products which accounts for ~ 84% of total global milk production and has been subject to extensive characterization (Thompson et al., 2009). Bovine milk proteins and their physical, chemical, functional and nutritional properties will be the focus of this review.

Bovine milk contains ~ 3.4% protein which was initially believed to be in the form of one protein only. Between 1883 and 1885, the Swedish scientist Hammersten (1883) showed that milk proteins could be divided into two groups, casein proteins and serum (whey) proteins, by adjusting the pH of bovine milk to the isoelectric point (pI) of caseins (pH 4.6). At this pH, the casein proteins were found to precipitate from milk while the whey protein fraction remained soluble. Later, studies would establish that both casein and whey protein fractions were in turn composed of a number of different proteins.

The concentrations of these two fractions in the milk of any particular mammalian species again differ, and are presumed to be tailored to the nutritional and physiological requirements of the young (**Table 1**). The whey protein:casein ratio of bovine milk is ~ 20:80 (Jensen, 1995).

### Casein Proteins

Caseins are defined as milk proteins that precipitate from raw skim milk when the pH is adjusted to pH 4.6 (i.e. pI of casein) at temperatures greater than 10 °C. At temperatures less than 10 °C, aggregation of caseins does occur but the aggregates are fine enough to remain in suspension (Fox et al., 2015b).

### Fractionation and Heterogeneity of Caseins

The heterogeneous nature of caseins was first described by Linderstrøm-Lang (1925) who fractionated isoelectric/acid casein using an ethanol-hydrochloric acid (EtOH-HCl) extraction process (O'Mahony and Fox, 2013). The four proteins that were identified from isoelectric casein are:  $\alpha_{s1}$ -,  $\alpha_{s2}$ -,  $\beta$ - and  $\kappa$ -casein, which account for ~38%, ~10%, ~35% and ~15% of total casein, respectively. Variations occur between different casein proteins such as molecular weight (MW) and differences in AA profile (**Table 2**). More subtle variations (e.g. single AA substitutions) may occur in each of the individual proteins also yielding different forms of the same protein, which is termed micro-heterogeneity. All caseins are phosphorylated, i.e., have phosphate groups attached to side chains of serine, threonine and tyrosine (Klump and Kriegelstein, 2002), while  $\alpha_{s1}$ - and  $\alpha_{s2}$ -casein are more highly phosphorylated than  $\beta$ - and  $\kappa$ -casein (typically 8, 11, 5 and 1 phosphate groups, respectively (**Table 2**) (Eigel et al., 1984). The degree of

phosphorylation of each casein protein is commonly included in the abbreviated name of the casein protein, e.g.  $\alpha_{s1}$ -8P,  $\alpha_{s2}$ -11P,  $\beta$ -5P and  $\kappa$ -1P.

Additionally,  $\kappa$ -casein is a glycosylated protein, meaning that carbohydrate moieties (e.g., N-acetylneuraminic acid, galactose and N-acetylgalactosamine) are attached to the C-terminal end of the  $\kappa$ -casein molecule. The extent of glycosylation of  $\kappa$ -casein that occurs can vary; 0–4 glycosides may be present on any given  $\kappa$ -casein protein, yielding 9 different possible molecular forms of  $\kappa$ -casein (Dziuba and Minkiewicz, 1996).

## Properties of Caseins

### Structure and Heat Stability

Caseins are relatively small molecules (MW ranging from 19–25 kDa) that lack high levels of secondary ( $\alpha$ -helices and  $\beta$ -turns) or tertiary protein structures. This is somewhat due to high concentrations of the amino acid proline in the proteins: 17, 10, 35 and 20 proline residues are present in  $\alpha_{s1}$ -,  $\alpha_{s2}$ -,  $\beta$ - and  $\kappa$ -casein, respectively (Swaigood, 1982). Proline inhibits the formation of  $\alpha$ -helices and  $\beta$ -turns due the presence of a cyclic amine in its side chain (Morgan and Rubenstein, 2013). As secondary and tertiary structures are not prevalent in the structural analysis of caseins they are considered to have a non-ordered and open structure (Holt and Sawyer, 1993; Holt et al., 2013).

Protein denaturation occurs when a protein loses its native secondary or tertiary structure, strongly influencing the biological and technological functionality of that protein. As caseins have a low level of secondary or tertiary structure, high temperature treatments have little effect on the caseins, as evidenced by the fact that bovine milk can be heated at 140 °C for ~20–30 min without gelation occurring (Singh and Latham, 1993). Such high heat treatments will, however, have other effects on caseins, such as dephosphorylation of AA (Fox et al., 2015a).

### Hydrophobicity and Calcium Sensitivity

All casein proteins have a high concentration (35–45%) of hydrophobic AAs such as valine, leucine, isoleucine, phenylalanine, tyrosine and proline (Swaisgood, 1982). In structured proteins, hydrophobic AAs are generally buried within the protein's tertiary structure; however, as caseins have an open and unordered structure these AAs remain exposed, which leads to caseins being regarded as having a high surface hydrophobicity (Creamer et al., 1982; O'Mahony and Fox, 2013). Hydrophobic bonds readily form between the hydrophobic regions of caseins leading to caseins having a strong tendency to self-associate (Horne, 1998).

Hydrophobic amino acids are associated with bitterness, meaning that the hydrolysis of casein molecules has the potential to yield bitter hydrolysates, which is problematic in some applications such as cheese production (Lemieux and Simard, 1992). Caseins can act as amphipathic molecules which adsorb readily at air–water and oil–water interfaces in order to reduce interfacial tension, thereby stabilizing emulsions and foams (Dickinson, 1989).

All caseins (excluding  $\kappa$ -casein) are insoluble in the presence of calcium (Ca) which is naturally present at high concentrations in bovine milk (~30 mM; Gaucheron, 2005), it would therefore be expected that caseins would precipitate out of milk due to their insolubility and Ca-sensitivity.  $\kappa$ -casein, which is Ca-insensitive, and soluble, at all Ca concentrations found in dairy products acts to stabilise the other, Ca-sensitive, caseins from precipitation in milk by combining with both Ca and the Ca-sensitive caseins to form large colloidal structures termed casein micelles (Müller-Buschbaum et al., 2007; O'Mahony and Fox, 2013). Although  $\kappa$ -casein only accounts for ~ 15% of total casein protein in milk, it can stabilise up to 10 times its own weight of the Ca-sensitive caseins *via* the formation of the casein micelle (Fox and Brodtkorb, 2008).

### Casein Micelle

Holt et al. (2013) summarized the three main biological functions of the casein micelle, based on its structure and stability. It ensures that very high levels of Ca and phosphate can be secreted from the mammary gland and transported to the neonate by ensuring that these minerals are colloiddally stable in milk (prevents calcified build-up in mammary glands). The micelle also provides a means of safe excretion of the potentially fibrilligenic caseins (may build up in fibril structures causing blockages) through the mammary gland. Finally, the casein micelle also allows caseins to be retained in the stomach of neonates for a length of time required for sufficient proteolysis of the caseins into smaller peptides which can then be more readily absorbed in the small intestine.

The structure of the casein micelle has been widely debated over recent years (De Kruif and Holt, 2003; Horne, 2006, 2008; Farrell et al. 2006; Fox and Brodtkorb, 2008; Dalgleish, 2011; Dalgleish and Corredig, 2012) and different models for the structure of the casein micelle have been suggested and will be discussed briefly below. It is widely agreed that casein micelles are large, spherical (diameter = 50–500 nm) (de Kruif, 1998; O'Mahony and Fox, 2013) and highly hydrated (3.5 kg H<sub>2</sub>O per kg of protein) (Jeurnink and de Kruif, 1993) structures containing ~ 70,000 individual protein molecules. The dry matter of the casein micelle is 94% protein and 6% low MW species, referred to as colloidal calcium phosphate (CCP). This CCP is composed mainly of Ca (~1,400,00 Ca<sup>2+</sup>) and phosphorus (~1,000,000 PO<sub>4</sub><sup>3-</sup>) with small amounts of magnesium, citrate and other species (O'Mahony and Fox, 2013). The external surface structure of casein micelles is rich in  $\kappa$ -casein where it acts to stabilise the micellar structure and protect against destabilization or aggregation of casein micelles (Dalgleish et al., 1989). The glycosylated, hydrophilic C-terminal of the  $\kappa$ -casein molecule (termed macropeptide) can be found protruding ~ 7 nm out of the casein micelle into the aqueous phase of milk. This creates a hairy  $\kappa$ -casein layer surrounding the casein micelle, responsible for micellar stabilization *via* steric and electrostatic repulsion (zeta potential of ~ -20 mV at pH 6.7) (Müller-Buschbaum et al. 2007; O'Regan et al., 2009).

In comparison, the arrangement of  $\alpha$ - and  $\beta$ -casein and CCP within the internal structure of the casein micelle has yielded greater debate in the various models proposed in recent years. The simplest model was proposed initially by Waugh and Von Hippel (1956) and suggested that the  $\alpha$ - and  $\beta$ -caseins are surrounded by a layer of  $\kappa$ -casein. In the intervening period to now, two main models have been developed detailing the internal structure of the casein micelle: the submicelle and the nanocluster model.

The submicelle model was firstly proposed by Schmidt (1982) and suggests that the casein micelle is composed of smaller submicelles fused together by CCP. This model has not generated widespread support as it relies on the hypothesis that there are two forms of submicelle units present in a casein micelle - a  $\kappa$ -casein-rich and a  $\kappa$ -casein-depleted submicelle. The  $\kappa$ -casein-rich submicelles are located at the surface of the micelle, with the  $\kappa$ -casein-depleted submicelles in the internal structure of the casein micelle. Research has never confirmed that these different submicelles actually exist. Following this, the nanocluster model was introduced by Holt (1992, 1998). This model depicts the internal structure of casein micelles as a tangled web of  $\alpha$ - and  $\beta$ -caseins linked by hydrophobic interactions. This casein web contains nanoclusters of CCP (radius of 2.3 nm) which act to stabilize the casein web structure. Dalgleish (1998, 2011) has presented an updated nanocluster model which incorporates large pores within the casein micelle and a more sparse distribution of  $\kappa$ -casein in the  $\kappa$ -casein layer on the surface of the casein micelle.

These pores are large enough to allow (I) easy access to the protruding  $\kappa$ -casein for proteolytic enzymes (important for digestibility and destabilization of caseins) (Diaz et al., 1996) and denatured whey proteins (formation of disulfide linkages between denatured  $\beta$ -lactoglobulin ( $\beta$ -LG) and  $\kappa$ -casein) (Singh and Creamer, 1991; Anema and Li, 2003) and (II) movement of individual proteins in and out of the casein micelle structure (e.g.  $\beta$ -casein leaving and re-entering the micelle on heating and cooling) (Creamer et al., 1977). Both the submicelle and nanocluster models retain the key feature that CCP, which is

**Figure 1** (a) Holt's nanocluster model, depicting an internal protein matrix of  $\alpha$ - and  $\beta$ -casein which contains nanocluster like particles of CCP (●) with steric stabilization provided by the protruding  $\kappa$ -casein at the micelle surface, from [De Kruif et al. \(2012\)](#). (b) Dual-binding model proposed by [Horne \(1998\)](#), depicting the hydrophobic bonding occurring between  $\alpha$ -,  $\beta$ - and  $\kappa$ -casein, as well as the CCP nanocluster bridging.

located within the casein micelle, plays a vital role in stabilizing the Ca-sensitive casein present in the interior of the casein micelle ([Fig. 1](#)).

## Whey Proteins

Whey proteins were traditionally separated from caseins *via* isoelectric precipitation of the caseins by adjusting the pH of milk to 4.6. The whey proteins remained in the soluble phase at this pH, producing a whey stream termed acid whey ([O'Mahony and Fox, 2013](#)). Another common practice for the separation of the whey from the caseins is through the addition of an enzyme preparation such as rennet (primary enzyme chymosin) to milk, as is done during cheese making, which causes the destabilization (cleaving of  $\kappa$ -casein at the micelle surface), aggregation and precipitation of casein micelles (the curd), leaving the whey proteins and glycomacropeptide (GMP) (C-terminal of  $\kappa$ -casein which is cleaved off by chymosin) in the soluble phase. Whey produced *via* enzymatic coagulation of milk is termed sweet whey and contains GMP.

In industrial and lab scale applications, the separation and further enrichment of whey proteins from caseins is routinely achieved using unit operations such as chromatography (e.g., ion exchange chromatography) membrane filtration and centrifugation which exploit the physico-chemical differences (such as molecular weight and charge) between whey proteins and caseins to achieve separation. The form of whey produced from these operations is sometimes termed technical whey.

## Heterogeneity and Fractionation of Whey

Work carried out throughout the 20th century by [Palmer \(1933\)](#), [Sorensen and Sorensen \(1939\)](#), [Gordon and Semmet \(1953\)](#) and [Polis et al. \(1950\)](#) showed that many different whey proteins are present in bovine milk and established that the major proteins of bovine whey are:

- $\beta$ -LG-; (~50% of total whey protein in bovine milk)
- $\alpha$ -Lactalbumin ( $\alpha$ -LA); (~20% of total whey protein in bovine milk)
- Immunoglobulins (Ig); (~10% of total whey protein in bovine milk)
- Bovine serum albumin (BSA); (<10% of total whey protein in bovine milk)
- Lactoferrin (LF); (~1% of total whey protein in bovine milk)

Whey proteins differ in terms of their amino acid composition, size and physicochemical properties (e.g., charge and surface hydrophobicity); however, for the purpose of this review, whey proteins will be discussed as a collective.

## Properties of Whey Proteins

### Structure and Heat Stability

Whey proteins are highly structured with high levels of secondary and tertiary structure.  $\beta$ -LG, which is the predominant whey protein in bovine milk, is highly structured with more than half of its structure existing in the form of  $\alpha$ -helices (15% of  $\beta$ -LG structure) or  $\beta$ -sheets (50% of  $\beta$ -LG structure) ultimately forming a tightly packed globular structure (Whitney, 1988; Kinsella and Morr, 1984a; Creamer et al., 1983), held together strongly by internal disulfide (S-S) bridges. This highly ordered globular structure is common for most of the major whey proteins, and thus whey proteins are very heat-labile as they are susceptible to loss of structure during processing treatments common in the dairy industry (e.g., high heat treatments, and high-pressure homogenization).

On exposure to temperatures greater than 65 °C, whey proteins tend to unfold from their native structure, exposing AAs such as Cysteine (which contains a free sulfhydryl (–SH) group). The now exposed free–SH group is readily accessible and highly reactive, allowing other denatured whey proteins and proteins containing exposed–SH groups (e.g.,  $\kappa$ -casein) to interact and aggregate via the formation of new S–S bonds (Kinsella and Morr, 1984a; Mulvihill and Donovan, 1987; Kinsella and Whitehead, 1989; Singh and Creamer, 1991; Wijayanti et al., 2014).

### Charge and Hydrophobicity

As seen in Table 3, whey proteins contain high levels of polar and charged AAs. Kinsella and Whitehead (1989) stated that proteins with high levels of polar and/or charged AAs, such as whey proteins, interact strongly with water due to their highly hydrophilic nature. Whey proteins, due to their hydrophilic nature are associated with good solubility characteristics and proteins in whey protein isolate have been shown (Pelegrine and Gasparetto, 2005) to be highly soluble over a wide range of pH (Table 4). Due to their heat sensitivity, the solubility of whey proteins is very temperature dependent, as influenced by denaturation and aggregation.

Due to their charge and hydrophilic nature, whey proteins (unlike the caseins) display a very limited tendency to self-associate and are less sensitive to changes in pH and ionic strength when compared to caseins (O'Regan et al., 2009).

## Functionality of Milk Proteins

The functional properties of proteins are defined as physical and chemical properties that influence the behavior of food systems during processing, storage and consumption. Milk proteins have a wide range of functional properties that lend to their application in numerous food systems (Kinsella and Melachouris, 1976; Kinsella and Morr, 1984a). For the purpose of this article, the functional properties, solubility, gelation and surface activity will be of focus for both casein and whey proteins.

**Table 3** Amino acid composition of the major whey proteins in bovine milk

AA	$\beta$ -LG	$\alpha$ -LA	BSA	LF

<sup>a</sup>Whey protein solutions were made by adding ~ 0.5 g of whey protein isolate (94.3% protein) to a volumetric flask and making to 50 mL volume.

## Solubility

The solubility of a protein is defined as the amount of protein that goes into solution or colloidal dispersion under specified conditions (temperature and ionic strength) and does not sediment out by defined centrifugal force (Morr et al., 1985; IDF, 1995). The solubility of a protein is regarded as the most important functional property as it is a prerequisite for many other functional properties and acts as a useful index of overall protein functionality. If a protein has good solubility, its potential applications are naturally expanded (Kinsella and Morr, 1984a; Zayas, 1997c). The solubility of a protein is ultimately decided by a combination of (I) the balance of intermolecular hydrophobic and electrostatic interactions, which themselves, are controlled by surface hydrophobicity and (II) the state (native or denatured) of the protein under specific environmental conditions of temperature, pH and ionic strength (O'Regan et al., 2009).

## Gelation

Gelation refers to the ability of proteins to form a gel under practical conditions during processing or storage of a food product (Zayas, 1997b) and is a very important functional attribute in many food systems, e.g., yoghurt and cheese production. A gel is defined as a system containing a relatively small proportion of solid in a relatively large proportion of liquid, yet the system has mechanical rigidity, thus a protein gel is composed of a three dimensional network of proteins entrapping a large amount of water (Kinsella and Whitehead, 1989). A protein gel is formed when protein molecules are altered in a way which allows unfolding (denaturation) to occur, yielding polypeptide regions which are capable of forming various interactions (protein–protein and protein–water), resulting in a three-dimensional, cross-linked network (O'Regan et al., 2009). The alteration of milk proteins to form gels is most commonly achieved *via* thermal denaturation or enzymatic coagulation.

## Surface Active Properties

Molecules with surface active properties are used routinely in food processing to stabilize emulsions (oil dispersed in water, O/W, or water dispersed in oil, W/O) and foams (air dispersed in a liquid phase) in formulated foods (e.g., mayonnaise, cake batter). In order for proteins to act as surface active agents they must be amphipathic, meaning they contain both hydrophilic and hydrophobic regions (Kinsella and Morr, 1984a). Milk proteins adsorb readily at the interface and surface of emulsions and foams, respectively, and act to reduce interfacial and surface tension between the hydrophobic and hydrophilic phases, in turn stabilizing emulsions and foams (Table 5).

**Table 5** Functionality and applications of milk protein ingredients

	Solubility		Gelation		Surface Activity	
	Casein	Whey	Casein	Whey	Casein	Whey
<b>Description</b> (Kinsella and Melachouris, 1976; Kinsella and Morr, 1984b; Zayas, 1997a; O'Regan et al., 2009)	<p>-Soluble to high conc. at pH values outside of pH 4–5 (casein pI = 4.6).</p> <p>-Caseins' heat stability allows them to remain soluble after heat treatment.</p> <p>-Solubility improved by use of calcium chelators (e.g., citrates).</p>	<p>-Soluble over entire pH range encountered in food applications (at low ionic strength).</p> <p>-Solubility decreases at high ionic strength due to salting out effect (de Wit and van Kessel, 1996).</p> <p>-Thermal denaturation and aggregation causes a reduction/loss in solubility.</p>	<p>-Casein gels are formed from milk by acid and enzymatic coagulation</p> <p>-Rennet gelation occurs via proteolysis of the <math>\kappa</math>-casein layer of the casein micelle leading to micelle destabilization and aggregation.</p> <p>-Acid gelation of casein occurs on adjustment of pH to 4.6 (pI of caseins) and produces gels that are prone to syneresis (whey expulsion).</p>	<p>-Due to their heat labile nature, whey proteins have excellent thermal gelation properties.</p> <p>-The characteristics (hardness, elasticity and turbidity) of the gels formed is dependent on the solution environmental conditions: mainly pH and ionic strength.</p>	<p>Both types of milk proteins are known to have high surface-activity properties leading to their use as emulsion and foam stabilizers in food applications.</p> <p>Caseins, due to their open structure, allow for a large surface coverage at the interface/surface of an emulsion or foam.</p> <p>The emulsion properties of both casein and whey proteins are improved via conjunction with polysaccharides as forming a polysaccharide portion on the interface protruding outwards into the emulsion continuous phase, increasing steric stabilization of the emulsified droplets (Drapala et al., 2016).</p>	<p>Whey proteins, in their native globular state, adsorb in thicker films at the interface/surface of emulsions or foams. Denatured whey protein aggregates are associated with enhanced surface activity.</p>

	Solubility		Gelation		Surface Activity	
	Casein	Whey	Casein	Whey	Casein	Whey
<b>Applications &amp; Ingredients</b> (O'Regan et al., 2009)	<u>Beverages</u> Caseins used in nutritional beverages which require high heat treatments for protein fortification -Sodium caseinate	<u>Beverages</u> Whey proteins are used in the production of protein beverages due to their solubility over a wide pH range. –WPC, WPI	<u>Dairy Products</u> The formation of a casein gel is a core step in the production of cheese. Different cheese varieties are produced depending on the gelation mechanism (enzymatic vs acid)	<u>Dairy Products</u> Some cheese varieties such as ricotta are produced by forming a whey protein coagulum/curd using heat and acid gelation.	<u>Beverages</u> Caseins, due to their stability, are used as emulsifiers and stabilizers in cream liqueurs which is a challenging environment. -Sodium caseinate	<u>Beverages</u> Whey protein solubility at low pH lends to their use as emulsifiers in protein fortified fruit juices or soft drinks which contain volatile oil flavor compounds. –WPC, WPC
	<u>Dairy Products</u> Caseins and caseinates are commonly used in the production of analog cheese where one of their main functions is to bind water and emulsify oil. -Rennet casein, acid casein	<u>Bakery Products</u> Due to their solubility, whey proteins are incorporated into baked goods to retain water and to provide additional functionality. –WPC	Both caseins and whey proteins are utilized in the production of yoghurts. This not only improves the nutritional value of the yogurt but also allows increased yield, viscosity and gel strength (reduced syneresis)		<u>Dairy Products</u> In the production of table spreads, a water in oil emulsion is created. Emulsifiers are used to stabilise this emulsion but due to the very high level of oil in the dispersed phase, casein ingredients are used to further provide stabilization to the emulsion. -Sodium caseinate	<u>Bakery Products</u> Whey protein ingredients are used as a replacement for egg proteins in many bakery applications as both very effectively stabilise foams (e.g. meringues). –WPC, WPI
	<u>Meat Products</u> Caseins act to bind large amounts of water, assisting in fat emulsification and improving the final texture in the production of processed meat. -Sodium caseinate	<u>Confectionary Products</u> Protein-rich bars are produced with whey protein ingredients to increase their level of protein and to control texture via their water binding capabilities (Hogan et al., 2012) -Hydrolyzed WPC	Casein gelation occurs and is vital in the production of kefir which is a fermented dairy beverage. As fermentation occurs the pH of the kefir drops which causes acid induced gelation leading to an increase in the beverage viscosity.	<u>Textured Products</u> Whey proteins are used in the production of surimi due to their gelation properties, as a replacement for beef plasma protein or potato starch (Hsu and Kolbe, 1996). –WPC		<u>Meat Products</u> Fat used in processed meat product production is pre-emulsified with whey proteins to allow for the formation a strong fat containing gel network during cooking. –WPC

## Nutritional Properties of Milk Proteins

### Delivery of Amino Acids

The main nutritional function of bovine milk proteins is to act as the principal source of nitrogen and amino acids which are required for growth and maintenance of protein synthesis (Tipton and Wolfe, 2001). Amino acids are classified as essential or non-essential, with Rose et al. (1948) defining essential amino acids as those which cannot be synthesized in sufficient amounts by the body to maintain growth or nitrogen balance. Milk proteins have a high biological value as all essential amino acids (Histidine, lysine, phenylalanine, leucine, threonine, valine, tryptophan, methionine and isoleucine) are present at relatively high levels in the major milk proteins ( $\alpha_{s1}$ -,  $\alpha_{s2}$ -,  $\beta$ -,  $\kappa$ -CN,  $\beta$ -LG and  $\alpha$ -LA) (Table 3). Whey proteins have higher levels of essential AAs (Hambraeus and Lönnerdal, 2003) while caseins, in addition to delivering AAs, play a vital role in delivery of calcium *via* the CCP in casein micelles.

### Biologically-Active Proteins and Peptides

Biologically-active compounds are those that affect biological processes, beyond the nutritional value, in a way which has an impact on body function. For milk proteins, the proteins themselves, as well as the peptides formed from their proteolytic digestion, may be biologically active. For the purpose of this review the effect that milk proteins and peptides have on the immune, cardiovascular and nervous systems will be discussed.

Milk proteins and peptides that have a beneficial effect on the immune system are termed as either immunomodulatory or antimicrobial. Immunoglobulins (whey proteins) are an example of immunomodulatory proteins, and are in fact a family of proteins with varied structure and functions; however, their structures and functions critically revolve around their ability to identify and bind specific antigens presented by bacteria and viruses which aids host protection (Schroeder et al., 2010). During proteolytic breakdown of LF in the stomach by pepsin, an antimicrobial peptide, lactoferricin, is formed which targets Gram-negative bacteria and binds to their cell wall. Once attached to the cell wall, lactoferricin causes the release of lipopolysaccharides, which irreversibly damages the cell wall, leading to further morphological changes to the structure and function of the Gram-negative bacteria (Bellamy et al., 1992; Appelmek et al., 1994; Tomita et al., 2002).

Antithrombotic milk peptides have a positive effect on the human cardiovascular system. These peptides are mainly formed during the enzymatic break down of  $\kappa$ -casein and have been shown to interrupt the formation of thrombi which, when formed, can block veins, arteries or the chambers in the heart (Clare and Swaisgood, 2000; Mills et al., 2011).

The nervous system of newborn infants has been shown to be affected by opioid peptides from milk, which obtain their name due to pharmacological similarities to opium. The major opioid peptides of milk are formed during the proteolytic digestion of  $\beta$ -casein and are called  $\beta$ -casomorphins, which are thought to be biologically potent (Teschemacher et al., 1997; Clare and Swaisgood, 2000).  $\beta$ -casomorphins have only been found in the intestinal tract and blood plasma of newborn infants and have yet to be identified in children or adults. The specific activity of  $\beta$ -casomorphins is somewhat unclear, while it has been shown to be associated with stimulating food intake and increasing the output of insulin in infants (Xu, 1998; Mills et al., 2011).

# Bioavailability of Minerals (Ca, Mg, Zn, K, Mn, Se) in Food Products

Mitra Nosratpour and Seid Mahdi Jafari, Gorgan University of Agricultural Sciences and Natural Resources, Gorgan, Iran

© 2019 Elsevier Inc. All rights reserved.

## Introduction to Minerals

Minerals as essential micronutrients are required for maintaining normal metabolic functions in human body. These chemical elements are classified as either major or trace elements, which are needed in larger or fewer amounts for the body, respectively. Some examples of major minerals are calcium (Ca), magnesium (Mg), and potassium (K), while some trace minerals are manganese (Mn), selenium (Se), and zinc (Zn). All the aforementioned minerals exist in specific food sources; moreover, they are vital for the health of bones, teeth, and structural parts of enzymes, which are explained briefly in [Table 1](#). Despite all the key roles of minerals in the body, they have to be consumed on a regular basis with a balanced diet. Therefore, having enough information about recommended dietary allowance (RDA) for these minerals is vital, which is provided in [Table 1](#) ([Lukaski, 2004](#)). Human requirements for essential minerals vary from a few micrograms per day up to about 1 g per day. Ca with an average RDA of 1200 mg per day has the highest RDA among minerals, and it needs to be consumed to be beneficial for health and bones ([Heaney, 1993](#)). Whereas Se with an average RDA of 30 µg per day for an adolescent has the lowest RDA, in which this Se level is essential for growth and development of a human body. However, consuming the minerals greater than the maximum tolerable intake leads to the toxicity symptoms. On the other hand, consuming less than the recommended intake can lead to the specific deficiencies ([Motarjemi, 2013](#)). The various side effects of toxicity and deficiencies for different minerals in our body are also shown in [Table 1](#).

## Bioavailability of Minerals

The total mineral content of foods is not a useful indicator of its available amounts in the body through absorption, since only a certain quantity is bioavailable ([Jafari and McClements, 2017](#)). The bioavailability of major and trace minerals is defined as the proportion of the ingested minerals, which is absorbed and available for metabolic functions. The bioavailability of minerals is varied from less than 1% to more than 90%, and it is a key factor to food effectiveness. The reasons that influence mineral bioavailability are the chemical form of the minerals in foods, chelating agents, redox activity of food components, mineral–mineral interactions, and physiological state of consumers ([Miller, 2007](#)). As a main rule, the mineral bioavailability in the body is associated with digestion, release from food matrix, absorption rate of the minerals by intestinal cells, and its transport to body cells ([Fairweather-Tait, 1993](#)).

## Bioavailability Enhancers

Organic acids, including ascorbic, citric, and lactic acids, can enhance the mineral bioavailability. Their effect is dependent on the food composition, type, and concentration of mineral and the concentration of organic acids. They can form soluble chelates with minerals, which protect the minerals from precipitation and bind to other inhibitors ([Miller, 2007](#); [Suh et al., 2003](#)).

## Bioavailability Inhibitors

Phytates are the main storage form of plant seeds known as potent inhibitors and chelators, limiting the bioavailability of particularly divalent and trivalent minerals ([Hurrell, 2004](#)). High levels of phytates are mainly found in cereals, legumes, roots, and vegetables ([Sandberg, 2002](#)). Polyphenolic compounds also decrease the mineral bioavailability, which exist in foods such as tea, coffee, and many vegetable and fruit extracts ([Graham et al., 2001](#); [Yeung et al., 2003](#); [Zijp et al., 2000](#)).

## Bioavailability of Major Minerals (Ca, K, and Mg)

The concentration of Ca in the food products and the existence of inhibitors and enhancers of Ca absorption determine the absorption of Ca from foods ([Weaver and Plawecki, 1994](#)). The prime dietary inhibitors of Ca absorption are oxalate and phytate; therefore, the poor Ca bioavailability is dedicated to the spinach and pinto beans due to their high concentrations of oxalate and phytate, respectively. Whereas dairy products are classified in food groups with the high bioavailability of Ca.

Potassium is generally absorbed well within the body up to 90% because of its high water solubility ([Agarwal et al., 1994](#)). Therefore, there is not a lot of information about its absorption from different foods.

The efficiency of Mg absorption varies largely depending on Mg intake, from 25% to 75% in high- and low-intake groups, respectively ([Schwartz et al., 1984](#); [Seelig, 1982](#); [Spencer et al., 1980](#)). High intakes of fiber result in lower Mg absorption because of the inhibitory effect of phytate associated with fiber. However, the high concentration of Mg in phytate and cellulose-rich products increases Mg intake and compensates the decrease in its absorption ([Kelsay et al., 1979](#)).

**Table 1** Food sources, functions, recommended dietary allowance (RDA) (Joint FAO/WHO, 2005), deficiency, and excessive intake effects of minerals

<i>Minerals</i>	<i>Food sources</i>	<i>Main functions</i>	<i>RDA (per day)</i>	<i>Deficiency effects</i>	<i>Excessive intake effects</i>
<b>Major minerals</b>					
Calcium (Ca)	Milk and dairy products, fortified juices, tofu, kale, broccoli, legumes	Essential for healthy bones and teeth, skeletal growth and development, nerve transmission, insulin release, blood coagulation	Men 1000 (mg) Women 1000 Children 500–700 Pregnant women 1200	Increased colon cancer risk, hypertension, osteoporosis and growth arrest	Hypercalcemia (nausea, kidney stones, constipation) and in extreme conditions coma and death
Magnesium (Mg)	Milk and dairy product, seafoods, nuts and seeds, legumes, leafy and green vegetables, unrefined cereal grains, chocolate,	Proper maintenance and growth of bones, cofactor for numerous enzyme, plays a vital role in proper functioning of nerves and muscles	Men 260 (mg) Women 220 Children 60–100 Pregnant women 220	Muscle cramps, weakness, nausea, tremors, anxiety, high blood pressure, and respiratory disorders	Rarely occurs, intestinal distress: diarrhea, cramping, nausea
Potassium (K)	Meats, fish (salmon), milk, yogurt, fresh and dried fruits and vegetables, whole grains, legumes	Nerve transmission, proper fluid balance, muscle contraction, maintains normal blood pressure, and waste elimination	No RDA	Gastrointestinal disorders, depression, and confusion	Rarely occurs
<b>Trace minerals</b>					
Manganese (Mn)	Seafoods, fish, hazelnut, seed (pumpkin), beans, tea (black, brewed), spinach, brown rice, raisin, almonds, tofu	Bone development, a part of many enzymes, important for the normal functioning of the brain and proper activity of nervous system, useful for postmenopausal women	Men 2.3 (mg) Women 1.8 Children 1.2–1.9 Pregnant women 2	Hypocholesterolemia, dermatitis, and weight loss	Extrapyramidal, amidal movement disorders, and hallucinations
Selenium (Se)	Skim milk, salmon, shrimp, chicken, beef, pork, and crab meat, Brazil nuts, brown rice, wheat bread	A component of special proteins in the body called antioxidant enzymes; stimulation of the immune system involved in conversion of thyroxine; protecting the organism from various viruses	Men 34 (μg) Women 26 Children 17–21 Pregnant women 28	Myalgias, cardiomyopathies, increased risk for some cancers	Nausea, diarrhea, and alteration in mental status and loss of hair and nails
Zinc (Zn)	Milk and dairy products, red meat, poultry, shellfish, oyster, dried beans, nuts, whole grains, soy food	A cofactor in metalloenzymes, a regulation of gene expression, growth and development of human body	Men 12 (mg) Women 10 Children 5–8 Pregnant women 12	Growth retardation, poor wound healing, delayed sexual maturation, impaired immune response	Inhibition of Cu and Fe absorption, impaired immune response

### Bioavailability of Trace Minerals (Mn, Se, and Zn)

The absorption of Mn is generally less than 5%. However, the Mn bioavailability has not been studied widely in humans. Ca, fiber, and phytate make an insoluble complex with Mn, leading to an increase in the requirement of Mn and decrease the available soluble fraction of Mn for absorption (Keen and Zidenberg-Cherr, 2003).

The Se absorption is fairly high, around 80%, but it depends on the existence of other trace minerals and proteins. It has been recognized that the total bioavailability of Se is around 14% of the original content in the food (Tsuji et al., 2016).

Zn is found in many diets. However, its bioavailability varies widely. Animal-based foods have more Zn bioavailability than grain-based products. This reason is all because of phytic acid that is found in whole grains and legumes; it binds to Zn and decreases Zn absorption from dietary sources. Thus, people with vegetarian diets need 50% more dietary Zn than nonvegetarians because of the large amounts of phytates consumption (Bel-Serrat et al., 2014).

### Effect of Food Processing on Bioavailability of Minerals

During food processing and storage, minerals are subjected to light; moisture; oxygen; various processing techniques including heating, soaking, grinding, germination, fermentation; and so on. These conditions can substantially influence the mineral bioavailability and degradation of special trace minerals by deactivating enzymes that degrade inhibitors or by generating insoluble mineral compounds. However, these treatments can also increase the mineral bioavailability and diffusion through separation, partitioning, or destroying inhibitors and transforming food components into complex ligands for metal ions (Gibson et al., 2006; Watzke, 1998).

Table 2 shows some bright and dark sides of different processing operations on the mineral bioavailability of food products.

### Fortification and Enrichment of Food Products With Minerals

Despite an ideal condition of food diversity and availability in many parts of the world, lots of people in low-income countries suffer from mineral deficiencies. Among varieties of methods for controlling mineral malnutrition, fortification is an advantageous strategy and long-term solution, which can satisfy peoples' nutritional needs in both developing and developed countries. FAO and WHO define food fortification as enrichment or addition of one or more nutrients to foods, even if it is naturally present in that food, with the aim of preventing or correcting nutrient deficiencies in a population. To make a plan for food fortification, some conditions should be considered: the whole process needs to be cost-effective and safe. Moreover, the selected food vehicles depend on their affordability and availability in all season; therefore, the foods are usually chosen from staple foods in which the specified amount of them are regularly consumed in the local diet. The minerals and their available fortified foods are shown in Table 3 (Fathima et al., 2017). Furthermore, the whole process of fortification should have no adverse effects on the sensory properties of the final products, with an increase in absorption and bioavailability of minerals, also with positive effects on consumers' healthiness (Gharibzahedi and Jafari, 2017a). With these aims and conditions, there are some suitable fortification methods, including mineral biofortification, direct addition of minerals to processed foods, and nanoencapsulation.

#### Mineral Biofortification

Biofortification is a breeding process of specific crops such as rice, wheat, beans, and other cereals and legumes, with the aim of enhancing both their mineral density and bioavailability. Mineral biofortification is implemented at the growing phase of agricultural crops (Dwivedi et al., 2012). Many researchers have focused on biofortification of Zn, Ca, and Se, since they are considered as limiting minerals in plant-based diets (Kim et al., 2006; Kutman et al., 2010; Morris et al., 2008; Park et al., 2005; Poblaciones and Rengel, 2016; Ram et al., 2016; Ramos et al., 2010; Thavarajah et al., 2015).

#### Direct Addition of Minerals

Direct addition of minerals prior to food consumption is another fortification method. One of the main benefits is that the minerals can be protected from different degradation factors during food processing, since they can be sprayed on the finished products.

Ca, as one of the essential major minerals, has lots of salutary properties, and its deficiency can lead to many diseases that are shown in Table 1. Therefore, it is vital to fortify foods with this mineral to improve its absorption and availability. However, fortification with major minerals may cause undesirable interactions in food structures such as coagulation and precipitation, which can lead to the chalkiness and bitter taste in the finished products (Singh et al., 2007). For choosing suitable Ca sources in foods, a variety of properties such as Ca level, solvability, bioavailability, and sensory characters of the whole product needs to be considered. Some Ca sources for milk and dairy products are calcium carbonate ( $\text{CaCO}_3$ ), calcium phosphate ( $\text{Ca}(\text{PO}_4)_2$ ), calcium lactate ( $\text{C}_6\text{H}_{10}\text{CaO}_6$ ), and so on (Münchbach and Gerstner, 2010).

Regarding trace minerals, some foods are fortified with sodium selenite ( $\text{Na}_2\text{SeO}_3$  or  $\text{Na}_2\text{O}_3\text{Se}$ ) and sodium selenate ( $\text{Na}_2\text{O}_4\text{Se}$ ), to increase Se bioavailability and reduce its deficiencies (Van Dael et al., 2001). Zn deficiency is one of the most common shortages in the world. Since beef, poultry, and fish are the best sources of Zn, population with predominantly plant-based diet is faced with

**Table 2** Impact of different processing techniques on the bioavailability of minerals

<i>Food processing techniques</i>	<i>Food products</i>	<i>Influence on mineral content</i>	<i>References</i>
Autoclaving	Lentils grown in Egypt	Significant reduction in calcium (Ca), potassium (K), magnesium (Mg), and copper (Cu) contents	Hefnawy (2011)
Baking	Fortified whole wheat flour	Decrease in manganese (Mn), Cu, and zinc (Zn) contents	Akhtar et al. (2010)
Baking	Bread from selenium (Se)-enriched whole meal/white flour	Without any significant reduction in selenomethionine content after bread processing and production	Hart et al. (2011)
Blanching	Spinach leaves	Increasing HCl extractability of Zn and Ca	Yadav and Sehgal (1995)
Cooking	Mineral enriched carrots	Improving the contents of major and trace minerals	Biezanowska-Kopeć et al. (2016)
Canning	Different processed foods	Complex destruction	Ranhotra and Bock (1988)
Debittering	Lupin seeds	High decrease in minerals and 71.4% phytic acid removal	Ertaş and Bilgiçli (2014)
Dehydration	Cabernet and Merlot grapes	Increasing the contents of major and trace minerals	Panceri et al. (2013)
Drying	Egg white	Maillard reaction, denaturation of binding proteins	Leahey and Thompson (1989)
Extrusion	Extruded foods	Inactivation of phytase enzyme	Mercier (1993)
Fermentation	Leavened bread	Decrease of phytate content	Gibson et al. (1998)
Fermentation	Milk	Increase Zn and Ca bioavailability in iron-fortified dairy products	Drago and Valencia (2002)
Freezing	Leafy vegetables	High retention of mineral constituents	Lisiewska et al. (2009)
Germination	African yam bean	Decrease of phytate content	Ene-Obong and Obizoba (1996)
Grilling	African catfish	Increase of mineral contents	Ersoy and Özeren (2009)
Microwave cooking	Lentils grown in Egypt	Lesser decrease of minerals than other preparation methods	Hefnawy (2011)
Microwave cooking	Cereals and green leafy vegetables	A considerable decrease in the bioavailability of Se	Khanam and Platel (2016)
Pressure cooking	Cereals and green leafy vegetables	A considerable decrease in the Se content	Khanam and Platel (2016)
Radiation	Cucumber	High mineral sensitivity of minerals to different doses of irradiation	Rahman et al. (2015)
Soaking	Brown rice	A significant decrease in Zn content	Albarracín et al. (2013)
Soaking	Maize flour	Activate endogenous phytase, reduce phytate levels, and improve zinc protoporphyrin	Manary et al. (2002)
Sonication	Apple juice	Increase in K, Mg, Cu, and Zn	Abid et al. (2014)
Refrigerated storage	Fruits and vegetables	Decrease in Ca, Mn, Zn, and Cu during storage	Bouzari et al. (2015)

**Table 3** Minerals and their associated fortified foods

<i>Minerals</i>	<i>Available fortified foods</i>
Calcium	Fortified orange juice, fortified milk and soy milk, fortified cereals (raisin bran, corn flakes), enriched breads, grains, and waffles
Magnesium	No fortified foods available
Potassium	No fortified foods available
Manganese	Cereals
Selenium	Noodles, milk, meat, cereals, flour, salt, sports drinks, and baked products
Zinc	Cereals, wheat flour, maize meal, corn/soy blend, and wheat/soy blend

Zn shortages with lots of side effects. Therefore, fortification of cereal staple foods with Zn could benefit this population (Badii et al., 2012). Some common Zn types for food fortification are zinc oxide (ZnO), zinc sulfate (ZnSO<sub>4</sub>), zinc acetate (C<sub>4</sub>H<sub>6</sub>O<sub>4</sub>Zn), and zinc chloride (ZnCl<sub>2</sub>) (Kahraman and Ustunol, 2012).

### Nano/Microencapsulation of Minerals

Nano/microencapsulation is a novel technology that involves coating a bioactive compound into a matrix at different capsule sizes. Encapsulation improves the retention time of the minerals in the food products and leads to the controlled release of minerals within the body. In general, nanoencapsulation can be a new delivery system for minerals and compensate many weaknesses of the direct addition method, since it can cover and mask the undesirable flavor of minerals and increase their bioavailability, water solubility, and physicochemical stability (Katouzian and Jafari, 2016; Pegg and Shahidi, 1999).

In recent years, nanoencapsulation of Ca, Zn, and Mg has attracted lots of attention. The encapsulated form of Ca, Mg, and Zn has been used in soy milk, dairy products, and additive supplements, respectively (Bonnet et al., 2009; Hirotsuka et al., 1984; Öner et al., 1988; Saeidy et al., 2014). Despite some efforts about fortification of bakery products with minerals, nanoencapsulation strategy can be implemented more and more for different minerals to incorporate them in various food products and widen the variety of fortified foods for people's consumption (Gharibzadeh and Jafari, 2017b).

### Conclusion

This article provides a useful and synopsis information about some minerals including Ca, Mg, and K as major minerals and Mn, Se, and Zn as trace ones, their bioavailability, and fortification strategies. Since bioavailability and absorption of minerals are roughly depending on dietary enhancers, inhibitors, and different processing techniques, there is a wide range of efficiency in mineral absorption. To overcome these weaknesses and have balanced and adequate mineral consumption, different fortification strategies have been conducted. However, because of significant differences between sensory properties of fortified foods with direct addition of minerals and original ones, some new technologies have been appeared. These technologies can encapsulate the minerals and protect them from different conditions until suitable release. Mineral encapsulation gives assurance to the food industries for improving their food production, packaging, shelf life, and bioavailability without changes in nutritional and sensory quality of their products. However, there is still a wide scope of demands on research about efficient fortification and encapsulation methods to have the highest bioavailability for minerals and to cure lots of mineral insufficiency all over the world.

## Introduction

Monoglycerides (MGs), diglycerides (DGs), and their derivatives account for about 70% of the total world production of emulsifiers and are widely used in food, detergent, plasticizer, cosmetic and pharmaceutical formulations, thus they are considered as the most important group of emulsifiers (Krog, 1997). In food science and nutrition, MGs have been investigated from at least four aspects: molecular structures and physical properties, preparation methods, functional properties, and applications in the food industry. Different types of MGs have different molecular structures and physical properties. There are mainly two kinds of preparation methods of MGs: chemical synthesis and enzymatic synthesis. Additionally, MGs have many functional properties, e.g., antimicrobial activity, emulsibility, and self-assembly in aqueous systems, and thus have various applications in the food industry. Although there were numerous independent studies on MGs, very limited information about an overall summarization was known. A specific review of MGs is necessary for a current understanding of the structures, properties, production, and industrial applications of MGs.

## Categories, Structures and Physical Properties of Monoglycerides

MGs can be divided into two categories: 1-monoglyceride (also named  $\alpha$ -monoglyceride) and 2-monoglyceride (also named  $\beta$ -monoglyceride) according to the position of the acyl group in MGs (Fig. 1) (Susi et al., 1961). Under different temperature conditions, the saturated 1-monoglyceride usually has four different polymorphic forms: sub  $\alpha$ ,  $\alpha$ ,  $\beta$ , and  $\beta'$  (Lutton, 1971; Vereecken et al., 2009). MGs in  $\alpha$  form are unstable and have active chemical property, which contributes to their emulsification of shortening into the water phase, as well as aids in the incorporation of air into the fat phase (Goldstein et al., 2012; Heertje et al., 1998). MGs crystallize directly in the  $\alpha$  polymorph, and they transition from  $\alpha$  polymorph to sub  $\alpha$  polymorph after being cooled at 35–50 °C (Vereecken et al., 2009). However,  $\alpha$  and sub  $\alpha$  polymorphic forms can transform into a more stable  $\beta$  polymorph during longtime storage at ambient temperatures, making it widely used in the design of firm food products such as fat spreads (Heertje et al., 1998; Vereecken et al., 2009). The  $\beta'$  polymorph is only formed during quick crystallization by using specific solvents, and it cannot be observed by differential scanning calorimetry (DSC) (Hagemann, 1988). On the other hand, 2-monoglyceride is only in one form (the  $\beta$  polymorph) due to its symmetric molecular structure (Susi et al., 1961; Vereecken et al., 2009).

MGs can also be divided into saturated MGs (e.g., glyceryl monostearate and glyceryl monopalmitin) and unsaturated MGs (e.g., glyceryl monooleate and glyceryl linoleate) depending on the degree of saturation of fatty acids attached to the glycerol (Alfutimie et al., 2014). Saturated MGs have greater ability to initiate fat crystallization and better emulsifying ability than unsaturated MGs, while unsaturated MGs have better health functional properties and are better at displacing protein from the interface than saturated MGs (Barford et al., 1991; Davies et al., 2001). Additionally, unlike saturated 1-monoglycerides, unsaturated 1-monoglycerides can only exist in the  $\beta$  polymorphic form (Vereecken et al., 2009).

According to the chain length of fatty acids attached to the glycerol, MGs can also be divided into short-chain MGs containing fatty acids with less than eight carbon atoms, medium-chain MGs containing fatty acids with eight to twelve carbon atoms, and long-chain MGs containing fatty acids with more than twelve carbon atoms. Long-chain MGs (e.g., monopalmitin, glyceryl monostearate, glyceryl monooleate, and glyceryl behenate) only have emulsifying ability, while medium-chain MGs (e.g., glyceryl monocaprylate, monocaprin, and monolaurin) have not only emulsifying ability but also antibacterial activity (Petschow et al., 1996).

Table 1 shows the structures and physical properties of some common MGs in the food industry. As the chain length of fatty acids increase, the melting point of MGs also increases and the physical appearance of MGs gradually harden (from an oily fluid into a hardened fat and then a waxy solid). Conversely, the hydrophilic property of MGs is inversely proportional to the number of carbon atoms of fatty acids. However, all kinds of MGs have strong lipophilic properties.

Figure 1 The structures of  $\alpha$ -monoglyceride and  $\beta$ -monoglyceride.

**Table 1** Structures and physical properties of some common monoglycerides

Name	Structural formula	Chain length	Degree of saturation	Physical appearance	Melting point (°C)	Hydrophilic property
Glyceryl Monocaprylate	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_6-\text{CH}_3$	C <sub>8</sub>	Saturated	Viscous liquid	40–42	Slightly dissolve in water, and dissolve in ethanol
Monocaprin	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_8-\text{CH}_3$	C <sub>10</sub>	Saturated	Fatty solid	48–55	Insoluble in water, but dissolve in ethanol
Monolaurin	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_{10}-\text{CH}_3$	C <sub>12</sub>	Saturated	Fatty solid	52–62	Insoluble in water, but dissolve in ethanol
Monopalmitin	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_{14}-\text{CH}_3$	C <sub>16</sub>	Saturated	Fatty solid	65–68	Insoluble in water, but dissolve in ethanol
Glyceryl Monostearate	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_{16}-\text{CH}_3$	C <sub>18</sub>	Saturated	Waxy solid	62–64	Insoluble in water, but dissolve in ethanol
Glyceryl Behenate	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_{20}-\text{CH}_3$	C <sub>22</sub>	Saturated	Waxy solid	65–77	Insoluble in water and ethanol
Glyceryl Monooleate	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_7-\text{CH}=\text{CH}-(\text{CH}_2)_7-\text{CH}_3$	C <sub>18</sub>	Unsaturated	Liquid	35	Insoluble in water, but dissolve in ethanol
Glyceryl Linoleate	$\text{CH}_2\text{OH}-\text{CHOH}-\text{CH}_2-\text{OOC}-(\text{CH}_2)_7-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-(\text{CH}_2)_4-\text{CH}_3$	C <sub>18</sub>	Unsaturated	Liquid	–	Insoluble in water

### Preparation Methods of Monoglycerides

The direct esterification of glycerol with fatty acids, the glycerolysis (also named the interesterification), and the hydrolysis of triglycerides (TGs) are the three most important processes for the preparation of MGs (Pouilloux et al., 1999). According to the type of catalyst used in these processes, preparation methods of MGs fall into two main categories: chemical synthesis (using homogeneous acid, basic, or metal oxide catalysts) and enzymatic synthesis (using lipase catalysts). However, the final product is usually a mixture of MGs, DGs, and TGs as well as free glycerol, fatty acids, and catalysts (Kuhrt et al., 1950). MGs are usually a minor constituent in the mixture, but only they have emulsifying ability (Kuhrt et al., 1950). Thus, preparation methods are constantly being improved, and the separation and purification technologies have been used to produce MGs with high purity (Fregolente et al., 2007; Kuhrt et al., 1950).

#### Chemical Synthesis of Monoglycerides

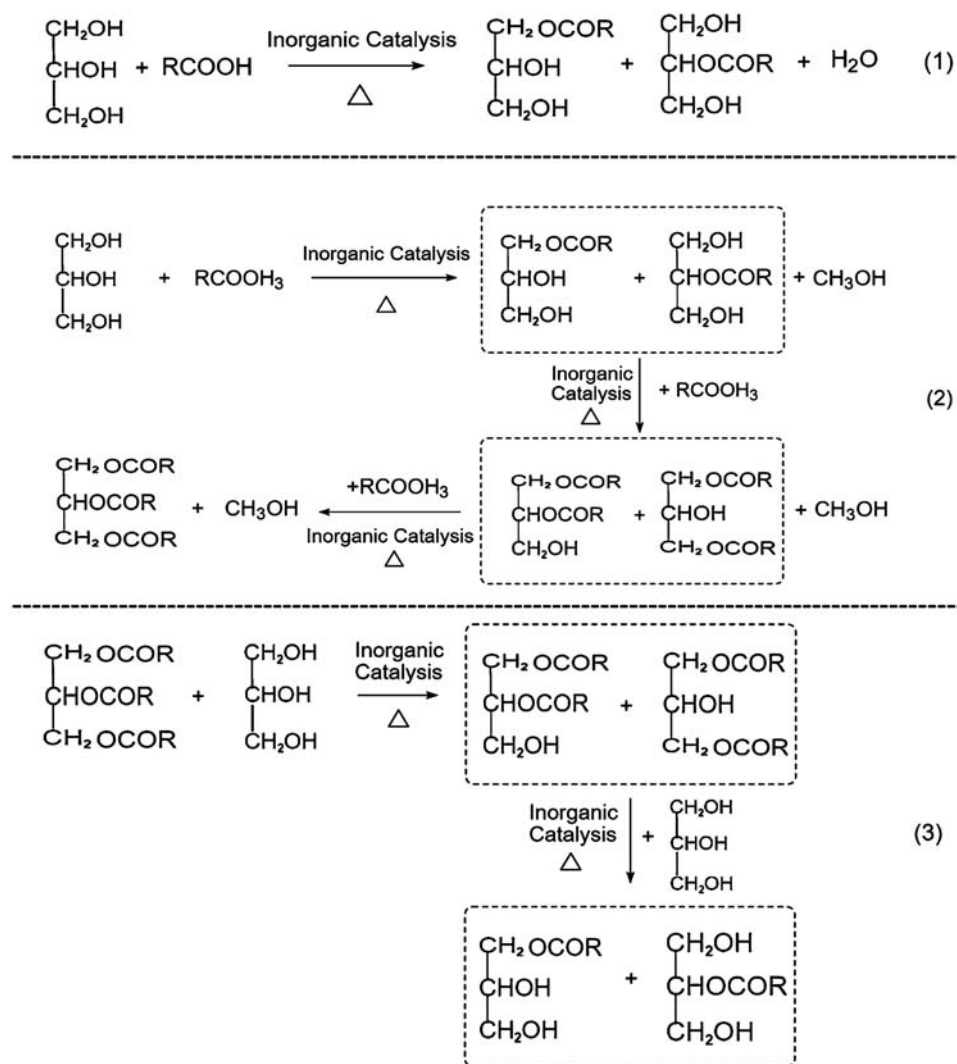

Fig. 2 presents the schemes of the esterification and the glycerolysis of chemical synthesis of MGs. The direct esterification of glycerol with fatty acids has been known since the mid-19th century (Kuhrt et al., 1950). An acid catalyst (e.g.,  $\text{H}_2\text{SO}_4$  and  $\text{H}_3\text{PO}_4$ ) or a base catalyst (e.g., NaOH) is required for the esterification (Corma et al., 2005). However, this process was considered uneconomic because of rising prices of fatty acids, which made the glycerolysis preferred. Additionally, the glycerolysis is less corrosive, and has a higher miscibility of reactants and lower level of acidic contaminants in the final products than the esterification (Siri-nguan and Ngamcharussrivichai, 2016). In the glycerolysis, glycerol is transesterified with fatty acid methyl esters or triglycerides (the major components in vegetable oils and animal fat). In addition, a base catalyst (e.g., KOH, NaOH, and  $\text{Ca}(\text{OH})_2$ ) is required for this process (Corma et al., 2005).

The main advantage of chemical synthesis is the short reaction period (2–3 h) (Siri-nguan and Ngamcharussrivichai, 2016). However, this reaction is carried out at relatively high temperatures (220–250 °C), which involves high-energy consumption. In addition, high temperature and the use of homogeneous catalysts usually lead to undesirable side reactions and produce dark colored by-products with an undesirable flavor, and thus results in low monoglycerides selectivity (40%–50%) with poor quality (Wee et al., 2013). Thus, separation and purification technology is required to purify MGs from the mixture, which is complicated and energy consuming (Wee et al., 2013).

In recent years, researchers used severe novel heterogeneous acidic catalysts (e.g., Keggin type heteropoly acid and silicotungstic acid) or solid metal oxides (e.g., MgO and ZnO) impregnated on support materials (e.g., molecular sieves, activated carbon, silicon dioxide, clay, titanium, and zeolites) as catalysts to produce MGs (Hoo and Abdullah, 2016; Yu et al., 2003). This process has many advantages: increased surface area of catalysts, high monoglyceride selectivity, environmental friendliness, ease of catalyst separation and hence inexpensive product purification processes (Hoo and Abdullah, 2016; Simsek et al., 2015). However, it is more time consuming than using acid or base catalysts (Ferretti et al., 2010). Additionally, protected glycerol (e.g., 1,2-O-isopropylidene glycerol) was also used to instead glycerol to produce highly pure MGs (Yu et al., 2003).

#### Enzymatic Synthesis of Monoglycerides

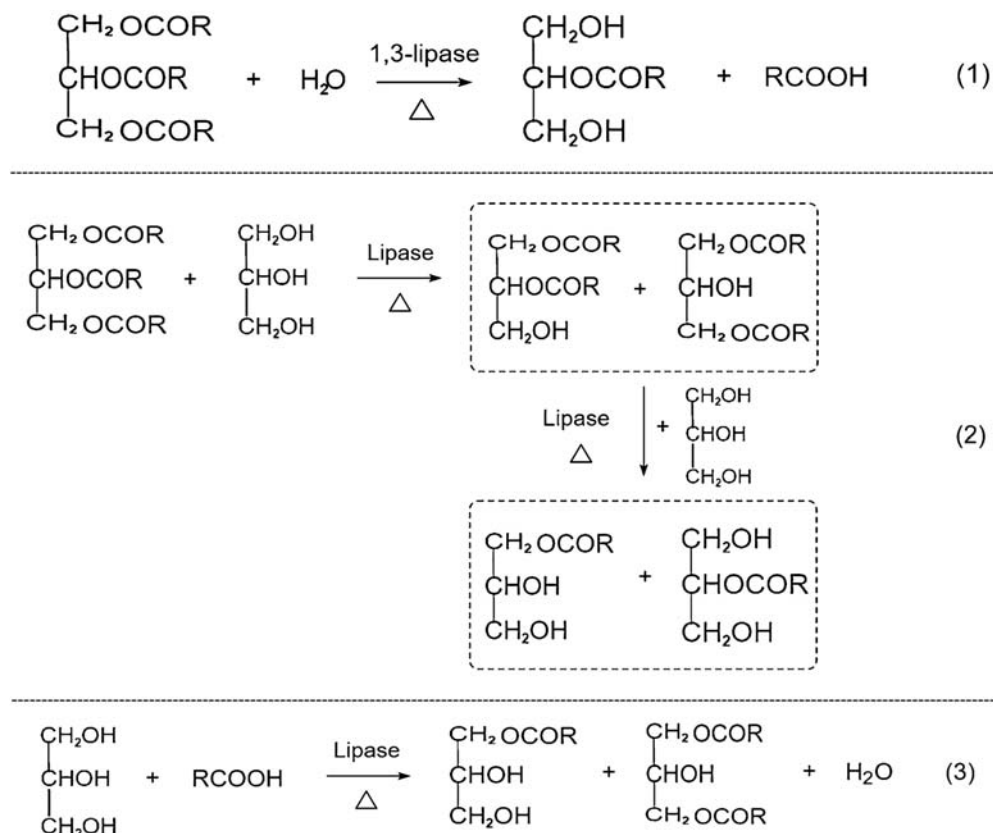

Over the last decades, enzymatic synthesis of MGs has received increasing attention. Lipase-catalyzed selective hydrolysis of triglycerides, glycerolysis, and direct esterification of glycerol with fatty acids are the three most important enzymatic processes for

**Figure 2** Chemical methods for preparation of monoglycerides: (1) direct esterification of glycerol with fatty acids (Pouilloux et al., 1999), (2) glycerolysis of fatty acid methyl ester with glycerol (Ferretti et al., 2012), and (3) glycerolysis of triglycerides with glycerol (Corma et al., 1998).

the preparation of MGs (Fig. 3) (Zhao et al., 2011). In the process of hydrolysis, TGs are converted to 2-monoglycerides in a selective manner by 1,3-regiospecific lipases (Holmberg and Osterberg, 1988). One problem of this process is the low yield of MGs, because 2-monoglycerides usually convert to 1-monoglycerides by acyl migration that can be further hydrolyzed by 1,3-regiospecific lipases to glycerol and fatty acids. Thus, most studies focused on the enzymatic glycerolysis and esterification in different reaction systems, including organic solvent systems (Cetina et al., 2011), solvent-free systems (Zhao et al., 2011), supercritical carbon dioxide systems (Rezaei and Temelli, 2000), and reversed micelle systems (Fan et al., 2010) with immobilized enzyme or free enzyme. In the processes of esterification and glycerolysis, organic solvents are usually used to form aqueous-organic two-phase systems or microemulsion, and thus improve mutual miscibility of the glycerol-fatty acids-lipases mixture or the glycerol-oil-lipases mixture (Yahya et al., 1998). However, the use of organic solvents may lead to pollution, produce various undesirable effects on enzyme molecules, and bring additional separation steps for solvent removal. Thus, solvent-free systems and supercritical carbon dioxide systems can be used to avoid these problems (Esmelindro et al., 2008). However, in the solvent-free systems, the concentrations and viscosity of the reactants are high, thus affecting the yield of MGs. And in supercritical carbon dioxide systems, the non-polarity of carbon dioxide can lead to improper dissolution of both hydrophobic and hydrophilic compounds (Esmelindro et al., 2008). This problem can be solved by reverse micelles, which are nanometer-sized aqueous or polar dispersion in a polar media in which the interface is controlled by surfactants/cosurfactants (Hayes and Gulari, 1991). In this technology, the lipases are encapsulated into reverse micelles, which provide large degree of interface area. However, organic solvents are also necessary in this technology.

The reaction temperature of enzymatic synthesis has a big influence on the yield of MGs. Many studies suggested that enzymatic synthesis must be carried out below a critical temperature ( $T_c$ ), which depends on the type of fat and is related to the melting point

**Figure 3** The enzymatic methods for preparation of monoglycerides: (1) lipase-catalyzed selective hydrolysis of triglycerides (Holmberg and Osterberg, 1988), (2) glycerolysis of triglycerides with glycerol (Wongsakul et al., 2003), and (3) direct esterification of glycerol with fatty acids (Multzsch et al., 1994).

of the fat (Mcneill et al., 1992). At a higher temperature than  $T_c$ , the yield of MGs is approximately 30%, while at a lower temperature than  $T_c$ , the yield of MGs can reach up to > 70% (Mcneill et al., 1990).

Compared to chemical synthesis, the advantages of enzymatic synthesis are milder reaction conditions, higher yields, lower energy consumption, more pure products, and stronger positional specificity (Freitas et al., 2010; Lee et al., 2004), however drawbacks also exist. The enzymatic processes are time consuming and complex (Lin et al., 1999). Another disadvantage is that it is difficult to separate the enzyme from the products (Avander et al., 1992). Immobilized lipases can be used to solve this problem, but they are uneconomic (Elfman-Börjesson and Häröd, 1999). Additionally, although enzymatic synthesis has been shown to be quite successful in producing long-chain MGs, it may not be applicable to the preparation of short-chain MGs because of the high acidity of short-chain fatty acids (Lee et al., 2004).

## Functional Properties of Monoglycerides

### Self-assemble in Water or Organic Liquids

MGs are insoluble in water but can swell and self-assemble into four liquid crystal phases: the coagel (the  $\beta$ -gel), gel phase (the  $\alpha$ -gel), liquid-crystalline lamellar phase ( $L_\alpha$ ), and cubic phase, depending on water content and temperature (Alberola et al., 2006). At room temperature, when a small amount of water was added to MGs (usually less than 5%, w/w), MGs-water system is in the form of isotropic fluid with a relatively low viscosity in coexist with the gel phase (Chen and Terentjev, 2011; Sagalowicz et al., 2006). With the increase in water content, the liquid-crystalline lamellar phase (approximately 10%, w/w) and cubic phase (approximately 15%, w/w) are formed (Sagalowicz et al., 2006). The phase transition of MGs in water are also dependent on the temperature for the formation of gel phase ( $T_G$ ) and the Krafft temperature of the system ( $T_K$ ), which is defined as the melting temperature of an amphiphilic component (Alberola et al., 2006; Luzzati et al., 2010) (Fig. 4). Above the  $T_K$ , layers between the polar head group of crystalline MGs are penetrated by water molecules, thus forming the liquid-crystalline lamellar phase in the presence anionic co-surfactant. With further increases of temperature (above 80 °C), the cubic phase is formed (Chupin et al., 2001). Below the  $T_G$ , the liquid-crystalline lamellar phase converts into the gel phase. The gel phase is not thermodynamically stable, and subsequently transforms into the coagel (Van Duynhoven et al., 2005). When the temperature of the system is between

**Figure 4** The effect of the temperature for the formation of gel phase ( $T_G$ ) and the Krafft temperature of the system ( $T_K$ ) on monoglyceride phase transitions in water (Alberola et al., 2007).

$T_G$  and  $T_K$ , the liquid-crystalline lamellar phase can also slowly convert into the coagel (Alberola et al., 2006). In this changing process, water is fully expelled from the crystal lattice.

The liquid-crystalline lamellar phase and the cubic phase are considered promising crystal phases for food applications. The liquid-crystalline lamellar phase can form a fat-like gel network, and thus encapsulating large amounts of food ingredients (Calligaris et al., 2013; Wang and Marangoni, 2015). The cubic phase is usually highly viscous and can also be used to the preparation of controlled release systems due to its adhesive property (Stonewall et al., 2017).

In organic liquids, MGs can also self-assemble themselves to form organogels, which are thermoreversible, anhydrous, and viscoelastic materials with a three-dimensional supramolecular network (Da Pieve et al., 2010). When MGs are mixed with organic liquids, inverse bilayers are formed and subsequently grow and organize into lamellar platelet microstructures and eventually convert into a continuous three-dimensional network via capillary forces containing the liquid (Chen et al., 2009; Chen and Terentjev, 2009). MGs organogels can be used as organogelators for unsaturated oils with plastic structures (Zheng et al., 2016), oil migration inhibitors (Hughes et al., 2009), and vehicle for the delivery of lipophilic bioactive compounds in the food industry (Da Pieve et al., 2010).

### Emulsifying Property

MGs are very common emulsifiers in the food industry, due to their hydrophilic head (the hydroxy of glycerol) and hydrophobic tail (the tail of fatty acid). At the air–water interface, GMs can form closely packed Langmuir monolayers (Pantoja-Romero et al., 2016). At the oil–water interface, crystallized GMs self-assemble to lamellae to form walls (hydrogel) surrounding oil droplets (Manzocco et al., 2012). However, MGs are low polar emulsifiers and have weak solubility in water, thus co-emulsifiers (e.g., fatty acids, and sodium salts of fatty acids) are usually used to increase their dispersibility in water (Hughes et al., 2009).

The molecular structure of MGs influences their chain packing and emulsifying stability at the air–water or oil–water interface (Shen et al., 2008). Many researchers indicated that emulsions or foams stabilized by unsaturated MGs or short-chain MGs are less stable due to the desorption and collapse than those stabilized by saturated MGs or long-chain MGs (Rodríguez Patino et al., 1999). Additionally, saturated MGs are better initiators of fat crystallization than saturated MGs (Zhang and Goff, 2005). Saturated MGs can accelerate fat crystallization by inducing heterogeneous nucleation, which is essential for the production of edible fat products with desirable melting and crystallization properties (Daels et al., 2015). On the other hand, unsaturated MGs are considered better destabilizing agents of the protein stabilized-emulsion than saturated MGs, and promote partial coalescence of fat globules, which contributes to the formation of a fat network (Zhang and Goff, 2005).

Mixing MGs with other types of emulsifiers (e.g., sodium caseinate and  $\beta$  lactoglobulin) is a good method to improve mutual emulsifying property (Cho and Cornec, 1999; Doxastakis and Sherman, 1984). Additionally, concentration and particle size of each emulsifier have significant effects on the structures of mixtures. For instance, after mixing MGs (low molecular weight) with proteins (high molecular weight), the adsorption of proteins at air–water interface was enhanced with in a shorter time possibly due to the

interaction between proteins and MGs. However, after a long time, a densely packed monolayer formed by MGs completely displaces proteins, possibly because of the surface pressure and exclusion effects (Cho and Cornec, 1999).

### Antimicrobial Activity and Antivirus Effect

Medium-chain MGs (especially monolaurin) are regarded as safe and “natural” antimicrobial preservatives (Branen and Davidson, 2004). They have significant inhibitory effects on fungi (e.g., *Aspergillus niger*, *Saccharomyces cerevisiae*, and *Penicillium italicum*) (Altieri et al., 2007; Nikolovska, 2012), Gram-positive spoilage bacteria (e.g., *Staphylococcus* and *Lactobacillus* species) (Blaszyk and Holley, 1998; Fu et al., 2009) and pathogenic bacteria (e.g., *Bacillus cereus*, *Staphylococcus aureus* and *Listeria monocytogenes*) (Kabara, 2010; Stecchini et al., 1996). The mechanism is that the hydrophobic tail (the tail of fatty acid) of MGs can attach to cell membranes and puncture them, thereby altering membrane permeability and disrupting the cell metabolic activity (Altieri et al., 2007). However, Gram-negative bacteria are resistant to MGs because Gram-negative bacterial cell walls are protected by an outer membrane (Branen and Davidson, 2004; Proctor and Cunningham, 1988). Combining MGs with other antimicrobials (e.g., nisin (Branen and Davidson, 2004), herbs (Hamed et al., 2014), lactoperoxidase (McLay et al., 2002), and ethylenediamine-tetraacetic acid (Sadiq et al., 2016)) can increase their antimicrobial effects and even inactivate Gram-negative bacteria.

In addition, MGs have been found to possess antiviral activity. For instance, monocaprin has been shown to be effective against enveloped viruses, such as vesicular stomatitis virus, herpes simplex virus and human immunodeficiency virus type 1 (HIV-1) (Schlievert et al., 2008). In addition, unsaturated MGs (e.g., glyceryl monooleate) were found to be extremely potent inactivators of enveloped viruses (Sands et al., 1979). Future research may focus on the clinical use of these MGs as virucidal agents after addressing the technical challenges, such as the poor solubility in aqueous buffer solutions, and the sensitivity to the concentration (e.g., critical micelle concentration) and environmental factors (Jackman et al., 2016).

### Applications of Monoglycerides in the Food Industry

MGs are mainly used in bread, accounting for approximately 40% of all MGs used in the food industry (Van de Walle et al., 2008). There are two main advantages for using MGs in bread. First, MGs can be used with oil to reduce the overall fat and saturated/trans fat intake and so reduce the health and economic burden of overweight, obesity and their clinical sequelae (Calligaris et al., 2013). In addition, MGs possess the capacity to favor oil spreading over flour and the anti-stale properties based on their ability to complex with the major starch components, amylose and amylopectin (Calligaris et al., 2013; Sawa et al., 2009). Thus, MGs can improve dough machining properties, enhance slicing performance and achieve superior bread quality (e.g., increased bread volume and bread crumb softness, and reduced bread stale) (Inoue et al., 1996). Generally, the chain length of MGs can influence their anti-stale performance in bread. Longer chain MGs (e.g., glyceryl monomyristate, monopalmitin, and glyceryl monostearate) perform better than monolaurin with shorter chain length and glyceryl behenate with a very long chain length (Sawa et al., 2009).

Approximately 20% of all MGs are used in sponge cakes and cakes (Van de Walle et al., 2008). Saturated MGs can be used to reduce the overall fat content in cakes and increase bread volume probably due to the interaction between MGs and proteins and their increased foaming properties (Kuhrt and Welch, 1950; Manzocco et al., 2012). However, the use of unsaturated MGs in sponge cakes leads to a less voluminous and harder structure (Vereecken et al., 2010). In addition, MGs have some adverse effects on the quality of cakes, such as increased water-loss during reheating or storage, crunchier crust, higher acrylamide content and higher tendency to going stale, probably because of the development of a peculiar system morphology promoted by hydrogel incorporation in the food matrix (Cloke et al., 1984; Manzocco et al., 2012).

MGs can also be used as dough conditioners and amylose complexing agents in noodles (Charutigon et al., 2008). Many studies indicated that noodles prepared with MGs showed induced stickiness, higher cooking time, lower cooked weight and lower cooking loss (Charutigon et al., 2008; Kaur et al., 2005). The presence of MGs in noodles probably leads to the restricted supply of water to the starch granules and thus prevents the swelling of starch granules to their full extent, and thereby increasing cooking time and reducing cooking weight (Kaur et al., 2005). In addition, the complexes formed by the interaction between MGs and the amylose may result in lower cooking losses and longer cooking time of noodles (Kaur et al., 2005; Moorthy, 1985).

Saturated MGs and unsaturated MGs have different effects at different stages of ice cream preparation. In the first step, the preparation of a protein-stabilized oil-in-water emulsion, although MGs are not required to aid emulsification, they are still added and function as follows (Davies et al., 2000; Govin and Leeder, 2010). During the low temperature aging step, the surface tension between the fat and the water phases decreases due to MGs crystallization, and protein molecules are displaced by MGs due to their lower molecular weight, which make the fat droplets more susceptible to subsequent destabilization (Davies et al., 2000). However, the competitive adsorption of unsaturated MGs against proteins is better than saturated MGs, which makes unsaturated MGs better destabilizing agents (Barford et al., 2010; Johansson and Bergenstahl, 1992). During the concomitant freezing/whipping step, partial coalescence or fat destabilization contributes to the formation of a fat network, and crystallization of emulsified oil occurs in this step also (Méndez-Velasco and Goff, 2012). However, saturated MGs are better initiators of fat crystallization than unsaturated MGs (Davies et al., 2000).

Furthermore, MGs are also used in cookies (Goldstein and Seetharaman, 2011), margarines (Vereecken et al., 2010), cheese (Bunka et al., 2007), and sausages (Kouzounis et al., 2017). The function of MGs in cookies is similar to that in bread (Goldstein and Seetharaman, 2011). On the other hand, MGs act as emulsifiers and structural stabilizers in margarines, cheese and sausages,

due to their good emulsifying performance and the property of self-assembling to create a gel with “fat-like” properties (Alfutimie et al., 2015; Kouzounis et al., 2017).

## Conclusions

We can conclude that the structures of MGs (e.g., chain length and degree of saturation of fatty acids attached to the glycerol) have a big effect on their physical (e.g., the polymorphism, melting point, physical appearance, and hydrophobicity) and chemical (e.g., the self-assemble, emulsifying property, antimicrobial activity, and antivirus effect) properties, and thus their applications in the food industry. We also found that the esterification and the glycerolysis used in both chemical and enzymatic processes are the two most common methods for the preparation of MGs. However, many problems associated with both chemical and enzymatic processes remain to be solved. In addition, there is a need for further studies elucidating the interactions between MGs and other polymers (e.g., proteins, fat, and starch), properties of these complexes and their applications in the food industry.

### Introduction

Muscle proteins are an important part of the diet in many cultures, as they make up the major proportion (other than water) of lean meat. These proteins provide most of the texture, color and nutritive value of meat and most meat products. In life, muscle proteins provide motive power to the animal. Following slaughter, muscle tissue forms meat.

Meat and meat products are today regarded in the developed world as a luxury, and in many Western countries meat consumption is on the decline due to both the price and the environmental cost. But strong demand for meat and meat products is expected to continue because of strong meat-eating traditions in many cultures, a general recognition of meat as one of the best sources of high quality bioaccessible protein and iron, and a general preference for the textures and flavors of meat-containing dishes. Further to this, meat plays an important part in many developing countries, particularly meat from pigs and chickens that can convert waste materials, and from ruminants that can convert plant materials that are inedible to humans, into high quality food.

### Structure of Muscle

Skeletal muscles consist of multinucleated muscle fibers made up of bundles of elongated myofibrils in a parallel configuration (Fig. 1) (Gault, 1992; Strasburg et al., 2008). Depending on animal species, muscle size and anatomical location, muscle fibers differ in length (a few millimeters to 30 cm), diameter (10  $\mu$ m to 100  $\mu$ m), and orientation (parallel or at a specific angle to the length). Most of the skeletal muscles are composed of muscle fiber type I, IIA, IIX and IIB (Pette and Staron, 2000; Schiaffino and Reggiani, 2011; Spangenburg and Booth, 2003). These muscle fiber types are characterized based on their contraction speed (slow-twitch or fast-twitch) and preferred metabolic pathway for glycogen degradation (glycolytic or oxidative). Different muscle types vary in ATPase activity, which reflects their contractile characteristics as well as enzyme activities involved in their metabolic pathways. Type I fibers are slow-twitch, red, with oxidative metabolism; type IIA fibers are fast-twitch, red, with intermediate (oxidative glycolytic) metabolism; whereas type IIB and IIX fibers are fast-twitch, white, with glycolytic metabolism (Lefevre et al., 1999; Peter et al., 1972).

A muscle fiber is ensheathed by a fine connective tissue layer, the endomysium, which contains blood capillaries and nerves. Each muscle fiber is composed of a few dozen myofibrils and is enclosed by the muscle plasma membrane, called the sarcolemma, which is made up of a phospholipid bilayer with embedded proteins, glycoproteins and glycolipids. The myofibrils are bathed in sarcoplasm containing several nuclei, sarcoplasmic reticulum, Golgi apparatus, mitochondria, lysosomes, glycogen granules, enzymes and other soluble constituents, that are vital for muscle function. The sarcoplasmic reticulum acts as a calcium ion reservoir for muscle contraction. Bundles of muscle fibers are organized into fascicles that are encased in another layer of connective tissue containing larger blood vessels and nerves called the perimysium. Several fascicles are assembled into a whole muscle by an outer layer of connective tissue known as the epimysium, which extends into tendons to join the muscles and bones together.

Unlike those of terrestrial animals, the muscles of fish are much shorter and are segmented into myotomes by a fine connective tissue layer called the myocommata, or myosepta, as depicted in Fig. 2 (Johnston, 2001; Venugopal and Shahidi, 1996). Each myotome consists of muscle fibers organized in parallel to the length axis of the fish body. Fish muscle fibers are enclosed by the sarcolemma. However, the connective tissue of the extracellular matrix in fish fuses with myocommata at the myotome-myocommata junction, in contrast to terrestrial animal muscles, that are tapered into a tendon.

Regardless of the animal species, myofibrils in muscle fibers consist of longitudinal myofilaments comprising thick and thin filaments (Fig. 3) (Strasburg et al., 2008; Tortora and Derrickson, 2013). Thick filaments are made up of myosin molecules and several cytoskeletal proteins such as titin, while thin filaments are composed of actin, tropomyosin and troponin. Alternating light isotropic (I-band) and dark anisotropic (A-band) bands are seen on myofibrils under a polarized light microscope. At ultrastructural scale, each I-band is separated into two by a dark and narrow band called the Z-disk. The region between two Z-disks is known as a sarcomere, which is the repeating longitudinal contractile unit of the myofibril. A sarcomere comprises an I-band consisting purely of thin filaments, an A-band containing alternatively overlapping thin and thick filaments, an H-zone that is in the center region of the A-band, where the thin filaments are absent, and an M-line that is in the middle of the H-zone. When a muscle contracts, the Z-disks shift closer together due to shortening of the I-bands, and the length of the sarcomere is decreased (Gault, 1992).

Skeletal muscle proteins can be classified into myofibrillar (50%–60%), sarcoplasmic (30%) and stromal (10%–20%) proteins, based on their solubility at varying salt concentrations (Strasburg et al., 2008).

## Myofibrillar Proteins

The myofibrillar proteins consist of contractile, structural and regulatory proteins (Hopkins, 2014). The contractile proteins are myosin and actin, which form the thin and thick filaments that control the skeletal muscle contraction and relaxation. The regulatory proteins include troponin and tropomyosin. The structural proteins comprise mainly titin, nebulin,  $\alpha$ -actinin,  $\beta$ -actinin, tropomodulin, desmin, filamin, C-protein, H-protein and myomesin.

## Contractile Proteins

Myosin (molecular weight of 520 kDa) is a filamentous protein that forms the thick filaments of muscle cells and is the principal protein of the A-band (Gault, 1992; Strasburg et al., 2008). A myosin molecule has a quaternary structure consisting of six subunits, which include two myosin heavy chains (MHC), two essential myosin light chains (MLC1) and two regulatory myosin light chains (MLC2), with molecular weights (MW) of approximately 220 kDa, 23 kDa and 20 kDa correspondingly (Clark et al., 2002; Swartz et al., 2009). Each myosin molecule can be hydrolyzed by enzymatic digestion into two portions, which are light meromyosin (LMM) and heavy meromyosin (HMM) (Fig. 4) (Choi and Kim, 2009; Pearson and Young, 1989a; Strasburg et al., 2008). LMM

**Figure 2** Schematic drawing of fish muscle displaying the orientation of myotomes and myocommata.

is important for the construction of thick filaments from myosin molecules while HMM is responsible for the regulation of ATPase activity and actin binding ability. HMM can be further broken down into fragment S1 and S2 where the former contains the globular myosin heads with the binding site of MgATP and actin, while the latter comprises the  $\alpha$ -helix region which binds both MLC1 and MLC2. In adult mammalian skeletal muscle, there are primarily four MHC isoforms, namely MHC I, IIa, IIb, and IIx, which exist in pure slow-twitch fiber type I, fast-twitch fiber type IIa, IIb and IIx, correspondingly (Kohn et al., 2007; Pette and Staron, 2000). Hybrid fiber types containing different myosin isoforms have also been reported.

Actin (molecular weight of 42 kDa) is the building block of thin filaments and is present in two forms namely globular actin (G-actin) and filamentous actin (F-actin) (Gault, 1992; Strasburg et al., 2008). F-actin is formed by the polymerization of G-actin into double-stranded, coiled filaments. F-actin is bound to tropomyosin and troponin as shown in Fig. 5.

During muscle contraction, actin binds myosin to form actomyosin cross-bridges, which activate the myosin ATPase, leading to the pulling of thin filaments by myosin toward the M-line, resulting in shortening of the sarcomere (Lawrie, 2006).

### Regulatory Proteins

Tropomyosin and troponin are two main proteins that regulate muscle contraction and relaxation (Choi and Kim, 2009; Zot and Potter, 1987). They prevent the activation of actomyosin ATPase in the absence of calcium ions by interacting with actin filaments to block the myosin binding site. Tropomyosin is a long, coiled protein (MW 65 kDa) that comprises two  $\alpha$ -helix polypeptide subunits, called  $\alpha$ - and  $\beta$ -tropomyosin. Tropomyosin molecules bind head-to-tail along the F-actin filament. Each tropomyosin molecule is attached to a troponin complex (MW 80 kDa) which is made up of troponin C (MW 18 kDa), troponin I (MW 21 kDa) and troponin T (MW 31 kDa) (Fig. 5). Troponin C acts as the calcium binding site; troponin T connects troponin complex to tropomyosin while troponin I inhibits actomyosin ATPase activity when it is bound to actin (Lehman and Craig, 2008). At high calcium ion concentration, calcium ions bind to Troponin C, which initiates a conformation change in the tropomyosin-troponin complex, dislocating troponin I, allowing the action of actomyosin ATPase for muscle contraction.

### Structural Proteins

The structural proteins control the filamentous structure and integrity of myofibrils (Fig. 3) (Obinata et al., 1981). Titin, also known as connectin, with a molecular weight of 4200 kDa, serves as the backbone of thick filaments in the A-band. It also acts as a molecular spring in the I-band, which provides elasticity to the sarcomere during muscle contraction (Fig. 3) (Labeit and Kolmerer, 1995).

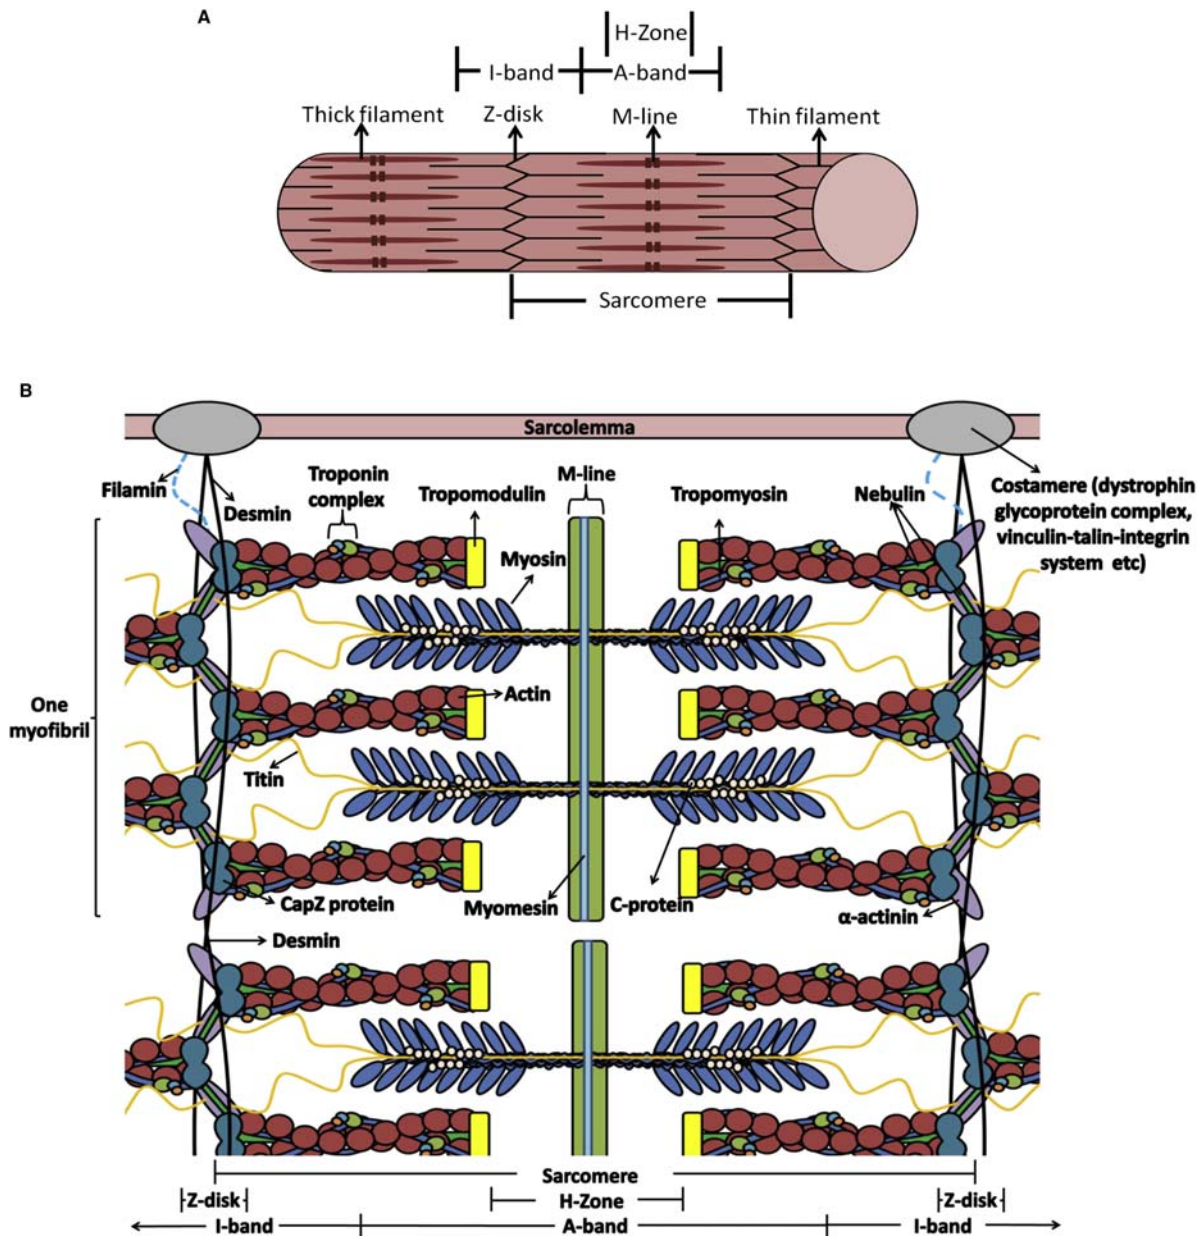

Nebulin (MW 800 kDa) is a structural protein that regulates the length of the thin filaments (McElhinny et al., 2003; Strasburg et al., 2008).

$\alpha$ -Actinin (MW 95 kDa) is the principal constituent of the Z-disk, supporting and attaching actin to the Z-disk (Obinata et al., 1981).

$\beta$ -Actinin, also known as CapZ protein, is a heterodimer consisting of  $\alpha$ - and  $\beta$ -subunits (MW 37 and 34 kDa respectively). It binds  $\alpha$ -actinin in the Z-disk and prevents network formation between the actin filaments (Swartz et al., 2009).

Tropomodulin (MW 40 kDa) binds tropomyosin and actin as well as controlling the length of thin filaments by maintaining the number of G-actin monomers (Clark et al., 2002).

Both desmin (MW 55 kDa) and filamin (MW 300 kDa), play a major role in linking the myofibrils to the sarcolemma as well as stabilizing muscle structure (Capetanaki et al., 1997; Strasburg et al., 2008; Vander Ven et al., 2000).

(Eds), *Fennema's Food Chemistry*, fourth ed. CRC Press, Boca Raton FL, pp. 923–973.

C-protein (MW 140 kDa) and H-protein (MW 58 kDa) are myosin-binding proteins that are found in the A-band of thick filaments (Koretz et al., 1993; Xiong, 1997). These proteins are believed to contribute to the alignment and stabilization of the thick filaments.

Myomesin (MW 185 kDa) is the major protein in the M-line. It is responsible for the binding of titin and myosin and for maintaining the structure of the thick filaments.

## Stromal Proteins

Stromal proteins constitute the connective tissue, which provides mechanical support and protection to the muscle in the form of tendons, epimysium, perimysium and endomysium (Fig. 1) (Gault, 1992). Connective tissue is composed mainly of collagen (90%) along with other fibrous proteins including elastin, laminin and fibronectin, and proteoglycans (Chagnot et al., 2012; Voermans et al., 2008). Connective tissue contains different types of cells, including fibroblasts, macrophages, lymphoid cells, mast cells and eosinophils. Collagen and elastin are bound to an amorphous ground substance formed by proteoglycans and glycoproteins for the reinforcement of the connective tissue network.

## Collagen

Collagen is the predominant stromal protein in skeletal muscles and is synthesized by fibroblasts (Bailey and Light, 1989; Duance et al., 1977; Gault, 1992). It is classified into four major types based on its aggregation characteristics: striated and fibrous (Types I, II, III, V and XI); non-fibrous and network forming (Type IV); microfibrillar or filamentous (Type VI), and fibril-associated collagen (Type VII) (Bailey, 1991).

Collagen consists of three polypeptide alpha chains with -Gly-X-Y- repeating units, where X is commonly proline and Y can be any amino acid (except tryptophan), but is often hydroxyproline, that coil to create a triple helix structure, forming tropocollagen (Astruc, 2014a; Bailey and Light, 1989; Gault, 1992; Strasburg et al., 2008). Tropocollagen molecules are polymerized into collagen fibers via covalent intermolecular cross-links that offer substantial tensile strength to collagen fibers. As the collagen fibers age, the divalent reducible cross-linkages interact to form mature trivalent, non-reducible, more heat-stable cross-links, which further enhances their stability and mechanical strength.

Collagen has been linked to the toughness of muscle-based food, and its content and extent of cross-linking differ among different animal species and breeds, age, muscle function, history of exercise and treatment with growth promoter (Strasburg et al., 2008). Small aquatic animals like fish generally have a lesser amount and less cross-linking of collagen compared to larger terrestrial animals that require higher weight-bearing strength. Some authors have reported an increase in meat toughness as the animal aged due to an increase in collagen cross-linking and a decrease in collagen solubility (McCormick, 1999; Purslow, 2005; Taylor, 2004). It was also found that the tender meat cut, bovine Longissimus dorsi, contains only half to two-thirds of the total collagen content and hydroxylslypyridinoline cross-links of that found in the tougher cut, Biceps femoris. Various studies have shown improved meat quality by partial solubilization of collagen in tough meat cuts such as Semitendinosus (Christensen et al., 2011a,b; Combes et al., 2004; Sullivan and Calkins, 2010).

## Elastin

Elastin is a minor constituent of connective tissue that offers elasticity to the blood vessels and ligaments in the muscles (Debelle and Alix, 1999). Elastin is an insoluble, hydrophobic, heat-stable and cross-linked protein fiber that behaves in a highly elastic manner in the presence of water. Elastin content varies among different muscle types. In Semitendinosus muscle, epimysium and perimysium are rich in coarse elastin fibers which are believed to be one of the contributors in meat toughness (Rowe, 1986). In contrast, Longissimus dorsi has limited coarse elastin fibers present in the epimysium and even less in the perimysium.

## Sarcoplasmic Proteins

The sarcoplasmic proteins occur in the sarcoplasm surrounding the myofibrils (Pearson and Young, 1989b). They are involved in various metabolic functions such as protein metabolism, fatty acid oxidation, electron transportation, glycolysis, glycogenesis and glycogenolysis (Pearson and Gillett, 2012; Smith, 2000; Strasburg et al., 2008). The sarcoplasmic proteins include the heme pigments (myoglobin), the glycolytic enzymes (glyceraldehyde phosphate dehydrogenase), the mitochondrial oxidative enzymes (such as succinate dehydrogenase, cytochrome), the lysosomal enzymes (notably cathepsin), the nucleoproteins and others. Among them are the proteolytic enzymes that are involved in the post-mortem muscle tenderization process, and myoglobin that is responsible for meat color. The amount of different sarcoplasmic proteins is largely dependent on the muscle fiber type, which in turn depends on the animal species, breed, age, genetics, and muscle anatomical position and function (Strasburg et al., 2008). Sarcoplasmic proteases are vital in protein catabolism and post-mortem muscle softening. Both calpains and cathepsins are responsible for post-mortem proteolysis, with calpains and more specially calpain 1 or  $\mu$ -calpain considered to be playing a major role (Ouali et al., 2006; Veiseth and Koohmaraie, 2005).

## Calpains

The calpains are a family of calcium-activated, cysteine proteases that have maximum activity at neutral pH (Sentandreu et al., 2002). Calpains degrade myofibrillar proteins during protein turnover for muscle growth (Goll et al., 2008; Huang and Forsberg, 1998). There are two types of calpains responsible for post-mortem proteolysis, which are ubiquitous:  $\mu$ -calpain and *m*-calpain (Table 1) (Raynaud et al., 2005; Strasburg et al., 2008). The calcium ion concentrations for the activation of  $\mu$ -calpain and *m*-calpain are in the range of micromolar and millimolar respectively (Camou et al., 2007). Calpains are found and act along the Z-disk. Calpastatin is the natural inhibitor of  $\mu$ -calpain and *m*-calpain.

## Cathepsins

Cathepsins are sarcoplasmic proteins that are released from the lysosomes in post-mortem muscle, which are active at an acidic pH (Table 1) (Geesink and Veiseth, 2008). Among the family of cathepsins, cysteine cathepsin B, H and L and aspartic cathepsin D are the most abundant in muscles. Cathepsins break down MHC, troponin T, troponin I, tropomyosin and collagen (Bechet et al., 2005) and collagen (Goll et al., 1983). The proteolytic activity of cysteine cathepsins and cathepsin D can be inhibited by cystatins (Geesink and Veiseth, 2008) and pepstatin (Bohley and Seglen, 1992) respectively.

## Myoglobin

Myoglobin is a heme protein that acts as an oxygen carrier in muscle cells and is responsible for the color of both raw and cooked meat. The amount of myoglobin varies between different muscle types. Oxidative muscle fibers type I & IIA have higher myoglobin content than glycolytic muscle fibers type IIB and IIX (Hoekstra, 1969). Poultry has a paler appearance than beef due to a higher content of fast glycolytic fibers and consequently a lower level of myoglobin.

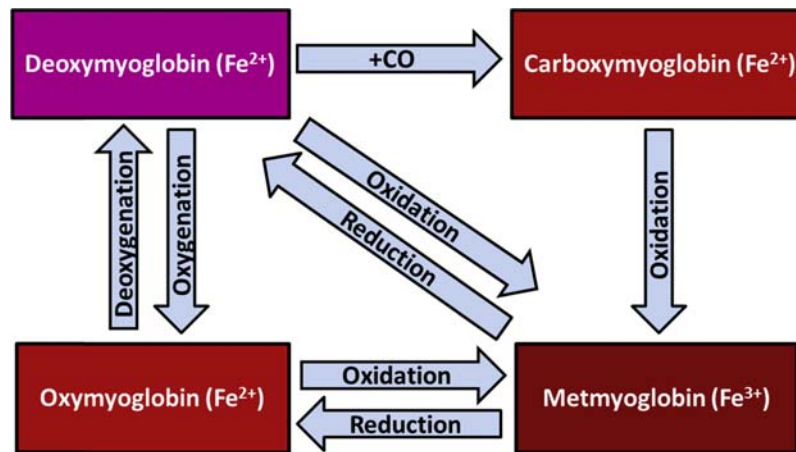

Four forms of myoglobin exist in the muscle, depending on the state of the heme group: deoxymyoglobin (purplish red), oxymyoglobin (cherry red), metmyoglobin (brown) and carboxymyoglobin (cherry red) (Fig. 6) (Suman and Joseph, 2013). The color of the muscle depends on the ratio of these forms of myoglobin (Baldwin, 2012). Cooking of meat results in denaturation of myoglobin and causes the oxidation of heme which induces a change in meat color.

**Table 1** Characteristics of cathepsins and calpains associated with meat tenderness during ageing<sup>a,b</sup>

	Calpains	Cathepsins
Nature	Cysteine proteases; calcium-dependent	Acid proteases
Occurrence	Cytosol	Lysosomes (in sarcoplasm)
Class/Isoform	<i>m</i> -Calpains, $\mu$ -calpains and calpain 3.	Main cathepsins involved in muscle ageing are cathepsins B, L, H and D
pH for optimum activity	Neutral	4–6.5 (varies with enzyme class)
Target proteins	Proteins in the Z-disk and cytoskeleton (mainly titin and desmin). Some breakdown of nebulin, troponin and tropomyosin.	Troponin T, collagen cross-links and mucopolysaccharides of connective tissue. Actin and myosin at pH < 5

### Other Sarcoplasmic Proteins

Most of the enzymes involved in the metabolic processes in muscles are sarcoplasmic proteins (Pearson and Young, 1989b; Strasburg et al., 2008). For instance, the enzymes creatine kinase and adenylate kinase take part in the synthesis and dissociation of high energy phosphate compounds such as ATP, ADP and AMP. Caspases, metalloproteases, thrombin and plasmin have been reported to be involved in post-mortem proteolysis (Sentandreu et al., 2002). Other sarcoplasmic proteins such as hemoglobin play an essential role in the exchange of oxygen and carbon dioxide (Pearson and Young, 1989b; Tahergorabi et al., 2011).

## From Muscle to Meat

### Postmortem Biochemical Changes

Meat comes from the transformation of skeletal muscle after slaughter. After bleeding, cells survive for a short time by regenerating ATP (essential for maintaining ionic and potential membrane gradients) through anaerobic metabolic pathways. The synthesis of ATP is mostly based on the degradation of phosphocreatine and anaerobic glycolysis. When phosphocreatine is depleted, the poor performance of glycolysis does not maintain ATP at a constant value. Its cellular concentration gradually decreases. As the ATP level decreases and glycogen is degraded, protons and lactate molecules accumulate in muscle cells resulting in decreased muscle pH (Bendall, 1973; Greaser, 1986; Monin, 1988). When the ATP level falls by half the resting muscle content, the actin and myosin molecules bind to form an actomyosin complex. The relative sliding of the filaments becomes impossible and the whole of the myofibrillar apparatus is transformed into a rigid system called rigor. Subsequently, the muscle stiffness gradually fades, but not the inextensibility. This 'resolution' of rigor results from the lysis of the proteins constituting the myofibrillar structure during the so-called maturation period.

When the glycogen is depleted and/or when the enzyme co-factor AMP disappears, the pH stabilizes at a value called the ultimate pH (usually close to 5.7). The acidification of the muscle reduces the net charge of myofibrillar proteins and is close to their isoelectric point (around 5). The slightest repulsion of the proteins comprising the myofilaments leads to a tightening of the latter and a lateral contraction of the myofibrils (Pearce et al., 2011), which expels part of the intramyofibrillar water into the sarcoplasm that then migrates into the extracellular space. In addition to the decrease in pH, the osmotic pressure of the muscle evolves after slaughter. Its value doubles during the onset of rigor mortis (from 270–300 mosmoles to 500–600 mosmoles) (Ouali, 1990a, 1990b, 1992). This increase is directly related to the decrease in pH (Ouali, 1992). The resulting increase in ionic strength, close to 0.30, is sufficient to damage myofibrillar proteins and to promote the action of muscle proteases.

### Fast Postmortem Metabolism Effects on Muscle Proteins and Meat Quality

Pronounced stress just prior to slaughter, coupled with the effects of stunning (especially electrical stunning), accelerates the muscle metabolism that continues after the animal dies and leads to a rapid drop in pH while the muscle temperature is still high (Charpentier and Goutefongea, 1963). The low pH/high temperature combination leads to the denaturation of the sarcoplasmic proteins (Bendall and Wismerpedersen, 1962; Charpentier, 1969; Charpentier and Goutefongea, 1963; Fischer et al., 1979; Lawrie et al., 1963; Scopes, 1964; Scopes and Lawrie, 1963) and the myofibrillar proteins, with myosin being the most sensitive (Bendall, 1973; Offer and Knight, 1988; Penny, 1967; Stabursvik et al., 1984). The denaturation of muscle proteins leads to reduction in their water holding capacity. The myofilament lattice retracts, expelling water to the extracellular space (Bendall and Swatland, 1988; Fialik, 1983; Guignot et al., 1993), increasing the ability of meat to reflect light (Macdougall, 1970, 1982). These meats are characterized by strong exudations, a lighter color and a soft texture, hence their name PSE (Pale Soft Exudative) (Adzitey and Nurul,

2011). This phenomenon was first observed in meat from pigs (Bendall and Wismerpedersen, 1962; Briskey, 1964; Hamm, 1960) and then in meat from poultry (Barbut, 2009; Owens et al., 2000; Swatland, 2008) and more recently in meat from sheep (Kim et al., 2014a,b; Warner et al., 2014) and cattle (Aalhus et al., 1998; Guignot et al., 1993; Warner et al., 2014).

Protein denaturation is also observed when the PSE trait is induced by maintaining a muscle at 37 °C for a few hours post slaughter (Penny, 1967, 1977).

## Postmortem Proteolysis

### Proteolytic Systems

Conditions after slaughter and during carcass chilling favor degradation of intracellular muscle proteins by proteolytic systems. Calpains seem to represent the major system involved in tenderizing meat (Goll et al., 2003; Koohmaraie, 1994; Koohmaraie and Geesink, 2006; Raynaud et al., 2005; Taylor et al., 1995a). It has been concluded that post-mortem muscle tenderization is due mainly to the action of  $\mu$ -calpain and to a lesser extent the action of  $m$ -calpain.

Cathepsins and proteasome seem less involved (Sentandreu et al., 2002; Koohmaraie and Geesink, 2006; Koohmaraie, 1994; Taylor et al., 1995b). Other proteolytic systems such as caspases, metalloproteases, thrombin or plasmin could also be involved in the postmortem degradation of muscle tissue (Sentandreu et al., 2002; Ouali et al., 2013).

It has been reported that low pH, elevated temperature and electrical stimulation can all accelerate the release of cathepsins from lysosomes and eventually facilitate muscle tenderization.

### Postmortem Muscle Protein Degradation

The consequences of postmortem proteolysis on the ultrastructure of muscle are well understood (Davey and Dickson, 1970; Davey and Gilbert, 1969; Koohmaraie, 1994; Koohmaraie and Geesink, 2006; Ouali, 1990b; Taylor et al., 1995a). Surprisingly, myosin and actin are little affected by post mortem proteolysis, and it is rather the degradation of cytoskeleton proteins that causes a -modification of myofibril ultrastructure and tenderness of the meat. Overall, post mortem proteolysis leads to a transverse rupture of the myofibrils at the connecting junction of the I-band to the Z-disks. This zone is essentially composed of actin, titin, and neb-ulin. Their postmortem degradation is likely to be responsible for myofibril breakdown (Koohmaraie and Geesink, 2006; Robson et al., 1997; Taylor et al., 1995a).

The cytoskeleton is also disorganized by the degradation of the desmin and the filamin, which bind the Z-disks of myofibrils to each other and also to the sarcolemma from peripheral myofibrils (Huff Lonergan et al., 2010; Taylor et al., 1995b; Koohmaraie and Geesink, 2006). The degradation of the constitutive proteins of the costamere (dystrophin-vinculin-talin-integrin) which constitutes the anchor point of desmin on the sarcolemma (Taylor et al., 1995a; Koohmaraie and Geesink, 2006) is also suspected to change the muscle fiber ultrastructure. The intermediate filaments which bind the myofibrils at the level of the M-lines are also partially hydrolyzed.

Deterioration of these major cytoskeletal proteins causes misalignment of the myofibrils relative to each other, detachment of the sarcolemma and rupture of the myofibrils along the Z-disks. Nevertheless, it appears that the degradation of desmin and titin are the most important of the mechanisms underlying development of tenderness during meat maturation (Koohmaraie and Geesink, 2006). Troponin T, incorporated into the thin filaments, is also degraded during the meat maturation phase, and its disappearance is related to the appearance of a 30 kDa peptide and the tenderness of the meat (Huff Lonergan et al., 2010). This protein is involved in the mechanism of muscle contraction, but it is also suspected to stabilize interactions between myofilaments. Its degradation may favor the disorganization of myofibrils.

Structural changes in intramuscular connective tissue become significant only after 10 days of maturation (Nishimura et al., 1995). In general, maturation increases the solubility of collagen (Purslow, 2005), causing an improvement in the texture of raw meat. However, the effects of postmortem changes in connective tissue on the texture of cooked meat are controversial (Nishimura, 2010; Purslow, 2005).

### Postmortem Protein Oxidation

An increase in myofibrillar protein oxidation is observed during ageing (Martinaud et al., 1997; Rowe et al., 2004a,b), that results in carbonyl derivative formation (Levine et al., 1994; Martinaud et al., 1997) and protein disulfide cross-links (Martinaud et al., 1997; Stadtman, 1990). In general, both of these changes reduce the functionality of proteins (Xiong and Decker, 1995). Calpains are particularly susceptible to inactivation by oxidation (Lametsch et al., 2008). Therefore, oxidizing conditions in postmortem muscle decrease the calpain activity and are likely to affect the tenderization of meat. Myoglobin also undergoes oxidation during the refrigeration of carcasses and meat, with significant effects on the color of the meat (Renerre, 2000).

## Effects of Processing on Meat Proteins

Meat processing affects the physical and chemical properties of the product by the action of physical forces, heat or the addition of salts, additives or processing aids (Lewis, 1992). For instance, meat tenderization through electrical stimulation, ultrasonic waves, blade tenderization and pressure treatment have been reported to modify the muscle structure and protein profile (Hopkins, 2014).

These processes decrease the overlapping of actin and myosin, cause physical damage to the sarcomere and connective tissues or improve proteolysis rates through the activation of calpains by calcium ions released after membrane disruption.

### Electrical Stimulation of Carcasses

Electrical stimulation of carcasses has no detectable influence on the degradation of desmin and troponin T (Ho et al., 1997), but could slightly accelerate the degradation of the cytoskeletal proteins titin and nebulin in postmortem muscle (Ho et al., 1996).

### Pulsed Electric Field

There has been recent interest in meat tenderization applications of PEF. PEF causes the electroporation of muscle cell membranes, which potentially facilitates the meat ageing process by releasing the calcium ions from sarcoplasmic reticulum, which triggers the calcium-activated proteases and/or speeds up pre-rigor glycolysis, and also by releasing the cathepsins from the lysosomes (Warner et al., 2017). Compared to untreated muscles, PEF-treated cold- and hot-boned beef Longissimus lumborum muscles had increased degradation of troponin T and desmin (Suwandy et al., 2015a, b).

### Exogenous Enzyme Technology

Exogenous proteases have been applied in meat tenderization for many years (Payne, 2009; Sullivan and Calkins, 2010). Most plant-based proteases can hydrolyze myofibrillar proteins efficiently (Bekhit et al., 2014; Kim and Taub, 1991). For the stromal proteins, under heating conditions, both papain and ficin were found to be effective in hydrolyzing elastin and collagen whilst bromelain degraded only collagen (more actively than papain and ficin) (El-Gharbawi and Whitaker, 1963; Miyada and Tappel, 1956; Payne, 2009). These enzymes have wide substrate specificity and can break down many of the peptide bonds present in meat proteins (Bekhit et al., 2014; Huff-Lonergan, 2014). Excessive proteolytic action can cause over-tenderization, leading to mushy meat texture (Ashie et al., 2002; McKeith et al., 1994; Weir et al., 1958).

### Shockwave Hydrodynamic Processing

Hydrodynamic processing generates a shockwave up to 1 GPa which travels through water in fractions of a millisecond (Bolumar et al., 2014; Hopkins, 2014). A shockwave process can be set up by subjecting the sealed meat in a water-filled container to electrically-generated shockwaves (Hopkins, 2014). Shockwave treatment caused increased intramyofibrillar and endomysium spaces between muscle fibers (Zuckerman and Solomon, 1998; Bolumar et al., 2014) myofibrillar fragmentation alongside the Z-disk (Zuckerman and Solomon, 1998), destruction of collagen fibrils of the endomysium (Zuckerman et al., 2013) and degradation of C-protein, which is responsible for the integrity of the thick filaments (Spanier and Fahrenholz, 2005a). The physical disruption of muscles may lead to the release of endogenous proteases such as calpains and cathepsins, or their activators such as calcium ions, thus enhancing the tenderization effect. This was seen in a study where troponin T of shockwave-treated samples was degraded more than in an untreated control after ageing (Bowker et al., 2008a,b). Conversely, no enhancement in the activity of endogenous proteolytic enzymes (cathepsins and peptidases) was detected after the shockwave process, suggesting that the tenderization effect is mainly due to physical disruption. The effect of shockwave processing on the protein profile is debatable. It has been reported that there was no distinct difference in the myofibrillar, sarcoplasmic and stromal protein profiles between control and shockwave-treated samples (Bolumar et al., 2014; Schilling et al., 2002). However, it has also been reported that shockwave-treated muscle had higher myofibrillar solubility (Bowker et al., 2008a,b; Spanier and Fahrenholz, 2005a, 2005b) and increased collagen solubility.

### High Pressure Processing

HPP is one of the technologies applied in the meat industry to improve shelf life, safety, and quality characteristics (texture and color) of foods (Bajovic et al., 2012). HPP subjects the meat to high pressure, usually ranging from 100 MPa to 800 MPa, via a surrounding liquid and is sometimes accompanied by heat treatment at 60 °C (Hopkins, 2014; Troy et al., 2016). HPP causes the destruction of microorganism, leads to protein denaturation and inactivation of endogenous enzymes (Sikes and Warner, 2016; Torres and Velazquez, 2005).

HPP alters protein secondary, tertiary and quaternary structures in the muscles by disrupting their conformations and molecular interactions (Campus, 2010; Sikes and Warner, 2016; Strasburg et al., 2008). For example, at pressures above 100 MPa protein tertiary structure unfolds and protein aggregation occurs (Cheftel and Culioli, 1997). However, covalent bonds are mostly unaffected. High pressure has been reported to denature myofibrillar proteins (Anderson and Parrish, 1989), cause depolymerization of actin (Ikkai and Ooi, 1966), and release cathepsins into the cytoplasm by degrading muscle membranes (Homma et al., 1994; Jung et al., 2000). For example, at pressures between 100 MPa and 300 MPa, myosin and actin were denatured (Angsupanich and Ledward, 1998; Sikes et al., 2010). The effect of high pressure on muscle structure depends on the applied pressure, processing temperature and time, and the muscle type (pre- or post-rigor) (Cheftel and Culioli, 1997). For instance, increases in

intermyofibrillar spaces and myofibril shrinkage were observed in Atlantic salmon meat with increasing applied pressure (from 400 to 900 MPa) and time (Gudbjornsdottir et al., 2010).

The tenderness of pre-rigor meat can be improved by HPP (Sikes and Warner, 2016). Accelerated glycolysis of pre-rigor meat may occur when high pressure is applied, resulting in shear force reduction of myofibrillar-based food (Elgasim and Kennick, 1982; Hopkins, 2014; Kennick et al., 1980). The effect of high pressure on the texture of post-rigor meat depends on the processing temperature (Sikes and Warner, 2016). In most studies, high pressure treatment at 30 °C or below did not have a tenderization effect in post-rigor meat. The tenderness of post-rigor sheep muscle (Macfarlane et al., 1981; Macfarlane and Morton, 1978) and chicken breast (Kruk et al., 2011; Zamri et al., 2006) remained unchanged after high pressure, low temperature processing. In contrast, high pressure processing combined with heat treatment was effective in improving meat tenderness (Bouton et al., 1977; Rusman et al., 2007; Sikes et al., 2010).

High pressure processing affects the color of meat (Cheftel and Culioli, 1997). At pressures higher than 400 MPa, the oxidation of heme iron and denaturation of myoglobin in raw meat occur and cause an increase in lightness and decrease in the redness of meat. This increase in lightness was also observed in bluefish *Pomatomus saltatrix* as the applied pressure increased from 100 to 300 MPa (Ashie and Simpson, 1996).

## Effects of Cooking on Meat Proteins

### Sous Vide Cooking

Sous vide is a culinary technique developed in fine dining restaurants, where food is sealed under vacuum and cooked at a controlled temperature, usually in a water bath (Baldwin, 2012; Schellekens, 1996). Cooking in this way results in uniform and efficient heat transfer from the water to the food, overcoming the drawback of uneven heating encountered in conventional cooking processes, while retaining water, soluble components and volatiles in the food and avoiding oxidation. During the cooking process, heat denatures proteins, leading to physical changes in the meat. The effect of cooking on muscle texture largely depends on the cooking time and temperature as well as the heating rate.

The myofibrillar proteins (mostly myosin and actin) shrink during heating, causing the contraction and shrinkage of the muscle fibers (Baldwin, 2012; Christensen et al., 2011a,b). When meat is subjected to heat from 40 °C to 60 °C, muscle fibers shrink transversely which causes a widening of the gap between them (Palka and Daun, 1999; Tornberg, 2005). As the temperature further increases, muscle fibers shrink longitudinally, and the water held between thick and thin filaments is expelled. The sarcoplasmic proteins start to aggregate and gel when heated at 40 °C to 60 °C (Baldwin, 2012). At sous vide cooking temperatures, most of the endogenous proteases remain active and contribute to enhancing the tenderness of the meat (Laakkonen et al., 1970a,b). At 55 °C, cathepsins B and L were found to be active during up to 24 hours of cooking, whereas both  $\mu$ - and *m*-calpains were inactivated within 10 minutes (Ertbjerg et al., 2012). Connective tissues, such as collagen, denature at around 60 °C (Baldwin, 2012). This leads to the formation of water-soluble random-coiled gelatin, decreasing the adhesion between muscle fibers. Collagen in beef perimysium was observed to melt when cooked at 50 to 60 °C, while elastin remained heat stable at 100 °C (Taylor, 2004). DSC analysis showed that prolonged heating at 53 °C (for 19.5 hours) resulted in diminishing of myosin and collagen peaks of meat from bull Semitendinosus muscle in the thermograph, suggesting potentially improved meat tenderness (Christensen et al., 2013).

The temperature of sous vide cooking should be set where it is high enough for collagen solubilization and microbiological inactivation, yet has minimum myofibrillar shrinkage to achieve optimum tenderization action (Ruiz et al., 2013). When a tough meat cut is cooked at a temperature between 55 °C and 60 °C for 24 hours, the tenderness is improved as the collagen is converted to gelatin and the myofibrillar proteins are hydrolyzed by the endogenous proteolytic enzymes (Bouton and Harris, 1981; Tornberg, 2005). A decrease in shear force was observed with an increase in cooking temperature from 50 °C to 65 °C, but the shear force increased when the temperature exceeded 65 °C and up to 80 °C (Baldwin, 2012). It has been suggested that the reduction in shear force is due to the gel formed from the sarcoplasmic protein, which filled the channels between fiber bundles, resulting in a decrease in elastic modulus that requires lesser tensile stress to fracture the meat (Tornberg, 2005).

### Other Cooking

Cooking of meat other than sous vide does not have the same precise control of temperature and generally exposes at least part of the meat to much higher temperatures than encountered in sous vide cooking, although other parts may be hardly heated at all (for example in the center of a "blue" steak). Chefs and consumers often judge the "doneness" of meat by its color, and this is mostly due to the degree of heme oxidation of myoglobin. During the cooking process, deoxymyoglobin, metmyoglobin and oxymyoglobin undergo oxygenation, oxidation and reduction reactions, and the ratio between them determines the color of final product (Liu and Chen, 2001). The color of the cooked meat also depends on the rate in achieving the designated core temperature and the duration held at that temperature. Cooked meat tends to be redder when the rate of heating is faster and paler when it is held at specific temperatures longer (Baldwin, 2012).

Important temperature effects are summarized in Table 2 (McGee, 2004).

**Table 2** Effects of heat on meat proteins and qualities

Temperature (°C)	Meat qualities	Proteolytic enzymes	Fibrillar proteins	Collagen	Protein-bound water	Myoglobin status
40	Soft Smooth Translucent	Active	Beginning to unfold		Begins to escape	
50	Firming Becoming opaque	Very active	Myosin begins to denature			
55	More fibrous, Juicy when cut	Denature and lose activity	Myosin coagulated			
60	Shrinking Losing resilience Losing juice Pink		Other proteins denature	Collagen sheaths shrink, squeeze cells	Flows from cells under collagen pressure	Begins to denature ("medium" doneness)
70	Shrinking Stiff Little juice Gray-brown			Begins to denature and dissolve	Flow ceases	
80			Actin denatures Cell contents compacted

## Nutritional Value and Digestion

Muscle-based food is an excellent source of protein nutrition. The compositions of lean tissue in muscle-based foods are consolidated in **Table 3** (Foegeding et al., 1996; Strasburg et al., 2008; Williams, 2007). About 17% to 23% of lean muscle is made up of protein that contains all the dietary essential amino acids. Consuming meat together with plant-based foods, such as cereals and legumes, can compensate for the lower levels of lysine (cereals), and sulfur amino acids (legumes) in the diet (Bodwell and Anderson, 1986). Protein from meat is highly digestible and bioavailable compared to plant protein (Černá, 2011), except after severe processing which can modify amino acid side chains (Soladoye et al., 2015). Muscle-based foods, especially red meats, are a rich source of highly bioavailable iron, due to their myoglobin content.

Protein digestibility, which is largely dependent on the source and processing history of food, is considered to be an important factor determining the amount of undigested dietary protein reaching the large intestine (Yao et al., 2016). It has been reported that increasing cooking temperature and time can decrease meat protein digestibility (Astruc, 2014b; Li et al., 2017; Kaur et al., 2014). High pressure-treated meat was found to be more digestible than the untreated control sample, both in vitro (Kaur et al., 2016) and in vivo (Elgasim and Kennick, 1980). Long-time salting and drying rendered the meat protein to be less digestible by pepsin in the stomach (Li et al., 2017).

## Sustainability of Meat as a Source of Protein

### Real Cost of Meat, Water and Carbon Footprints

There has been much comment on the environmental cost of producing meat. A commonly quoted "fact" is that it takes 10 kg of plant protein to produce 1 kg of meat protein. This is a worst-case figure and largely incorrect because:

**Table 3** Composition of lean muscle tissues

Species	Proximate composition (%)			
	Water	Protein	Lipid	Ash
Beef <sup>a,b,c</sup>	70–73	20–23	3–8	1
Pork <sup>b,c</sup>	68–70	19–20	9–11	1.4
Chicken <sup>b,c</sup>	73.7	20–23	4.7	1
Lamb <sup>a,b,c</sup>	73	20–22	5–6	1.6
Cod (lean fish) <sup>b,c</sup>	81.2	17.6	0.3	1.2
Salmon (fatty fish) <sup>b,c</sup>	64	20–22	13–15	1.3

<sup>a</sup>Williams (2007).

<sup>b</sup>Strasburg et al. (2008).

<sup>c</sup>Foegeding et al. (1996).

- It assumes the animal is eating food that could otherwise have been used by humans
- It ignores other contributions made by the animal – often a lifetime of milk or egg production or of providing motive power, as well as the other products from the carcass – offal, hides and gelatin, for example
- Animals are often farmed on land that is too steep or inaccessible to use for cropping, thus any opportunity cost for land use is, in the case of these animals, illusory
- In developing countries (and increasingly in developed countries) animals are fed on waste food that is no longer fit for human consumption.

Production of meat requires a lot of water. Meat animals are often farmed in regions where there is an excess of water available through plentiful rainfall – where no opportunity cost for water exists. Water management will be an increasingly important consideration for all kinds of farming. Farming for animal products, including meat, is appropriate under certain conditions.

The carbon footprint of meat production arises mostly because of production of methane by the animals during their lifetime. Methanogenesis occurs mostly in the rumen from the metabolism of methanogenic bacteria in the rumen population. It is generally undesirable, not only because it produces atmospheric methane, but because it results in lost energy and carbon that could otherwise benefit the animal. Research is underway globally to address this issue and there is hope that in the future ruminants will be able to be largely methanogen-free.

### Importance of the Ruminant

It is a simple fact that almost all food must originate from plant material, because photosynthesis is the ultimate source of almost all organic material. The route by which this material can become food for humans depends on the palatability and digestibility of the plant material. Ruminant animals, by virtue of their completely different digestive systems, can consume plant material such as grasses and the leaves of bushes and trees and convert it into forms that can be valuable nutrition for humans (milk and meat). Without the intervention of the animal, these food sources would be lost to us.

### The Future of Meat

The future of meat and the prospects of meeting future demand for meat and other animal-based sources of protein have been addressed by several groups, and potential solutions include more production through intensification and increasing grasslands (at an environmental cost that may be unacceptable), recycling food waste to feed animals and using alternative sources of animal fodder, such as insects. Laboratory-grown meat has also made an appearance, albeit only as a prototype, but may be expected to have an influence in the future, as will plant-origin meat substitutes, but meat will continue to occupy an important place in the planet's food ecosystem.

# Natural Antioxidants in Foods

Bingcan Chen and Minwei Xu, North Dakota State University, Fargo, ND, United States

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Antioxidant** A compounds that can inhibit oxidative processes.

**Free radical** A compound with an unpaired electron that can promote oxidative reaction.

**Free radical scavenger** A compound that can absorb a free radical to decrease the radical energy thus making it less likely to cause oxidation.

**Hydrogen atom transfer** Antioxidant transfer hydrogen to the lipid radicals.

**Metal chelator** Compounds that can bind metals and decrease their reactivity.

**Phenolic compounds** A group of chemical compounds found primarily in plants that act as antioxidant and are beneficial to health.

## Overview

Atmospheric oxygen is a low energy biradical (i.e. contains 2 unpaired electrons) in its ground triplet state. However, alterations can occur to produce highly reactive oxygen species (ROS) during metabolism of oxygen. This can cause oxidation of food constituents, including lipids, pigments, vitamins and proteins leading to off-flavor formation, discoloration and loss of important nutrients. Foods, which are derived from a variety of different biological tissues, contain a host of different antioxidant defense systems to prevent the damaging effect of reactive oxygen species. However, during the processing of biological tissues into foods, the formation of oxidizing species can increase and antioxidant systems can be overwhelmed leading to uncontrolled oxidative reactions resulting in loss of quality, decrease in shelf-life, and formation of potentially toxic oxidation products. In order to protect food quality and safety, antioxidants are often added to processed foods. These antioxidants can be synthetically derived compounds such as butylated hydroxytoluene (BHT) and ethylene diaminetetraacetic acid (EDTA). Concern over the use of synthetic food additives and customer's movement toward clean-label have driven the food industry to find effective natural antioxidants additives that are derived from biological sources.

In addition to the association of natural antioxidants with food quality, these compounds have also been associated with health benefits. The association of the protective effect of fruits and vegetable in the diet against metabolic diseases has been established for years. The consumption of an ample supply of fruits and vegetables provides a wide variety of phytochemicals that have been shown to have health benefits and antioxidant activity. In the context, natural antioxidants to protect biological system or food quality induced by free radicals, transition metals and singlet oxidation are reviewed.

## Free Radical Scavenger

Radical scavenging capacity of natural antioxidant can be classified as two major mechanisms: hydrogen atom transfer (HAT) and electron transfer (ET). Natural antioxidants possessing such capacity is named free radical scavenger (FRS). HAT means antioxidant transfer hydrogen to the lipid radicals for suspending the propagation step of lipid oxidation such as the mechanism of phenolic compounds (Eq. 1). Bond dissociation enthalpies (BDEs) are used to explain the principle of HAT. Lower BDEs of the antioxidant O—H bond are easier to transfer hydrogen, thus have a faster hydrogen transfer reaction. ET-based antioxidant reaction is a redox reaction with the transfer of electron (Eq. 2), such as carotenoids with  $\cdot\text{NO}_2$  and  $\cdot\text{CCl}_3\text{OO}$ , and catechin analogs with peroxy radicals ( $\cdot\text{OH}$ ). One electron reduction potentials ( $E^\circ$ ) is a typical parameter for indicating the capability antioxidants for electron transfer. The lower  $E^\circ$ , the easier the natural antioxidants to transfer electron. Generally, natural antioxidants always involve both HAT and ET mechanisms.

## Phenolic Antioxidants

Phenolics are compounds that have a hydroxyl group associated with an aromatic ring structure. There are numerous variations of natural phenolics (see Fig. 1 for examples). Natural phenolics are found predominately in the plant kingdom. Vitamin E or

**Figure 1** Chemical structures of some examples of phenolic antioxidants.

$\alpha$ -tocopherol is a plant phenolic required in the diet of humans and other animals. Phenolic compounds primarily inhibit lipid oxidation through HAT mechanism to scavenge free radicals and convert the resulting phenolic radicals into a low energy form that does not further promote oxidation. Physical partitioning of phenolics will also influence their reactivity. Initially, antioxidant efficiency is dependent on the ability of the free radical scavenger to donate a hydrogen to a high energy free radical. As the oxygen-hydrogen bond dissociation energy (BED) of the free radical scavenger decreases, the transfer of the hydrogen to the free radical is more energetically favorable and thus more rapid. The ability of a FRS to scavenge a free radical can sometimes be predicted from one electron reduction potentials ( $E^{\circ'}$ ). If a compound has a reduction potential lower than the reduction potential of a free radical found in a food or biological tissue (e.g. fatty acid based peroxy radical), it can donate hydrogen to that free radical unless the reaction is kinetically unfeasible. For example, FRS including  $\alpha$ -tocopherol ( $E^{\circ'} = 500$  mV), urate ( $E^{\circ'} = 590$  mV), catechol ( $E^{\circ'} = 530$  mV) and ascorbate ( $E^{\circ'} = 282$  mV) all have reduction potentials below peroxy radicals ( $E^{\circ'} = 1000$  mV, a common free radical in lipid oxidation reactions) and therefore can convert the peroxy radical to a hydroperoxide through hydrogen donation.

The efficiency of an antioxidant FRS is also dependent on the energy of the resulting antioxidant radical. If a FRS produces a low energy radical then the likelihood of the FRS radical to promote the oxidation of other molecules is lower and the oxidation reaction rate decreases. Phenolics are effective FRS because phenolic free radicals have low energy due to delocalization of the free radical throughout the phenolic ring structure. Standard reduction potentials can again be used to help illustrate this point. Radicals on  $\alpha$ -tocopherol ( $E^{\circ'} = 500$  mV) and catechol ( $E^{\circ'} = 530$  mV) have lower reduction potentials than polyunsaturated fatty acids ( $E^{\circ'} = 600$  mV) meaning that their radicals do not possess high enough energy to effectively promote the oxidation of unsaturated fatty acids. Effective phenolic antioxidants FRS also produce radicals that do not react rapidly with oxygen to form hydroperoxides

that could autoxidize, thus depleting the system of antioxidants. Instead, antioxidant radicals may undergo additional reactions that remove radicals from the system such as reactions with other antioxidant radicals or lipids radicals to form nonradical species through electron transfer (ET) mechanism. This means that each FRS is capable of inactivating at least of two free radicals, the first being inactivated when the FRS interacts with the initial oxidizing radical and the second when the FRS radical interacts with another radical via a termination reaction to form a nonradical product.

Phenolic compounds that act as antioxidants are wide spread in the plant kingdom. Plant phenolics can be classified as simple phenolics, phenolic acids, hydroxycinnamic acid derivatives, and flavonoids. The consumption of natural plant phenolics have been estimated to be up to 1 g per day. Overall, the presence of phenolics in the diet has been positively associated with the prevention of diseases such as cancer and atherosclerosis. Plant foods high in phenolics include cereals, legumes and other seeds (e.g. sesame, oats, soybeans and coffee); red, purple and blue colored fruits (e.g. grapes, strawberries and plums); and the leaves of herbs and bushes (e.g. tea, rosemary and thyme). Many natural phenolics are capable of inhibiting oxidative reactions. However, since phenolics have such a wide array of chemical structures, it is not surprising that antioxidant activities and health benefits vary greatly. This section will focus on the best studied natural phenolics from plant.

Tocopherols and tocotrienols are a group of lipophilic monophenolic FRS ( $\alpha$ ,  $\beta$ ,  $\delta$  and  $\gamma$ ; see Fig. 1 for the structure of  $\alpha$ -tocopherol) originating in plants and eventually ending up in animal foods via the diet. Interactions between tocopherols and fatty acid peroxy radicals lead to the formation of fatty acid hydroperoxides and several resonance structures of tocopheroxyl radicals, which can further interact with other compounds or with each other to form a variety of products. The types and amounts of these products are dependent on oxidation rates, radical species, lipid state (e.g. bulk vs. membrane lipids) and tocopherol concentrations. Tocopherol is found in plant foods especially those high in oil. Soybean, corn, safflower, and cottonseed oil are good sources of  $\alpha$ -tocopherol as are whole grains (in particular wheat germ) and tree nuts. All tocopherol isomers are absorbed by humans, but  $\alpha$ -tocopherol is preferentially transferred from the liver to lipoproteins which in turn transports  $\alpha$ -tocopherol to tissues. For this reason,  $\alpha$ -tocopherol is the isomer most highly correlated with Vitamin E activity.

Tea is an important source of dietary antioxidants for humans since it is one of the most common beverages in the world. Phenolics in tea are mainly catechin derivatives, including catechin (Fig. 1), epicatechin (EC), epicatechin gallate (ECG), gallic catechin (GC), epigallocatechin gallate (EGCG) and epigallocatechin (EGC). Tea originates from leaves harvested from the bush, *Camellia sinensis*. Processing of tea leaves involves either blanching to produce green tea or fermenting to produce oolong or black tea. Green tea leaf extracts contain 38.8% phenolics on a dry weight basis with catechins contributing over 85% of the total phenolics. Condensation of catechins can decrease their solubility; therefore, black tea extracts contain less phenolics (24.4%) of which 17% are catechins and 70% are condensed polyphenols (theaflavins). Ingestion of dietary phenolics from tea has been associated with cancer prevention.

Grapes and wines are also significant sources of dietary phenolic antioxidants. Grapes contain a wide variety of monomeric phenolics including anthocyanins, flavan-3-ols, flavonols (quercetin and rutin), and cinnamates (S-glutathionylcaftaric acid). As with many fruits, the majority of grape phenolics are found in the skin, seeds and stems. During extraction of juice, the pomace is left in contact with the juice for varying times in order to produce products of varying color, with increasing contact time resulting in increased phenolic extraction and thus darker color. Therefore, white grape juices and wines have lower phenolics contents (119 mg gallic acid equivalents/L) than red wines (2057 mg gallic acid equivalents/L). As would be expected, red grape juice and wines have greater antioxidant capacity due to their higher phenolic content. Both grape juice and wines have been suggested to have positive health benefits, however, their phenolic compositions are not the same due to differences in juice preparation and changes in phenolic composition which occurs during both fermentation and storage.

Isoflavones is the primary phenolics in soybeans. Included among the soybean isoflavones are daidzein (Fig. 1), genistein and glycitein and their glycosylation forms. Unlike the phenolics in tea and grapes, soybean isoflavones are associated with proteins and therefore are found in soy flour and not in soybean oil. The concentration of isoflavones in soybeans varies with the environmental conditions under which the beans were grown. In addition, isoflavone concentrations in soy-based foods are altered during food processing operations such as heating and fermentations. Besides whole soybeans, isoflavones are found in soy milk, tempeh, miso and tofu at concentrations ranging from 294–1625  $\mu\text{g/g}$  product. Genistein and daidzein are absorbed into human plasma from products such as tofu and soy milk. Recent research suggested that it is equol (Fig. 1), the metabolized daidzein by human intestinal microflora rather than daidzein itself to contribute to the beneficial effects of soy foods in preventing cardiovascular disorders.

Herbs and spices often contain high amount of phenolic compounds. For example, rosemary contains carnosic acid, carnosol and rosmarinic acid. Crude rosemary extracts are a commercially important source of natural phenolic antioxidant additives in foods meats, bulk oils, lipid emulsions and beverages.

## Phenolipids

Phenolic compounds combined with lipids are called phenolipids or lipophenols acting as oil soluble free radical scavengers. Due to its nature, it has improved solubility in oils compared to phenolics. The health benefits of phenolipids are anti-inflammatory, antiallergic, antimicrobial, antiviral, and anticarcinogenic, which are much the same as common phenolics. That is because the main functional groups are phenolics that still rely on the ability of donating electrons or hydrogen atoms. It means that their antioxidant ability depends on the number and position of the phenolic hydroxyls, the presence of some phenolic ring substituents and the electronic delocalization area.

Although the chemical properties of the phenolipids are much the same as phenolics, the physical properties are different. The lipid part confers special physical properties to the phenolipids, which make it not only react with polar compounds with phenolic aglycone, but also can react with nonpolar compounds through hydrophobic parts.

The natural sources of phenolipids are mainly from marine organisms ranging from 0.1%–15%. They can be related to analogs of n-3 PUFA phenolipids, since phenolics are linked to n-3 unsaturated carbon chain (C11–C21) with double bonds separated by bis-allylic positions. Hemiketal spiralisone (Fig. 1) and chromone isolated from brown algae *Zonaria spiralis*, acylphloroglucinol fatty acid esters from brown algae *Z. tournefortii*, and 5-alkenylresorcinol fatty acid esters from *Cystophora torulosa* have been reported recently. As to the marine animals, the 5-alkenylresorcinols fatty acid esters can also be extracted from the sponge *Haliclona* sp. As regard to the plants on the land, macamide, anacardic, 5-alkenylresorcinols and Z-*p*-coumaryl fatty acid esters can be extracted from Peruvian plant *Lepidium meyenii* (Maca), *Philodendron scadens* subsp. *Oxycardium*, liverwort *Omphalantus filiformis*, and cv. *Annurca* apple fruits, respectively. What's more, the phenolipids have been isolated from microorganism, such as 5-alkenylresorcinols fatty acid esters from heterotrich ciliate *Climacostomum virens*.

### Ascorbate

Ascorbic acid (vitamin C; Fig. 2) acts as a water-soluble free radical scavenger in both plant and animal tissues. Like phenolics, ascorbate ( $E^{\circ'} = 282$  mV) has a reduction potential below peroxy radicals ( $E^{\circ'} = 1000$  mV) and thus can inactivate peroxy radicals. In addition, its reduction potential is lower than the  $\alpha$ -tocopherol radical ( $E^{\circ'} = 500$  mV) meaning that ascorbate may have an additional role in the regeneration of oxidized  $\alpha$ -tocopherol. Interactions between ascorbate and free radicals result in the formation of numerous oxidation products. While ascorbate seems to primarily play an antioxidant role in living tissues, this is not always true in food systems. Ascorbate is a strong reducing agent especially at low pH. When transition metals are reduced they become very active prooxidants that can decompose hydrogen and lipid peroxides into free radicals. Ascorbate also causes the release of protein-bound iron (e.g. ferritin), thus promoting oxidation. Therefore, ascorbate can potentially exhibit prooxidative activity in the presence of free transition metals or iron-binding proteins. This does not typically occur in living tissues due to the tight control of free metals by systems that prevent metal reduction and reactivity.

Ascorbate is found in numerous plant foods including green vegetables, citrus fruits, tomatoes, berries and potatoes. Ascorbate can be lost in foods due to heat processing and prolonged storage. Transition metals and exposure to air will also cause the degradation of ascorbic acid.

### Thiols

#### Glutathione

Glutathione (Fig. 2) is a tripeptide ( $\gamma$ -glutamyl-cysteinyl-glycine) where cysteine can be in either the reduced or oxidized glutathione state. Reduced glutathione inhibits lipid oxidation directly by interacting with free radicals to form a relatively unstable sulfhydryl radical or by providing a source of electrons which allows glutathione peroxidase to enzymically decompose hydrogen and lipid peroxides. Total glutathione concentrations in muscle foods range from 0.7–0.9  $\mu\text{g/kg}$ . The bioavailability of glutathione in rats has also been reported to be low. Lack of, or low absorption of glutathione may be due to the hydrolysis of the tripeptide by gastrointestinal protease.

#### Lipoic Acid

Lipoic (thioctic) acid (Fig. 2) is a thiol cofactor for many plant and animal enzymes. In biological systems, the 2 thiol groups of lipoic acid are found in both reduced (dihydrolipoic acid) and oxidized forms (lipoic acid). Both the oxidized and reduced forms of the molecule are capable of acting as antioxidants through their ability to scavenge free radicals. Other than that, they can also quench singlet oxygen, chelate iron and possibly regenerate other antioxidants such as ascorbate and tocopherols. Lipoic and dehydrolipoic acids can protect LDL, erythrocytes and cardiac muscle from oxidative damage.

While lipoic acid has been found in numerous biological tissues, reports on its concentrations in foods are scarce. Lipoic acid is detectable in wheat germ (0.1 ppm) but not in wheat flour and it has been detected in bovine liver kidney and skeletal muscle. Oral administration of lipoic acid (1.65 g/kg fed) to rats for 5 weeks resulted in elevated levels of the thiol in liver, kidney, heart and skin. When lipoic acid was added to diets lacking in vitamin E, symptoms typical of tocopherol deficiency were not observed suggesting that lipoic acid acts as an antioxidant *in vivo*. However, lipoic acid was not capable of recycling vitamin E *in vivo* as determined by the fact that  $\alpha$ -tocopherol concentrations are not elevated by dietary lipoic acid in vitamin E deficient rats.

### Phospholipids

Phospholipids consist of two hydrophobic "tails," which are fatty acid chains, and one hydrophilic "head," which is phosphate group. They connect with glycerol and the "head" is typically found at the sn-3 position. With the amphiphilic structure, phospholipids can form bilayers on the cell membrane, which can be found in all living species. Lecithin, a commercially and widely available product, is a mixture of phospholipids. It mainly contains phosphatidylcholine (PC, Fig. 2), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI) and phospholipid-phosphoric acid (PA). In addition, lysophospholipids, whose fatty acid chain has been substituted by hydroxy group from either sn-1 or sn-2 position, is also a kind of phospholipids.

**Figure 2** Chemical structures of miscellaneous natural antioxidants.

Phospholipids are reported as natural antioxidants extracted from both animals and plants. The main principle of antioxidant ability can be classified as radical scavenging, synergistically working with other antioxidants, and also metal chelating. Phospholipids such as PE have a primary amine group, a necessary substrate for Maillard reaction. Primary amine group conducts Maillard reaction with carbonyl group from aldehydes or ketones, which are the secondary oxidation products of lipid oxidation. This is the first antioxidant mechanism that phospholipids participate in Maillard reaction. Then, Maillard reaction products such as browning pigments and melanoidin possess high free radical scavenging capability, which can inhibit lipid oxidation from the initiation and propagation steps. In addition, phospholipids can work as synergist with other antioxidants with the mechanism than alteration of location of other antioxidants and regeneration of antioxidant (e.g. tocopherol). In addition, regeneration of other antioxidants also plays an important role for phospholipids functioning as an antioxidant. Metal chelating ability is another antioxidant mechanism of phospholipids. In general, negative charged phosphate head group can react with metal

cations to inhibit lipid oxidation. It was reported that phospholipids acted as metal chelator where 1 ppm ferrous iron was added into bulk oil system.

Although phospholipids are proved to own antioxidant activity with various principles, reaction condition should be controlled to prevent phospholipids become prooxidants. Unlike common antioxidants, polyunsaturated fatty acids are present in phospholipids, which means the phospholipids itself can be oxidized. In addition, phospholipids, as an emulsifier, can increase interaction between hydrophilic and lipophilic compounds by aggregating them on the interface. As a result, initiation and propagation steps of lipid oxidation may be accelerated.

As phospholipids are an essential part of biological membranes, phospholipids can be extracted from all kinds of living plants or animals. The major phospholipids originated from animals are eggs, meats, fishes and milk. Among them, chicken whole eggs contain the highest proportion of phospholipids about 35 g/kg. PC is the main composition of animal phospholipids. Phospholipids from marine animals owning higher omega-3 polyunsaturated fatty acids, have higher demand than warm-blooded animals although they have same concentration of phospholipids. The major phospholipids originated from plants are soybean, corn germ, rapeseed, peanut, and wheat starch. Soybean with the phospholipids content of around 20 g/kg is higher than other plant sources.

## Singlet Oxygen Quencher

### Carotenoids

Carotenoids are a chemically diverse group (>600 different compounds) of yellow to red colored polyenes consisting of 3–13 conjugated double bonds and in some cases 6 carbon hydroxylated ring structures at one or both ends of the molecule.  $\beta$ -Carotene is the most extensively studied carotenoid antioxidant (Fig. 2). The major antioxidant function of carotenoids in foods is its ability to inactivate singlet oxygen. Singlet oxygen is an excited state of oxygen in which two electrons in the outer orbitals have opposite spin directions. Initiation of lipid oxidation by singlet oxygen is due to its electrophilic nature that will allow it to add to the double bonds of unsaturated fatty acids leading to the formation of lipid hydroperoxides. Carotenoids can inactivate singlet oxygen by both chemical and physical quenching. Chemical quenching results in the direct addition of singlet oxygen to the carotenoid leading to the formation of carotenoid breakdown products and loss of antioxidant activity. A more effective antioxidative mechanism of carotenoids is physical quenching. The most common energy states of singlet oxygen are 22.4 and 37.5 kcal above ground state. Carotenoids physically quench singlet oxygen by a transfer of energy from singlet oxygen to the carotenoid resulting in an excited state of the carotenoid and ground state, triplet oxygen. Energy is then harmlessly transfer from the excited state of the carotenoid to the surrounding medium by vibrational and rotational mechanisms. Nine or more conjugated double bonds are necessary for physical quenching with the presence of six carbon oxygenated ring structures at the end the molecule increasing the effectiveness of singlet oxygen quenching.

In foods, light will activate chlorophyll, riboflavin and heme-containing proteins to high energy excited states. These photoactivated molecules can promote oxidation by direct interactions with an oxidizable compounds to produce free radicals, by transferring energy to triplet oxygen to form singlet oxygen or by transfer of an electron to triplet oxygen to form the superoxide anion. Carotenoids inactivate photoactivated sensitizers by physically absorbing their energy to form the excited state of the carotenoid that then returns to the ground state by transfer of energy into the surrounding solvent.

## Metal Chelators

### Organic Acids

Transition metals will promote oxidative reactions by hydrogen abstraction and by hydroperoxide decomposition reactions that lead to the formation of reactive free radicals. Prooxidative metal reactivity is inhibited by chelators. Chelators that exhibit antioxidative properties inhibit metal-catalyzed reactions by one or more of the following mechanisms, i.e. prevention of metal redox cycling; occupation of all metal coordination sites thus inhibiting transfer of electrons; formation of insoluble metal complexes; steric hindrance of interactions between metals and oxidable substrates (e.g. peroxides).

Natural organic acids are employed in the food industry as chelating agents, such as polycarboxylic acids (citric, malic, tartaric, oxalic, and succinic), and phosphoric acids (adenosine triphosphate, and pyrophosphate). The prooxidative/antioxidative properties of a chelator can often be dependent on the amounts of functional groups such as  $-\text{OH}$ ,  $-\text{SH}$ ,  $-\text{COOH}$ ,  $-\text{PO}_3\text{H}_2$ ,  $\text{C}=\text{O}$ ,  $-\text{NR}_2$ ,  $-\text{S}-$  and  $-\text{O}-$ . The metal chelating capability of citric acid, which contains three carboxylic groups, is larger than that of oxalic acid, which only contain two carboxylic groups. In addition, chelator activity is pH dependent with pH below the  $\text{pK}_a$  of the ionizable groups resulting in protonation and loss of metal binding activity. Chelator activity is also decreased in the presence of high concentrations of other chelatable nonprooxidative metals (e.g. calcium) which will compete with the prooxidative metals for binding sites. Organic acids are typically water-soluble but many also exhibit some solubility in lipids (e.g. citric acid) thus allowing it to inactivate metals in the lipid phase. According to the solubility in different solvents, organic acids can synergistically work with radical scavengers. For instance, tocopherol, rosemary extract and citric acids have a synergic effect in sunflower oil.

Organic acid is widely distributed in all kinds of fruits and vegetables, especially citrus fruits, such as pineapples, lemons, oranges and limes. Consequently, vinegars made from these fruits often contain organic acids (e.g. citric, malic, lactic, and tartaric acids).

What's more, fermentation with microorganism is commercially available to produce organic acid, such as fermenting *Aspergillus niger* to produce citric acid.

### Peptides and Proteins

The reactivity of prooxidant metals in biological tissues are mainly controlled by proteins and peptides. Metal binding proteins in foods include transferrin (blood plasma), phosvitin (egg yolk), lactoferrin (milk) and ferritin (animal tissues). Transferrin, phosvitin and lactoferrin are structurally similar proteins consisting of a single polypeptide chain with a molecular weight ranging from 76,000–80,000 D. Transferrin and lactoferrin each bind 2 ferric ions while phosvitin has been reported to bind three. Ferritin is a multisubunit protein (molecular weight of 450,000 D) with the capability of chelating up to 4500 ferric ions. Transferrin, phosvitin, lactoferrin and ferritin inhibit iron-catalyzed lipid oxidation by binding iron in its inactive ferric state and possibly by sterically hindering metal/peroxide interactions.

Reducing agents (ascorbate, cysteine and superoxide anion) and low pH can cause the release of iron from many of the iron-binding proteins resulting in an acceleration of oxidative reactions. Copper reactivity is controlled by binding to serum albumin, ceruloplasmin and the skeletal muscle dipeptide (b-Alanine-His; b-Ala-His), carnosine. Caseinophosphopeptide, which have a main functional domain SerP-SerP-SerP-Glu-Glu, was reported to have transition metal chelating capacity, such as calcium, iron, copper, and zinc. The phosphoserine residues formatted a polar and anionic domain which can be responsible for chelating cationic metal ions.

### Phytic Acid

Phytic acid or myo-inositol hexaphosphate is one of the primary metal-chelators in seeds where it can be found at concentrations ranging from 0.8%–5.3% (Fig. 2). Phytic acid is not readily digested in the human gastrointestinal tract but can be digested by dietary plant phytases and by phytases originating from enteric microorganisms. Phytate is highly phosphorylated thus allowing it to form strong chelates with iron with the resulting iron chelates having lower reactivity. The antioxidant properties of phytic acid are thought to help minimize oxidation in legumes and cereal grains as well as in foods that may be susceptible to oxidation in the digestive tract. Phytic acid has been reported as a preventative agent in iron-mediated colon cancer. While phytate may be beneficial towards colon cancer, it should be noted that it can potentially have deleterious health effects because of its ability to dramatically decrease the bioavailability of minerals including iron, zinc and calcium.

### Polysaccharides

Polysaccharides and derivatives contain at least 20 monosaccharides connected with glycosidic linkages resulting in huge molecular weight. Prevention of oxidative stress with polysaccharide both *in vivo* and *in vitro* have been widely reported and metal chelating capability is the important mechanism accounting for antioxidant activity. In general, compounds contain at least two of the following functional groups:  $-\text{OH}$ ,  $-\text{COOH}$ ,  $-\text{SH}$ ,  $-\text{PO}_3\text{H}_2$ ,  $\text{C}=\text{O}$ ,  $-\text{S}-$ ,  $-\text{NR}_2$  and  $-\text{O}-$  can show metal chelation activity. Consequently, derivatives of polysaccharides such as uronic acid and sulphate substituted polysaccharides have the ability to chelating metals. Polysaccharides fractionated from the leaves of *Ilex latifolia* Thunb containing high contents of sulfuric acid and uronic acid carried stronger ferrous ion chelating ability.

Studies also reported that crude polysaccharides have potential free radical scavenging capability evaluated by DPPH free radical, ABTS free radical, hydroxyl radical scavenging activity, and superoxide anion radical scavenging activity. It is possible that small moieties of flavones, peptide, protein, and polyphenol conjugated on the polysaccharides exert the free radical scavenging capability rather than polysaccharides themselves. In addition, there is an interesting phenomenon that sulphation of polysaccharides can improve their radical scavenging ability although sulphation is not strict related with radical scavenging ability. Moreover, some study indicated that antioxidant activity of polysaccharides might come from the ability to improve the activity of antioxidant enzymes. For example, polysaccharides extracted from *Astragalus membranaceus*, pre-treated mice showed significantly increased antioxidant enzymes including Superoxide dismutase (SOD) and glutathione peroxidase (GSH-Px).

Overall, the comprehensive antioxidant properties of polysaccharides are affected by chemical characteristics like molecular weight, degree of substitution, type and ratio of monosaccharides, intermolecular associations of polysaccharides, glycosidic branching, and substitution of functional groups. For instance, lower molecular weight polysaccharides may incorporate into the cells more efficiently and chelating metals more effectively than high molecular weight polysaccharides.

Natural resource with rich polysaccharides are mainly from plant, fungus, and marine organism. Chinese herb medicine is a conventional plant source for bioactive polysaccharides, such as *Dendrobium* plants, *Angelica sinensis*, *A. membranaceus*, *Bupleurum* plants, Jujube fruit, and *Aloe vera*. Pectin, chitin, chitosan, guar and other more complicated polysaccharide extracted from medicine plants have been reported to have high antioxidant activity. Fungal polysaccharides are famous as its antioxidant function, which make it possible for food therapy. The source of novel bioactive compounds from marine organism has been concerned recently. The cell walls of marine algae, red algae, brown algae, and green algae are rich in sulfated polysaccharides such as fucoidans, carrageenans, and ulvans. These natural polysaccharides from algae are reported to be made into medicines with the outstanding antioxidant activity to prevent potential health risks like cardiovascular disease and cancer.

## Antioxidant Enzymes

### Superoxide Dismutase

Superoxide anion is produced by the addition of an electron to molecular oxygen. Superoxide anion can promote oxidative reactions by reduction of transition metals to their more prooxidative state; promotion of metal release from proteins; through the pH dependent formation of its conjugated acid which can directly catalyze lipid oxidation; and through its spontaneous dismutation into hydrogen peroxide (Eq. 3). Due to the ability of superoxide anion to participate in oxidative reactions, the biological tissues from which foods originate will contain superoxide dismutase (SOD).

Two forms of SOD are found in eukaryotic cells, one in the cytosol and the other in the mitochondria. Cytosolic SOD contains copper and zinc in the active site while mitochondrial SOD contains manganese. Both forms of SOD catalyze the conversion of superoxide anion ( $O_2^-$ ) to hydrogen peroxide by the following reaction:

### Catalase

Hydroperoxides are important oxidative substrates since they decompose via transition metals, irradiation and elevated temperatures to form free radicals. Hydrogen peroxide exists in foods due to its direct addition (e.g. aseptic processing operations) and by its formation in biological tissues by mechanisms including the dismutation of superoxide by SOD and the activity of peroxisomes. Lipid hydroperoxides are naturally found in virtually all food lipids. Removal lipid and hydrogen peroxide from biological tissues is critical to prevent oxidative damage. Therefore almost all foods originating from biological tissues contain enzymes that decompose peroxides into compounds less susceptible to oxidation. Catalase is a heme-containing enzyme that decomposes hydrogen peroxide by the following reaction (Eq. 4):

### Ascorbate Peroxidase

Hydrogen peroxide in higher plants and algae may also be decomposed by ascorbate peroxidase. Ascorbate peroxidase inactivates hydrogen peroxide in the cytosol and chloroplasts by the following mechanism (Eq. 5):

Two ascorbate peroxidase isozymes have been described which differ in molecular weight (57,000 D vs. 34,000 D), substrate specificity, pH optimum and stability.

### Glutathione Peroxidase

Many foods also contain glutathione peroxidase. Glutathione peroxidase (GSH-Px) differs from catalase in that it decomposes both lipid and hydrogen peroxides. GSH-Px is a selenium-containing enzyme which catalyzes hydrogen peroxide (Eq. 6) or lipidperoxides (Eq. 7) reduction using reduced glutathione (GSH):

or

where glutathione disulfide (GSSG) is oxidized glutathione and LOH is a fatty acid alcohol. Two types of GSH-Px exist in biological tissues of which one shows high specificity for phospholipid hydroperoxides.

Antioxidant enzyme activity in foods can be altered in raw materials and finished products. Antioxidant enzymes differ in different genetic strains and at different stages of development in plant foods. Heat processing and food additives (e.g. salt and acids) can inhibit or inactivate antioxidant enzyme activity. Dietary supplementation of selenium can be used to increase the glutathione peroxidase activity of animal tissues. These factors suggests that technologies could be developed to increase natural levels of antioxidant enzymes in raw materials and/or minimize their loss of activity during food processing operations.

## Conclusions

The biological tissues from which foods originate contain multicomponent antioxidant systems that include free radical scavengers, metal chelators, singlet oxygen quenchers and antioxidant enzymes. Our understanding of how these endogenous antioxidants protect foods from oxidation is still in its infancy. In addition, how factors that can alter the activity of endogenous food

antioxidants (e.g. heat processing, irradiation and genetic selection of foods high in antioxidants) is still poorly understood. Finally, research is continuing to show that natural food antioxidants in the diet are very important in the modulation of disease. Thus finding mechanisms to increase antioxidative activity of natural food antioxidants may be beneficial to both health and food quality.

### Introduction

Sweet taste perception is one of the most ancient taste modalities and is associated to the detection of carbohydrate-rich compounds in nutrients. Before the extraction of sucrose (or table sugar) in the 18th century, honey was the main source of sweetness. In the last centuries, sugar beet and sugar cane production grew rapidly to become the major source of sugar. Nowadays the overconsumption of sugar is considered a significant public health problem in industrial countries and has promoted the search for alternatives to high-calorie sweeteners. Many artificial sweeteners have been developed by the food industry but consumer interest in natural high potency sweeteners has grown spectacularly in recent years, fueled by concerns about sugar overconsumption and the use of artificial additives in foods. Though many low-calorie sweeteners are known, only few of them are used by the food industry (O'Brien Nabors, 2012). The search for novel intense sweeteners, possessing the same chemosensory profile as sucrose, remains open and challenging. In addition to physicochemical properties (such as thermal stability or water solubility), production cost and safety, one of the most important sensory properties of a sweetener is its sweetness potency. Sweetness potency can be measured by relative sweetness, which is defined as the ratio of concentrations of substances eliciting equivalent sweetness intensity. Sucrose is taken as the reference and its sweetness is traditionally set to 1. Numerous high-potency sweeteners are known but their noticeable aftertaste (bitter, metallic or licorice taste sensation ...) is a major restraint for consumer acceptability. Another major criterion of a "good" sweetener is its calorie content. For natural carbohydrate type of sweeteners, low calorie content is often associated with low sweetness potency. In the quest for sucrose alternatives, it has been questioned whether ideal sweeteners exist. At the beginning of the 2000s, the identification of the receptor responsible for the sweet taste perception (Nelson et al., 2001) is a major breakthrough in the understanding of the sweet taste modality. It opened new horizons for the rational development of new sweet-taste compounds. In this chapter, we briefly describe the structure and dynamics of the sweet taste receptor, which explain why the chemical space of sweeteners is so extended. Natural sweeteners belonging to saccharides, polyols, terpene glycosides, sweet proteins and other less common chemical families are presented. We also provide an overview of experimental strategies to discover new sweet compounds.

### Only One Sweet Taste Receptor Associated to a Large Chemical Space

All sweet tasting compounds are detected by a single taste receptor, the heterodimer TAS1R2-TAS1R3 (for Taste Receptor type 1 member 2 or 3), expressed on the surface of our taste buds (Nelson et al., 2001). The sweet taste receptor belongs to the class C G protein-coupled receptors (GPCRs) that share a similar structure: a large extracellular domain containing the orthosteric binding site and a seven-helix transmembrane domain (Pin et al., 2003) (Fig. 1). The two domains are connected by a cysteine rich domain structurally constrained by intramolecular disulfide bonds. Natural sweeteners such as sucrose interact with the orthosteric binding pocket of the receptor (Xu et al., 2004). The consensus mechanism of the sweet receptor activation is that orthosteric ligand binding involves a closure and a rotation of the TAS1R2 and the TAS1R3 extracellular domains. The chemical stimulus is then transmitted via the cysteine rich domain to the transmembrane domains where downstream signaling effectors bind. The transmembrane domain holds an allosteric binding site and the cysteine rich domain may bind sweet taste protein. Considering all the ligand binding sites of both the TAS1R2 and the TAS1R3 subunits, the sweet taste receptor can interact with sweet compounds through six different ways (DuBois, 2016) (Fig. 1). It gives a rational of the large chemical space of sweet-tasting compounds despite the fact that the sweet taste modality is controlled by a single taste receptor.

### Chemical Space of Natural Sweeteners

Natural sweeteners include natural sugars, sugar alcohols, terpenoid glycosides as well as some amino acids and polyphenols. In addition, a remarkable class of sweet agents will be reviewed: sweet tasting proteins originating from plants. Sweet taste compounds cover a large chemical space with high structural diversity as illustrated in Fig. 2.

### Natural Carbohydrates

Natural sugars, also called saccharides or carbohydrates, are polyhydroxylated aldehydes or ketones with the brute chemical formula  $C_n(H_2O)_m$  where  $n$  and  $m$  may be different. They are named by the suffix "-ose". There are notably two families: ketoses and aldoses, containing from 3 to 7 carbon atoms for natural oses. The simplest ones are erythrulose ( $C_4H_8O_4$ ) and glyceraldehyde ( $C_3H_6O_6$ ) for

**Figure 1** Structure of the sweet taste receptor and binding sites of various natural and artificial sweet taste compounds (DuBois, 2016).

**Figure 2** Chemical structure of natural sweet taste agents.

each family, respectively. The carbon atom carrying the aldehyde functional group is at position 1 in the carbon skeleton and the one defining the ketone functional group is at position 2. The orientation of the carbon atom at position  $n-1$  defines D or L series. In nature, D-sugars are preponderant. Fig. 3 shows the Fischer representation of linear-chain monosaccharides D-glucose and D-fructose, belonging to the ketose and the aldose chemical family, respectively.

**Figure 3** Fischer projection of monosaccharides D-glucose and D-fructose (left), hemiacetal/hemiketal formation (center) and glycosidic bond in sucrose (right).

The chemical structure becomes more and more complex as the number of carbon atoms increases since each carbon atom (except for the terminal ones) is a chiral center. A linear-chain ose is in equilibrium with its cyclic form that is produced by a hemiacetal or a hemiketal reaction depending on whether the linear form is an aldose or a ketose. The cyclisation of monosaccharides usually produces 5 or 6 atoms rings named furanoses or pyranoses. The orientation of the carbonyl functional group being below or above the plane of the carbon atoms determines the anomers (cyclic isomers) denoted by the  $\alpha$ - or  $\beta$ -prefix as shown in Fig. 3.

Polymers of monosaccharides can be produced via a dehydration reaction called a glycosidic linkage. The anomeric carbon atom is the reactive center to form glycosidic bonds. Two subunits form disaccharides. Oligosaccharides contain three to ten monomers and polysaccharides, more than ten. Sucrose, known as table sugar, is a disaccharide also named  $\alpha$ -D-glucopyranosyl-(1 $\rightarrow$ 2)- $\beta$ -fructofuranoside and is formed by the condensation of the monosaccharides D-glucose and D-fructose (Fig. 3).

Except for fructose, the relative sweetness of saccharides is systematically lower than the sucrose reference (Chéron et al., 2017; O'Brien Nabors, 2012; O'Donnel and Kearsley, 2012) (see Table 1). Fructose, the sweetest natural carbohydrate, occurs naturally in fruits and vegetables. Among monosaccharides, glucose and fructose are the most commonly used sweeteners in industry. High Fructose Corn Syrups (HFCS) are mainly composed of a variable ratio of fructose and glucose and are produced from corn starch through a sophisticated and automated industrial process. Other sources of high fructose syrup exist but HFCS is the most common commercial product. HFCS are used because of its flavor profile (quick perception of sweetness that does not linger) and its texturing capacity (Buck, 2012). Whichever is the fructose:glucose ratio, the relative sweetness is higher than sucrose. Due to health issues that have risen from high consumption of natural carbohydrates, there is a constant increase of low-caloric alternatives.

## Sugar Alcohols

Sugar alcohols are another chemical family of natural sugar substitutes, with the general formula  $\text{CHOH}_n\text{H}_2$ , where  $n = 4-6$ . They are widely used in the food industry for their sweetness and texturing properties (O'Donnel and Kearsley, 2012). They belong to the polyol chemical family which are polyhydric alcohols produced by the hydrogenation of the corresponding reducing sugars. Among the sugar alcohols accepted as food additives, glycerol, erythritol, xylitol, sorbitol and mannitol contain respectively three, four, five

**Table 1** Relative sweetness of saccharides compared to sucrose

Name	Chemical family	Relative sweetness
arabinose	monosaccharide	0.69
D-tagatose	monosaccharide	0.92
fructose	monosaccharide	1.43
fucose	monosaccharide	0.69
galactose	monosaccharide	0.65
glucose	monosaccharide	0.60
mannose	monosaccharide	0.52
psicose	monosaccharide	0.70
rhamnose	monosaccharide	0.32
ribose	monosaccharide	0.70
sorbose	monosaccharide	0.60
tagatose	monosaccharide	0.90
xylose	monosaccharide	0.52
isomaltulose	disaccharide	0.47
lactose	disaccharide	0.25
lactulose	disaccharide	0.50
leucrose	disaccharide	0.50
maltose	disaccharide	0.39
sucrose	disaccharide	1
trehalose	disaccharide	0.43
xylobiose	disaccharide	0.40
raffinose	oligosaccharide	0.25
stachyose	oligosaccharide	0.22

and six (for the two latter) hydroxyl functional groups and are derived from monosaccharides. Maltitol, isomalt and lactitol contain nine hydroxyl functional groups and disaccharide derivatives.

They are used as food additives because of their lower caloric content than sugars despite their lower sweetness (**Table 2**). Their sweetness profile is close to sucrose and they are generally used in combination with intense sweeteners to mask the unpleasant aftertastes of the latter ([Grembecka, 2015](#)). Sugar alcohols produce a cooling sensation in the mouth because their dissolution is an endothermic reaction. In addition to their interesting sensory properties, sugar alcohols are considered tooth-friendly because they are not metabolized by oral bacteria ([Grembecka, 2015](#)). However, like other nutrients that are incompletely digested, they may cause diarrhea, abdominal pain, and flatulence at high dosage level ([Grembecka, 2015](#)).

## Other Natural Sweeteners

Knowledge of the existence of intense sweeteners in plants dates from the mid-nineteenth century ([Kim and Kinghorn, 2002](#)). A non-exhaustive list of natural alternatives to saccharides and sugar alcohols is summarized in **Table 3**. However, most of them elicit licorice, metallic or bitter taste that are incompatible for commercial use. Only few natural high potency sweeteners have regulatory approval as sweetener. For instance, glycyrrhizin is not considered in the United States as a sweetener but as a flavoring agent and flavor enhancer and is still not approved in Europe.

Two types of high-intensity sweeteners have a 'generally recognized as safe' (GRAS) status and are permitted for use in food in the US: certain di- and tri-terpene glycosides obtained from the leaves of the plant *Stevia rebaudiana* and from extracts of *Siraitia grosvenorii* fruit (also known as Luo Han Guo or monk fruit). *Siraitia* fruits are used as food, beverage and traditional medicine in China.

**Table 2** Relative sweetness and glycemic index of sugar alcohols

Name	Chemical family	Relative sweetness	Glycemic index
erythritol	monosaccharide alcohol	0.63	1
xylitol	monosaccharide alcohol	0.97	12
mannitol	monosaccharide alcohol	0.50	2
sorbitol	monosaccharide alcohol	0.58	4
isomalt	disaccharide alcohol	0.54	2
lactitol	disaccharide alcohol	0.35	3
maltitol	disaccharide alcohol	0.87	35

**Table 3** Relative sweetness of various natural high potency sweeteners

<i>Name</i>	<i>Chemical family</i>	<i>Relative sweetness<sup>a</sup></i>
perillaldehyde	monoterpene	12
hernandulcin	sesquiterpene	1345
baiyunoside	diterpene	500
dulcoside A	diterpene	50–120
rebaudioside A	diterpene	250–450
rebaudioside B	diterpene	300–350
rebaudioside C	diterpene	50–120
rebaudioside D	diterpene	250–400
rebaudioside E	diterpene	150–300
rubusoside	diterpene	114
steviolbioside	diterpene	100–125
stevioside	diterpene	300
abrusoside (A-E)	triterpene	30–100
glycyrrhizin	triterpene	90
mogroside IV	triterpene	250–392
mogroside V	triterpene	250–425
osladin	triterpene	500
periandrin (I-IV)	triterpene	85–100
polypodoside A	triterpene	600
pterocaryoside A	triterpene	50
pterocaryoside B	triterpene	100
siamenoside I	triterpene	563
telosmoside A	triterpene	1000
anethole	phenylpropanoid	13
cinnamaldehyde	phenylpropanoid	50
phyllodulcin	coumarin	400–800
selliguaein A	flavonoid	35
taxifolin 3-acetate	flavonoid	80
monatin	amino acid	1200–1400
tryptophan	amino acid	35
brazzein	protein	800
curculin	protein	550
mabinlin	protein	100
monellin	protein	3000
pentadin	protein	500
thaumatin	protein	3000
neoculin	protein	<sup>b</sup>
miraculin	protein	<sup>b</sup>

<sup>a</sup>Some variation in sweetness values can be noticed and may arise from the protocol employed.

<sup>b</sup>Neoculin and miraculin are not sweet by themselves but they are taste modifying proteins.

In Asian and South American countries stevia is cultivated and its extracts are traditionally used to sweeten food. In Europe, only steviol glycosides (E960) have been approved as food additive.

*Stevia rebaudiana* is a plant native to south America has been known to have sweet tasting leaves for centuries by indigenous populations. It is a source of steviol glycosides that contain a common aglycone diterpene scaffold, steviol. Among the terpenoids present in this plant, stevioside and rebaudioside elicit a sweet taste hundreds of times sweeter than sucrose (Table 3), which makes them attractive sweeteners (Soejarto et al., 1982). Rebaudioside A generates a cleaner sweet taste similar to that of sucrose compared to stevioside, which delivers a stronger bitter aftertaste.

Mogrosides are a family of triterpenoid glycosides extracted from a Chinese plant locally known as *Lo Han Guo*. The structure of the two major constituents, mogrosides IV and V, have been characterized in the 1970s (Lee, 1975) and have been described as hundreds of times sweeter than sucrose (Table 3). The sweetness of mogrosides has a slow onset profile, typical of natural high-potency sweeteners (Lindley, 2012). Their liquorice aftertaste coupled with a cooling sensation may limit their use.

There exists another type of sweet agents of strong interest for the food industry: sweet tasting proteins. They are naturally produced by tropical plants and are hundreds to thousands of times sweeter than sucrose (Lindley, 2012). To date, eight intensely sweet-tasting proteins have been identified: thaumatin, monellin, brazzein, pentadin, mabinlin, neoculin and miraculin. Sweet proteins are expected to be digested just as any other dietary protein is. They have been used as sweetener for centuries in their native regions, which eases concerns about their toxicity.

Thaumatin I and II are the major sweet proteins obtained from the fruits of the West African plant *Thaumatococcus daniellii* Benth (also called katemfe). Thaumatin I (generally named thaumatin) is the only sweet protein that has been approved by both the FDA and the European Commission to be used as sweetener in food. Thaumatin has a very different sensory profile to that of sucrose, a very slow onset and a lingering sweet taste leaving a liquorice aftertaste (Lindley, 2012).

Brazzein is a small and heat-stable 54-amino-acid sweet protein isolated from a West African plant, *Pentadiplandra brazzeana* Baillon. Its taste profile is defined as closer to sucrose than any other sweet proteins (Lindley, 2012). Brazzein is intensely sweet with a slight licorice aftertaste and a cooling effect at high concentration levels. Because of its favorable taste profile and thermostability, academic and industrial research efforts have been made to develop various brazzein production protocols, from recombinant systems to fully synthetic solid-phase methods.

## Expanding the Chemical Space of Natural Sweeteners

The research of new natural sweeteners faces two main issues: purification of the molecules from a complex matrix and elucidation of their chemical structure. To achieve these goals, several methodologies have been developed using different analytical techniques.

A common approach to isolate sweeteners from natural extracts relies on targeted separation. Pharmacognosists usually perform bio-guided purifications to isolate active compounds from plants using dereplication and high throughput screening. Similarly, inductive strategies using sensory analysis have been developed to search for natural sweet-tasting compounds. A combination of various separation techniques is often needed. After each step, fractions are tasted and the most active one is kept for further fractionation. Crude plant extracts are partitioned sequentially in various solvents to give fractions containing molecules of different polarity (Kingham and Soejarto, 2002). Further fractionation can be carried on by using physical or chemical techniques such as multiple-step ultrafiltration and chromatography, respectively (Frank et al., 2006; Pickrahn et al., 2014). Recently, centrifugal partition chromatography (CPC) has been hyphenated to taste analysis for the identification of sweet triterpenes from oak wood (Marchal et al., 2011). Unlike solid phase chromatography, CPC presents no risk of irreversible adsorption and its load capacity is high (up to 10 g for a rotor of 1 L). These properties are particularly interesting for the study of natural sweeteners. However, CPC as low-pressure liquid chromatography offers a low chromatographic resolution and a final step using HPLC is often required to isolate pure compounds. Compared to olfactory analysis, tasting is destructive to the samples, so higher quantities of fractions are necessary for the sensory tests. Innovative sensory tools have been developed to replace classical tasting. The taste dilution analysis (TDA) coupled to half-tongue test dramatically decreases the required amount of fraction: serial dilutions of a sample are prepared. These dilutions are successively presented to a taster by applying one aliquot on one side of the tongue and water on the other as control. In this way, the taste dilution factor can be determined; it characterizes the taste-activity of the sample (Scharbert et al., 2004). Recent developments have also given rise to electronic tongues that offer new perspectives for guiding the purification of sweeteners (Zhang et al., 2012).

The identification of new sweeteners requires powerful spectroscopic methods commonly used for chemical elucidation of natural products. While NMR remains the technique of choice, mass spectrometry can also provide reliable structural information. In particular, the composition and the chemical class of an isolated molecule can be determined by high resolution mass spectrometry as well as the number, the type, the position or the sequence of its functional groups (Marchal et al., 2015). Moreover, stereochemistry strongly influences the taste properties of natural compounds and chiroptic techniques such as electronic or vibrational circular dichroism are particularly useful to characterize their absolute configuration (Cretin et al., 2015).

When a high-potency sweetener is identified, the search for structural analogs with similar, or even more interesting, properties is commonly conducted (Bassoli et al., 2011). Chemical synthesis can be a powerful tool in generating these analogs by making slight modifications to the stereochemistry or substituents of the sweetener (Machinami et al., 2002). However, natural biosynthetic pathways may also cause changes of the same type and several isomers and derivatives of a natural compound are often observed in the same plant. This biochemical diversity can be successfully explored to identify new sweet-tasting molecules (Marchal et al., 2015).

## Conclusion

In recent years, there has been growing interest in the replacement of sugars by natural sweeteners and numerous sugar substitutes have been developed and marketed. These include for instance bulk sweeteners (polyols), high fructose corn syrup and more recently steviol glycosides. The billions of years of evolution have allowed nature to create an incredible structural diversity of natural compounds suggesting that many regions of the sweet taste chemical space remain unexplored. The discovery of the sweet taste receptor has provided new opportunities to study the chemical structure – sweet taste relationships. However, the modes of ligand–receptor interactions are mostly unknown or poorly understood and the identification of new natural sweeteners still relies on botanical and ethnobotanical knowledge combined with sensory and analytical experiments.

## Introduction

Nitrates ( $\text{NO}_3^-$ ) are naturally occurring ions formed by the oxidation of nitrogen, and are an integral part of the nitrogen cycle in the environment (Cigulevska, 2002). Apart from the natural occurrence of nitrates in vegetables and fruits, they are also used as food additives for flavoring and preservation of meat and meat products (Song et al., 2015). Though the inclusion of nitrates has beneficial effects in terms of improving the texture, color, flavor and the shelf-life of meat and poultry products, it is, essentially, a double-edged sword as nitrates in food have been implicated in human toxicity and carcinogenicity due to their enzymatic conversion to nitrites ( $\text{NO}_2^-$ ) in the body (Silva and Lidon, 2016). This article discusses the natural and artificial occurrence of nitrates in food, the advantages and disadvantages associated with their presence in food, detection methods, as well as proposed alternatives.

## Occurrence of Nitrates

### Occurrence in Environment

In soil, nitrates are formed by the action of nitrifying bacteria, such as *Nitrosomonas* which oxidise ammonium ions to nitrites, which are further oxidised to nitrates by bacteria such as *Nitrobacter* and *Nitrococcus* spp. (Rao and Puttanna, 2000). These nitrates are absorbed by plants through the roots, and therefore, are natural constituents of plants (Keeton, 2017). A World Health Organization (WHO) estimate states that the average daily human consumption of nitrates is 43–141 mg, and of this, vegetables account for approximately 80% (World Health Organization, 2007; Lairon, 2011). Nitrates can be accumulated in high amounts by plant tissues, and vegetables, such as beetroot, and radishes, and leafy vegetables, such as celery, spinach and lettuce have been shown to accumulate more than 2500 mg of nitrates per 100 g, which is considered to be a very high value (Santamaria, 2006). Nitrate accumulation by plants can be influenced by several biological factors (such as plant cultivar and variety), environmental factors (such as light intensity, soil temperature, rainfall etc.), and processing methods (such as storage temperature) (Hmelak Gorenjak and Cencič, 2013). However, the drastic rise in the use of nitrogen fertilizers for improving crop productivity in face of the increasing global population is the primary reason for higher accumulation of nitrates by plants (Iammarino et al., 2013). Excessive use of nitrogen fertilizers can also cause an increase in the nitrate concentration of drinking water due to leaching into groundwater (Odorog, 2016).

### Nitrates as Food Additives

The earliest use of nitrates for food preservation was recorded in ancient India and China, as the use of “wall saltpeter” or  $\text{Ca}(\text{NO}_3)_2$  for the curing of meat, resulting in a distinctive red color and flavor (Binkerd and Kolari, 1975). It was only in the late 19th century that scientists were able to explain the mechanism of reddening of the meat on treatment with nitrates (Fig. 1) (Hoagland, 1908; Haldane, 1901).

It has been estimated that processed meats account for less than 5% of the total nitrate consumption (Milkowski, 2017). Cured meats have a characteristic reddish to pink color which is attributed to the action of nitrates. First, nitrates are reduced to nitrites by the enzyme nitrate reductase. Nitrites are then converted to compounds such as nitrous acid ( $\text{HNO}_2$ ) and nitric oxide (NO), which is a prerequisite for curing. Subsequently, the NO binds to the  $\text{Fe}^{2+}$  ion present in the porphyrin ring of the globular protein myoglobin, thus forming an unstable compound, nitrosomyoglobin. This intermediate, in the presence of high temperature or acidic pH gives a stable red pigment called nitroso-myochromogen (the nitrosoporphyrin ring), formed by the denaturation of the protein component of nitrosomyoglobin (Honikel, 2008; Govari and Pexara, 2015).

Additionally, nitrates are also added for activity against food spoilage bacteria and pathogens. Nitrates by themselves do not have any direct antimicrobial effect, however, they function as a precursor to nitrites, which are active against pathogens, such as *Clostridium botulinum* (thus preventing botulism), and *Staphylococcus aureus* (Sindelar and Milkowski, 2012; Mahindru, 2008).

Due to the toxic effects of residual nitrite concentrations in processed meat, the use of nitrates was gradually reduced, and currently, sodium nitrate (E 251) and potassium nitrate (E 252) which are classified as Class II preservatives according to the Commission regulation (EC) No. 1129/2011, are most commonly used in curing of meat, and in preservation of fish and poultry (Sebranek and Bacus, 2007; Anand and Sati, 2013). The permissible limits set by the Food and Drug Administration (FDA) for nitrate concentration in foods have been summarized in Table 1.

**Figure 1** Mechanism of formation of red coloration of during curing.

**Table 1** Permissible limits for nitrates in food

Additive	Food	Permitted limit	References
Sodium nitrate (as preservative and color fixative)	Smoked and cured seafood such as sablefish, salmon and shad	<500 ppm	(2017b) <sup>b</sup>
	Smoked and cured poultry and wild game	<500 ppm	(2017b) <sup>b</sup>
Potassium nitrate (as curing agent)	Cod roe	<200 ppm	(2017a) <sup>a</sup>

## Effects of Nitrates on Humans

For over a century, several concerns have been raised over the potential of nitrates and nitrites to form carcinogens, leading to strict regulations for their use as food additives. However recent studies have hinted that the dietary supplementation of nitrates may actually have a protective effect with respect to cardiovascular health, however little is understood of the actual mechanism for this effect (Fig. 2).

## Detrimental Effects of Nitrates

While nitrates do not have a direct effect on health, their conversion to nitrites in some physiological conditions in the body has been linked to toxicity and carcinogenesis in humans (Cigulevska, 2002). Chan et al. reported that 5%–7% of the nitrates ingested by humans through food is converted to nitrites by nitrate reducing bacteria present in the saliva in the oral cavity (Chan, 2011). The metabolism of nitrate to nitrite in the digestive system in high amounts (ranging from 0.4 mg kg<sup>-1</sup> to >200 mg kg<sup>-1</sup> body weight) can cause methemoglobinemia, or the blue baby syndrome. In this disorder, the nitrite formed oxidizes the Fe<sup>2+</sup> in hemoglobin to Fe<sup>3+</sup>, thus converting hemoglobin to methemoglobin, and consequently, reduces the oxygen carrying capacity of the blood. Symptoms of methemoglobinemia include tiredness, vomiting, diarrhea, and eventually suffocation and death (Chamandoost et al., 2016).

The indirect carcinogenic effect of nitrates has been attributed to conversion of nitrites to nitrous acid and nitrogen oxides (in acidic conditions such as the stomach), which can further react with secondary amines to form secondary nitrosamines (Butler, 2015; Stojnev et al., 2014). Nitrosamines, in the presence of high temperature or low pH, are converted to di-azonium ions which can react with DNA and cause gene mutations, and ultimately cancer (Chamandoost et al., 2016; Song et al., 2015). Apart from this, a high nitrate concentration in drinking water was implicated in the enlargement of the thyroid gland, as well as the prevalence of

**Figure 2** Mechanism of transformation of nitrates in humans.

Diabetes Mellitus type1 in children aged 1–18 years (Parvizishad et al., 2017). Studies have also linked high levels of dietary nitrates to increased number of deaths from Parkinson's disease and Alzheimer's disease (Anand and Sati, 2013).

Although the exposure to nitrates and nitrites have been linked to the increased incidence of gastrointestinal, nasopharyngeal and brains tumors, a conflicting report by the US EPA (Environmental Protection Agency) raised serious doubts regarding the association of these compounds with the development of cancers in children and adults (Gassara et al., 2016).

### Beneficial Effects of Nitrates

While several studies have proposed the link between dietary nitrates and their subsequent metabolites and adverse effects in humans, there is also emerging research on their health benefits (Lundberg et al., 2009). Several clinical trials have been conducted to evaluate the positive effect of dietary nitrates on cardiovascular health. Nitrate metabolites, such as nitrosothiols and nitroalkenes have been shown to have cryoprotective, hypotensive, antiplatelet effects (Hord, 2011). The DASH (Dietary Approach to Stop Hypertension) plan is based on the hypothesis that increased consumption of "nitrate-rich" vegetables, such as beetroots, spinach etc. is effective for the nonpharmacological management of high blood pressure by promoting vasodilation (d'El-Rei et al., 2016). S-nitrosothiols formed by nitrosation of thiol groups are known to be a part of signalling pathways involved in physiological functions including vasodilation and blood pressure regulation (Habermeyer et al., 2015). Webb et al. (2008) reported a reduction in blood pressure following consumption of beetroot juice, and attributed it to the nitrate load in beetroot. Larsen et al. (2007) reported that a dietary supplementation of nitrate rich vegetables resulted in lower oxygen demand during submaximal work, and a more efficient energy production. Similar results were also obtained by Bailey et al. (2009) on the supplementation of nitrate in the form of beetroot juice. However, so far, the exact mechanism for these hypotheses has not been elucidated.

### Detection of Nitrates

The WHO has set the permissible limits for dietary nitrates to be 300 mg kg<sup>-1</sup> body weight for adults, and 25 mg kg<sup>-1</sup> body weight for babies. Several studies have indicated the harmful effects of nitrates at high doses, therefore it is essential to identify and detect the concentration of these compounds in food. Nitrates can be detected directly, or indirectly by reduction to nitrite. Several techniques have been described for the analysis of nitrates in food, a few of which are summarized below, and in Table 2 (Azmi et al., 2017).

#### Colorimetry

The International Organization for Standardization defined the official method for the detection of nitrates in 1975 (ISO 3091:1975), by which nitrates are estimated indirectly after reduction to nitrites by metallic cadmium (Iammarino et al., 2017). Nitrite quantification is done spectrophotometrically by the Griess-Romijn reaction, which is based on the conversion of aromatic amines such as sulphanilamide to diazonium ions by nitrites. These ions then react with a coupler molecule (e.g., N-(1-naphthyl) ethylenediamine) to form a red compound, which is detected at 540 nm (Ferreira and Silva, 2008). Zatar et al. (1999) developed a method which utilises oxidation of a phosphomolybdenum blue complex by nitrite, causing a decrease in the intensity of the blue color of which was read at 814 nm. The nitrite concentration is proportional to the decrease in absorbance of the phosphomolybdenum blue complex. To account for nitrite present in sample before the reduction of nitrate to nitrite, Merino (2009) used zinc powder to reduce nitrate to nitrite, and nitrite concentration was determined both before and after reduction by the Griess-Romijn

**Table 2** Overview of some nitrate detection techniques

	Colorimetry	Chromatography	Electrochemical detection	Biosensors
Nitrate detection	Indirect	Indirect	Direct	Direct
Mechanism of detection	Spectrophotometer	UV, electrochemical, fluorimetric, mass spectroscopic	Change in current or electric potential	Specific interaction between analyte and biologically derived material
Advantages	<ul style="list-style-type: none"> <li>• Simple assay</li> </ul>	<ul style="list-style-type: none"> <li>• High sensitivity</li> <li>• Rapid analysis</li> </ul>	<ul style="list-style-type: none"> <li>• High sensitivity and selectivity</li> <li>• Rapid detection</li> <li>• Use of non-toxic reagents</li> <li>• Cost-effective</li> </ul>	<ul style="list-style-type: none"> <li>• Cost effective</li> <li>• Highly substrate selective</li> <li>• Portable due to small size</li> </ul>
Disadvantages	<ul style="list-style-type: none"> <li>• Low sensitivity</li> <li>• Use of toxic reagents</li> <li>• Subject to interference from other species</li> </ul>	<ul style="list-style-type: none"> <li>• Non-portable</li> <li>• Expensive</li> </ul>	<ul style="list-style-type: none"> <li>• Increased cost due to sensitive material used</li> <li>• Difficult to store</li> </ul>	<ul style="list-style-type: none"> <li>• Low activity of nitrate reductase</li> <li>• pH and temperature dependent sensitivity</li> <li>• Time-consuming</li> </ul>

reaction, and the nitrate concentration was calculated as the difference between nitrite concentration before and after reduction. Studies have also confirmed to use of Vanadium (III) and nitrate reductase enzyme for reduction of nitrate to nitrite (Miranda et al., 2001).

### Chromatography

Ion chromatography and High-Pressure Liquid Chromatography (HPLC) are the preferred techniques for nitrate detection. The most common pre-treatment technique converts nitrate to  $\text{NO}_2^+$  ions, followed by nitration of 2,4-dimethylphenol. The indicator species is 1,3,5-trimethoxybenzene (Tsikas et al., 1998). Chromatography techniques can be coupled to different detection systems such as UV, electrochemical, fluorimetric, electron capture, and mass spectroscopic for the analysis of the eluent (Moorcroft et al., 2001).

### Electrochemical Detection

Electrochemical detection of nitrates can be voltammetric or potentiometric. Nitrates are reduced to nitrites by a Cu/Cd column or by nitration of aromatic compounds, such as benzoic acid or salicylic acid. The derivative obtained is determined at a glassy carbon electrode by voltammetric analysis. For potentiometric analysis, commercial ion-selective electrodes (ISEs), are used to transfer charged particles from one phase to another, which creates a measurable potential difference (Moorcroft et al., 2001). The sensitivity can be improved by using a nitrate selective membrane. Capillary electrophoresis is a rapid method of detection of anions, and it requires smaller volumes of both the buffer and the sample for analysis. A polyethyleneimine-coated capillary is used for separation of anions, and nitrate detection is done by UV detection at 214 nm (Moorcroft et al., 2001).

### Biosensors

Biosensors consist of a bioreceptor, transducer and detector. The detector signal generated by binding of the analyte to the bioreceptor generates a signal, which is converted by the detector into a measurable signal such as voltage or current (Sohail and Ade-loye, 2016). Biosensors have been fast gaining attention due to their compact size which can reduce overall cost of biosensor use (Azmi et al., 2017). Nitrate reductase is used in synthesis of biosensors as it can convert nitrate to nitrite. Can et al. (2012) studied the efficacy of a carbon nanotube/Polypyrrole/nitrate reductase biofilm electrodes for nitrate detection with promising results.

### Alternatives

Due to the proposed detrimental health effects of nitrates, studies are being carried out to look for alternatives to these nitrates. One approach would be to eliminate nitrates in meat processing by “natural curing,” i.e., by using high-nitrate vegetable sources such as celery powder with nitrate reducing bacteria (Sindelar and Milkowski, 2012). The addition of chemicals such as fumarate esters, butylated hydroxyanisole, sulfur dioxide etc. could be effective, however, the long term effects of such chemicals cannot be predicted (Gassara et al., 2016). Another technique could be the addition of products such as ascorbate and ascorbic acids, which can prevent the formation of nitrosamines from nitrites, thus eliminating the carcinogenic potential of nitrates (Jiménez-Colmenero et al., 2001). The use of coloring agents, such as erythrosine to give the characteristic color of cured meats, as well as a combination of chemical antioxidants to obtain the flavor of cured meats could also be a possible alternative to nitrates (Pegg et al., 1997; Shahidi, 1989). An extensive review by Gassara et al. (2016) describes the potential of different spices as alternatives to nitrates due to their antioxidant and antibacterial properties.

### Future Perspectives

Despite recent years of research, there is still ambiguity regarding both, the positive and negative effects of nitrates. Therefore, extensive clinical studies should be conducted to understand the pharmacokinetics and metabolism of nitrates in humans (Keeton, 2017). While the Acceptable Daily Intake (ADI) value of nitrates is  $3.7 \text{ mg kg}^{-1} \text{ day}^{-1}$ , Rebelo et al. (2015) suggest that due to their potential to cause methemoglobinemia, determining the Acute Reference Dose (ARfD) value for nitrates may be more appropriate to evaluate safety of exposure. The American Academy of Pediatrics suggests that methemoglobinemia in infants can be prevented by excluding nitrate-rich vegetables such as carrots, squash, spinach etc. in their diet till the age of three months (Cunningham, 2013). Since a large portion of dietary nitrates comes from vegetables, the development of new cultivars that have reduced nitrate accumulation and higher stress tolerance could be an interesting option (Cavauiuolo and Ferrante, 2014). Additionally, more eco-friendly agricultural practices such as crop rotation, livestock management etc, can effectively reduce the amount of nitrogen fertilizers, without drastically affecting productivity (Socaci and Stănilă, 2007). Several studies have shown that organic vegetables have a lower nitrate content than conventionally grown ones, and therefore some scientists suggest that the consumption of organic vegetables could reduce dietary exposure of nitrates (Garcia and Teixeira, 2017). Modifications of culinary practices such as cooking at high temperatures could also reduce the toxic nitrosation products of nitrate metabolism (Celada et al., 2016). With respect to the

use of nitrates in food preservation, further studies of alternate technologies such as UV radiation, ionizing radiation, high-pressure processing etc., are being studied to improve their cost efficacy (Carocho et al., 2014).

## Conclusion

The use of nitrates for preservation of meat is an ancient practice. During the late 90s, the use of nitrates of curing reduced drastically, however in recent times there has been some ambiguity regarding the proposed detrimental effects of nitrates in human health. On the one hand, alternatives for addition of nitrates for meat curing are being looked into, and on the other hand, vegetables that are rich in nitrates are being evaluated for their beneficial effect on cardiovascular health. As nitrates are naturally occurring ions, and a part of our regular diet, closer understanding of the mechanism of nitrates in the human body is needed to educate the public regarding the possible risks and benefits associated with nitrates.

## Glossary

**Galactosylation** The reaction in which a galactosyl donor is attached to a hydroxyl or other functional group of another molecule (a glycosyl acceptor). Likewise, transgalactosylation is the transfer of a galactose residue from one glycoside to another.

**MALDI-TOF-MS** Matrix Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry is used to analyze large biopolymers such as proteins, carbohydrates and DNA through ionization with low fragmentation followed by mass spectrometry.

**Microbiota** A microbial community; commonly used to refer to the microbial population itself located within a specific habitat (e.g. the gut microbiota).

**-omics** The high-throughput research methods that are used to analyze the interactions of information objects in the complete sets of molecules within biological systems (-omes), such as metagenomics, transcriptomics, proteomics and metabolomics.

**Prebiotic** Is a food ingredient that is not digestible by humans, and that promotes the growth of beneficial microorganisms in the gastrointestinal tract.

**Probiotics** Are live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.

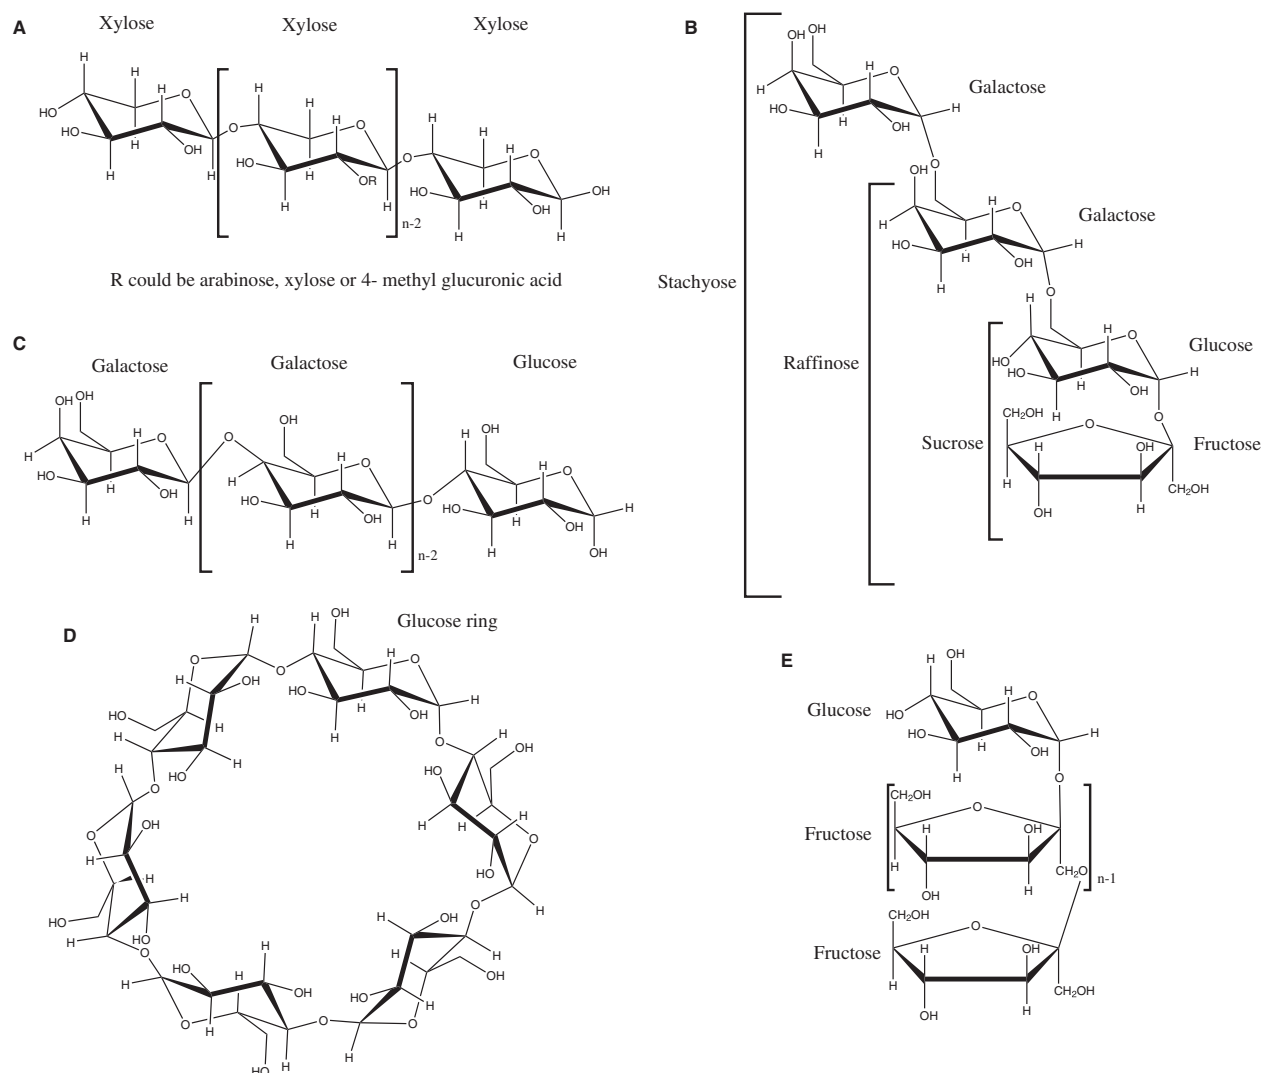

## Introduction

Non-digestible oligosaccharides possess many important physicochemical and physiological properties, e.g. they function as prebiotics to improve gut microecology and immunomodulation and provide protection against pathogen adhesion. These properties have greatly advanced their rapid industrial applications in the last few years.

Compared to polysaccharides, oligosaccharides have much lower molecular weight, therefore high water solubility. By definition (IUBIUPAC nomenclature), oligosaccharides are saccharides with Degree of Polymerization (DP) value ranging from 3 to 10. However, molecules of DP 11 to 19 are generally also recognized as oligosaccharides due to their similar properties. The types of naturally occurring oligosaccharides and their sources have been well summarized in **Table 1** according to a previous review paper (Mussatto and Mancilha, 2007). The typical structural features of oligosaccharides are differentiated by monosaccharides and linkages (**Fig. 1**). For example, fructooligosaccharides are D-fructose residues linked by  $\beta$  (2 $\rightarrow$ 1) bonds with a terminal  $\alpha$ -(1 $\rightarrow$ 2) linked D-glucose; xylooligosaccharides are constructed by  $\beta$ -XylP bonded by 1 $\rightarrow$ 4 linkages, occasionally branched by arabinose, xylose or 4-methyl-glucuronic acid sugar residues according to the source; the raffinose family is comprised of sucrose bonded by one (raffinose) or two (stachyose)  $\alpha$ -galactose residues through 1–6 linkages. However, the low abundance of the naturally occurring polysaccharides cannot meet the high needs for their industrial applications. Most of the oligosaccharide products on the market are commercially produced by either polysaccharide hydrolysis or enzymatic/chemical synthesis from disaccharide substrates, e.g. xylooligosaccharides from hydrolysis of arabinoxylan polysaccharides (**Fig. 2**); fructooligosaccharides from hydrolysis of inulin; galactooligosaccharides and some fructooligosaccharides produced by transgalactosylation (Fischer and Kleinschmidt, 2018) and transfructosylation, respectively (**Fig. 3**). Soybean oligosaccharides and raffinose, however, are still commercially produced by direct extraction.

**Table 1** Sources of naturally occurring oligosaccharides

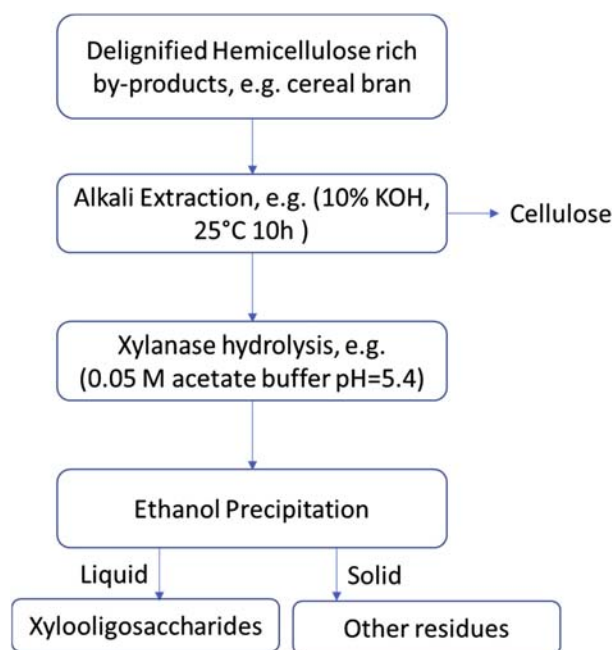

<i>Naturally occurring oligosaccharides</i>	<i>Example sources</i>
Fructooligosaccharides	Asparagus, sugar beet, garlic, chicory, onion, Jerusalem artichoke, wheat, honey
Xylooligosaccharides	Bamboo shoots, fruits, vegetable, milk, honey
Galactooligosaccharides	Human milk
Raffinose oligosaccharides	Seeds of legumes, lentils, peas, beans, chickpeas, mallow, composite, and mustard
Cyclodextrins	Water soluble glycans

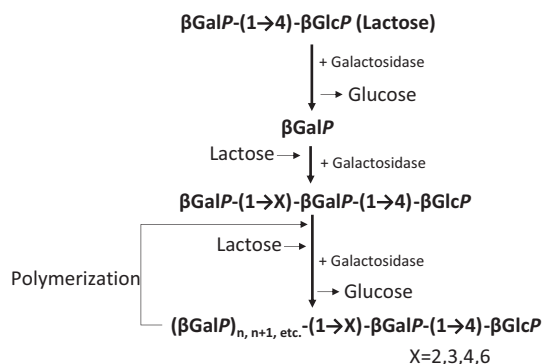

**Figure 1** Demonstration of typical structures of different oligosaccharides. (A): xylooligosaccharides; (B): raffinose family; (C): galactooligosaccharides; (D): cyclodextrin (CD); (E): fructooligosaccharides.

## Structural Characterization

Structural characterization is a must for the labeling of commercial products as well as for establishing their structure and function relationships. However, the commercially produced oligosaccharides differ in degree of polymerization, branching character and concentrations for each oligosaccharide molecule, which increase the difficulties for their structural analyses. Most of the naturally occurring oligosaccharides, and oligosaccharides generated from polysaccharide hydrolysis or enzymatic and chemical synthesis, exist in mixtures. Therefore, isolation, purification and fractionation are always prerequisites prior to structural analysis. For example, galactooligosaccharides produced by  $\beta$ -galactosidase hydrolase could be separated into various DP fractions using bio-gel P-2 column, as previously reported (van Leeuwen et al., 2014; Guo et al., 2017). These fractions can be monitored either by high performance size exclusion chromatography (HPSEC) coupled with an RI detector on a Rezex RSO-01 oligosaccharide Ag+ column (Fig. 4A and B), or by high performance anion exchange chromatography coupled with a PAD detector on a CarboPac PA-1 column (Fig. 4C). The whole mixture can also be monitored by MALDI-TOF-MS (van Leeuwen et al., 2016). The building blocks of the oligosaccharides and corresponding linkage patterns can be revealed by monosaccharide analysis combined with methylation analysis. The detailed sequencing information as well as the configuration ( $\alpha$ - or  $\beta$ -) of each sugar residue can be obtained with the help of 1D & 2D NMR analyses. Using the above mentioned methods, over 40 different molecular structures were successfully uncovered in commercially produced galactooligosaccharide mixtures, providing a structural coverage of over 99% of the products (van Leeuwen et al., 2014).

**Figure 2** Xylooligosaccharides enzymatically produced from hemicellulose rich agricultural by-products. Adapted from [Bian et al. \(2013\)](#).

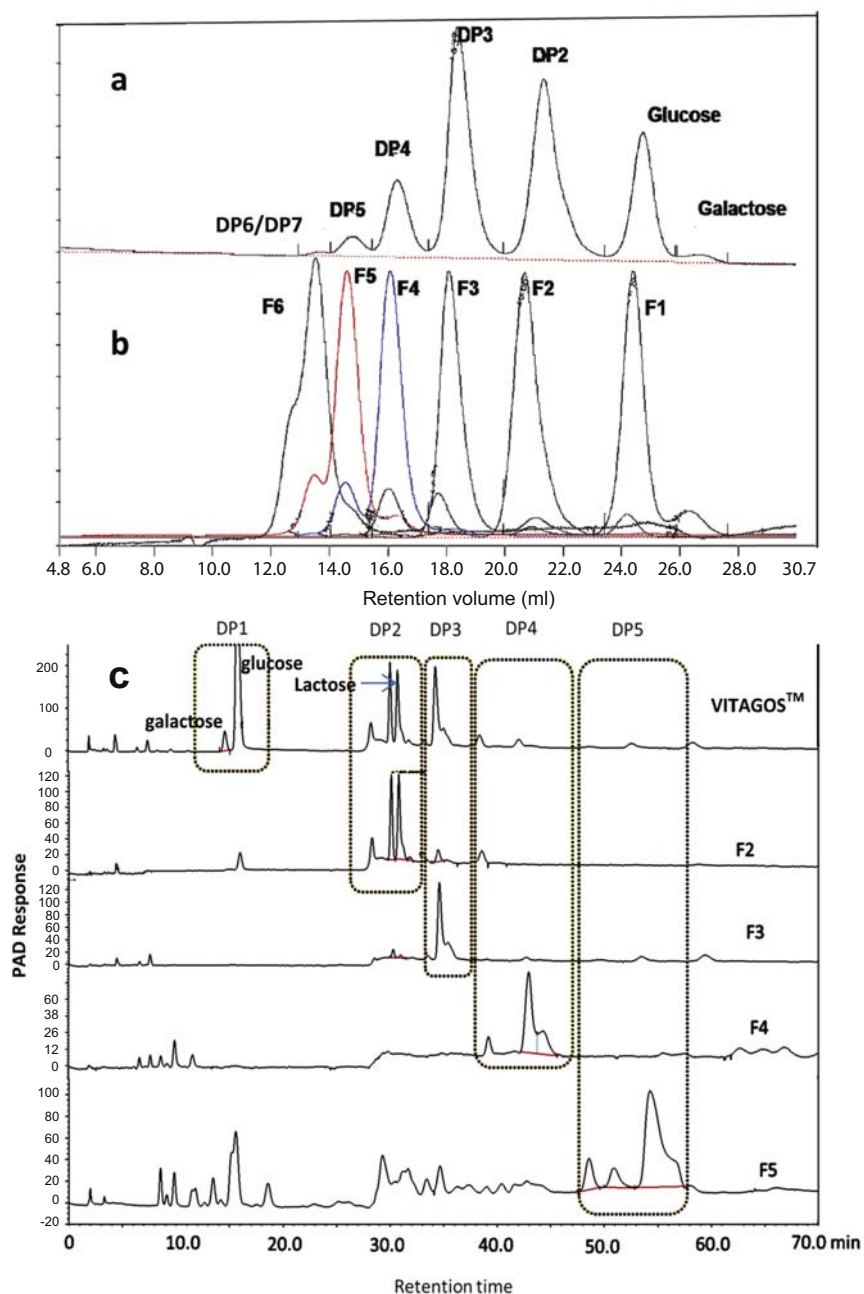

**Figure 3** Demonstration of the main reactions occurring during lactose hydrolysis and GOS synthesis. Numerous other side reactions are also possible to generate free galactose and other by-products.  $X=2,3,4,6$  indicates that the glycosidic bond can occur at several carbon atom positions on the galactose molecule, leading to many different oligosaccharides.

## Commercial Products and Naturally Occurring Oligosaccharides

A number of non-digestible oligosaccharides have been used in the food industry as prebiotic supplement products or food ingredients ([Table 2](#)). As food ingredients, the non-digestible oligosaccharides may be used in beverages, dairy foods, synbiotic products (combining probiotics and prebiotics), bakery, chocolate products, sweeteners and meat products. Aside from their prebiotic or health role, their other main technologically functional role would be as bulking agents or texturing agents to enhance total solids without greatly increasing viscosity, as polysaccharides would.

It should be noted that although many galactooligosaccharides and fructooligosaccharides have been commercially produced using enzymatic synthesis methods to mimic naturally occurring ones in milk, structurally they are quite different. For example, human milk oligosaccharides are comprised of the five monosaccharides glucose, galactose, N-acetylglucosamine, fucose and sialic acid, with N-acetylneuraminic acid. However commercially synthesized galactooligosaccharides and fructooligosaccharides added to infant formula contain galactose and fructose oligomers, which do not naturally occur in human milk. In addition, the fructose monomer itself is not found in human milk. Furthermore, synthesized galactooligosaccharides and fructooligosaccharides are neither fucosylated nor sialylated as they are in human milk. These structural differences could cause some function deficiency in the commercial products, such as antiadhesive antimicrobial effects. However, galactooligosaccharides and fructooligosaccharides could still influence the microbiota composition of the infant's feces and function as prebiotics ([Bode, 2012](#)).

## Functional Properties of Oligosaccharides

Non-digestible oligosaccharides elude hydrolysis and absorption in the small intestine due to limited carbohydrate active enzymes in human cells (Sarbin and Rastall, 2011). They are fermented by the anaerobic bacteria in the small and large intestines as energy sources (Mussatto and Mancilha, 2007). In the human gut, most anaerobic bacteria are benign; however, certain species are associated with acute and/or chronic disorders (Mussatto and Mancilha, 2007). Some non-digestible oligosaccharides have prebiotic activity, meaning they are selectively fermented by a limited number of gut bacteria (including probiotics) such as *Bifidobacteria* and *Lactobacillus*, and may promote human health by increasing populations of beneficial microbes and/or their metabolic activity (Sarbin and Rastall, 2011; Mussatto and Mancilha, 2007; Rivi re et al., 2016). For instance, the well-known prebiotic oligosaccharides such as fructooligosaccharides (FOS), galactooligosaccharides (GOS), xylooligosaccharides (XOS), isomaltoligosaccharides, soybean oligosaccharides and lactosucrose have been shown to increase *Bifidobacteria* and/or *Lactobacilli* populations. This can improve human health due to increasing fecal dry weight and producing more vitamins of the B group and nicotinic acid (Sarbin and Rastall, 2011; Mussatto and Mancilha, 2007; Rivi re et al., 2016).

The gut microbes fermenting prebiotic oligosaccharides produce short chain fatty acids (SCFAs), such as acetate, propionate, and butyrate (Mussatto and Mancilha, 2007; Rivi re et al., 2016). For instance, *in vivo* studies report that arabinoxylan-oligosaccharide (AXOS) consumption increases faecal butyrate concentrations (Rivi re et al., 2016). The pH value in the colon decreases through SCFA production, which can inhibit the growth of pathogenic bacteria, as well as increase mineral absorption by an osmotic effect (Mussatto and Mancilha, 2007). Furthermore, SCFA also exerts anti-inflammatory action and are implicated in the regulation of lipogenesis (Flint et al., 2015), contributing to other beneficial effects on human health. Butyrate is the preferred energy source for epithelial cells, stimulating colonic epithelial cell growth and increase salt and water absorption, thus relieving constipation (Mussatto and Mancilha, 2007; Rivi re et al., 2016). Moreover, butyrate was also found associated with inhibiting proliferation of colorectal cancer cells and changing cancerous cells to a normal cell type (Lim et al., 2005). Depending on the type of prebiotic oligosaccharides and composition of the gut bacteria, the quantity and ratio of SCFA product could be changed (Mussatto and Mancilha, 2007). For instance, *Bifidobacteria* produce acetate, lactate and formate, but no study reported that it could produce butyrate (Sarbin and Rastall, 2011). Butyrate is mainly produced by *Faecalibacterium prausnitzii* and *Eubacterium rectale*, which are two of the most dominant butyrate-producing bacterial species, belong to *Clostridium* clusters IV and XIVa, respectively (Rivi re et al., 2016).

Although non-digestible oligosaccharides have significant beneficial effects on human health, excessive consumption of non-digestible oligosaccharides may cause flatulence through gas production, or osmotic diarrhea in some instances (Mussatto and Mancilha, 2007). Furthermore, recent studies reported that consuming FODMAPs (Fermentable oligosaccharides, disaccharides, monosaccharides and polyols) may exacerbate symptoms of bowel inflammation in certain individuals who either malabsorb or are sensitive to FODMAPs (Rao et al., 2015).

## Relationship Between Non-digestible Oligosaccharides and Human Gut Bacteria

Over the last decade, *in vivo* studies have shown that some non-digestible oligosaccharides change gut microbiota composition at the species level (Scott et al., 2013; Flint et al., 2015). There are many structural factors, such as monomer saccharide composition and glycosidic linkages, that affect the selective utilization of non-digestible oligosaccharides by gut bacteria at the strain level (Sarbin and Rastall, 2011; Hamaker and Tuncil, 2014). This is primarily because the gut bacteria have different oligosaccharide digestive abilities, preferences and metabolite processes (Hamaker and Tuncil, 2014; Sarbin and Rastall, 2011). For instance, the  $\alpha$ -linkage of glucosyl-glucose has higher selectivity than that of galactosyl-galactose, but for  $\beta$ -linkages, the selectivity is opposite (Sarbin and Rastall, 2011). The  $\beta$ -1,3 and  $\beta$ -1,6 linkages of galactose have higher selectivity than  $\beta$ -1,4 linkages of galactose for *Bifidobacteria* (Sarbin and Rastall, 2011). Furthermore, molecular weight or degree of polymerization (DP) of non-digestible oligosaccharides can also influence selective fermentation (Sarbin and Rastall, 2011). Oligosaccharides of low molecular mass or DP are more selectively fermented than high molecular mass or DP by *Bifidobacteria* and *Lactobacilli*. This is because the oligosaccharides with low molecular mass (low DP) have more non-reducing ends that are preferentially attacked, for example by the exo-glycanase produced by *Bifidobacterium* spp (Sarbin and Rastall, 2011). However, low molecular mass or DP of non-digestible oligosaccharides may cause rapid consumption before reaching the distal regions of the colon, and thus leading to loss of its selective function (Sarbin and Rastall, 2011). For instance, a DP of 3 of isomalto-oligosaccharides has a higher selective stimulation than a DP of 2 for human fecal *Bifidobacteria* (Sarbin and Rastall, 2011).

As gut bacterial species differ in oligosaccharide degradation mechanisms and preferences, they may cooperate with each other when they utilize oligosaccharides (Rivi re et al., 2016; Scott et al., 2013). Recently, simple batch modeling, such as mono-culture and co-culture *in vitro* studies, were widely used for tracking the communities of specific gut bacteria and their metabolites when degrading oligosaccharides (Flint et al., 2015). For instance, in a co-culture study, *Bacteroides longum* LMG 11047 was able to consume released fructose and oligo-fructose from inulin, while another strain, *Bacteroides thetaiotaomicron* LMG 11262, had high digestive ability of both oligo-fructose and inulin. When the two strains were co-cultured in a medium with inulin as the sole carbon source, the *B. longum* LMG 11047 was outcompeted by *B. thetaiotaomicron* LMG 11262, which became the predominant strain (Sarbin and Rastall, 2011). Although we have less understanding about how they competed with each other, we know that *Bifidobacteria* have about 5% of their genome coding genes involved in carbohydrate internalization and prefer the transport of short

chain oligosaccharides into the cell (Rivière et al., 2016). The internal or cell-bound degradation is more efficient than extracellular degradation in a highly competitive gut ecosystem (Rivière et al., 2016; Sarbini and Rastall, 2011). However, a strain of *Bifidobacteria* was reported that could cross feed with other gut bacteria by carbohydrate breakdown (Sarbini and Rastall, 2011; Rivière et al., 2016). *Anaerostipes caccae* DSM 14662 and *B. longum* BB536 were co-cultured in the presence of oligo-fructose. The release of free fructose into the extracellular environment by *B. longum* BB536 fed *A. caccae* DSM 14662, a strain without digestive ability of oligo-fructose (Sarbini and Rastall, 2011). These observations indicate that interactions between *Bifidobacteria* and other gut bacteria are strain-dependent (Flint et al., 2015). Many studies also reported that metabolite production could be the substrate for the cross-feeding mechanism as well (Flint et al., 2015). For instance, lactate is associated with certain gut disorders, which is produced by *Bifidobacteria* as one fermentation product (Sarbini and Rastall, 2011). However, lactate can be utilized by *Megasphaera elsdenii* and converted into propionate, or converted into butyrate by *E. hallii* (Sarbini and Rastall, 2011; Flint et al., 2015). Acetate is converted into butyrate via the butyryl CoA: acetate CoA transferase route by butyrate-producing bacteria, such as *F. prausnitzii* and *E. rectale* (Scott et al., 2013). Furthermore, these two species grow better in the presence of acetate (Rivière et al., 2016). However, the result of *in vitro* co-culture studies do not fully reflect *in vivo* complexity of the gut microbiome (Sarbini and Rastall, 2011).

There is presently a need for better understanding of the potential effect of the prebiotic oligosaccharides on human health. Accordingly, molecular microbiological techniques, metagenomics, transcriptomics, proteomics and metabolomics studies are very useful for yielding more detailed information on the interaction between the specific structure of substrate and metabolism of the gut bacteria at the strain level (Sarbini and Rastall, 2011; Scott et al., 2013). Combining *in vivo* and *in vitro* results together will accelerate our understanding about the relationship between probiotics and prebiotics (Scott et al., 2013; Sarbini and Rastall, 2011).

## Pectin in Foods

Randall G Cameron, Citrus and Other Subtropical Products Research Unit, Ft. Pierce, FL, United States

© 2019 Elsevier Inc. All rights reserved.

### Source and Structure

Pectin is a major component of primary cell walls in all flowering plant genera except for the grasses of the Poales (Jarvis et al., 1988; Chan et al., 2017). Consequently, all fruits and vegetables consumed by humans contain pectin (Baker, 1997; Van Buggenhout et al., 2009; Taylor, 2012). Pectin synthesis within a plant cell occurs in the Golgi apparatus and the *Trans*-Golgi Network and is then trafficked to the plasma membrane within secretory vesicles (Driouich et al., 2012; Anderson, 2016; van de Meene et al., 2017). It has been hypothesized that at least 67 different glycosyl, methyl and acetyl transferases are required for pectin biosynthesis (Mohnen, 2008). Pectin's biological functions are numerous and mirror many of its technological applications. Pectin functions in plant cells include cell–cell adhesion, structural support, hydration control, positioning of leaf and floral primordia and as signaling molecules in plant biochemical pathways (Mohnen, 2008; Peaucelle et al., 2008; Atmodjo et al., 2013).

Pectin is composed of up to 20 different sugar moieties (Vincken et al., 2003; Paniagua et al., 2017). Galacturonic acid (GalA) is the dominant component comprising 50%–85% the pectic sugars (Yapo, 2009; Yuliarti et al., 2015; Müller-Maatsch et al., 2016). Arabinose, galactose and rhamnose are the other major pectic sugars. Structurally pectin is a hetero, block-copolymer. Although three dimensional models of pectin structural domains have been described (Pérez et al., 2000) an accurate three dimensional model of its global *in-vivo* structure has been elusive. Pectin has been shown to interact with cellulose, arabinogalactan proteins and xyloglucan to form a single interconnected network (Wang et al., 2016; Phyto et al., 2017). Small angle X-ray scattering (Alba et al., 2017) has also been used to look at the influence of pH on pectin's *in-vivo* structure where it was found that only strongly acidic environments affected structure. Contact between pectin and cellulose has been demonstrated in intact cell walls using solid state NMR (Dick-Perez et al., 2012). The majority of our understanding of pectin structure and functionality has been garnered from pectin that has been extracted from plant tissues. Global structural characterization has been approached with the use of atomic force microscopy (AFM) (Fishman et al., 2015; Kozioł et al., 2017; Paniagua et al., 2017), which has allowed pectin structures to be described as rods, segmented rods, kinked rods, branched chains, spheres and aggregates (Posé et al., 2012; Cybulska et al., 2015; Fishman et al., 2015).

Within these AFM visualized pectin structures are two commonly described dominant regions or block polymers. They are the homogalacturonan (HG) region and the rhamnogalacturonan I (RG I) region (Fig. 1). A structurally minor, but functionally important region is known as rhamnogalacturonan II (RG II) (Mohnen, 2008; Atmodjo et al., 2013; Shi et al., 2017). The HG region is a linear homopolymer of  $\alpha$ -1,4 linked D-GalA. Reports on the degree of polymerization (number of contiguous GalA subunits) for HG regions generally range between 80–120 GalAs (Tanhattan-Nasseri et al., 2011). The GalA subunits within the HG may be methylesterified at the C6 carboxyl group. The pectin being deposited in new cell walls is highly methylesterified but may be subsequently modified by the enzyme pectin methylesterase (PME) (Mohnen, 2008). Consequently the proportion of these subunits that are methylesterified, commonly known as the degree of methylesterification or esterification (DM or DE), varies within a population of pectin molecules. This leads to variability in the distribution of charge within the HG regions RG I is a branched copolymer with a backbone of repeating  $[\rightarrow 2)\text{-}\alpha\text{-L-rhamnosep-(1}\rightarrow 4)\text{-}\alpha\text{-D-galacturonic acidp-(1}\rightarrow 3)]_n$  (Voragen et al., 2009). Both neutral arabinan and (arabino-) galactans may be attached to O-4 of the rhamnose residues (Albersheim et al., 1996; Prade et al., 1999; Ridley et al., 2001). Some of these neutral side chains have been shown to occur in previously unknown configurations (Wefers and Bunzel, 2016). Other minor neutral sugars may also occur (Mohnen, 2008).

**Figure 1** Schematic representation of pectin rhamnogalacturonan I and homogalacturonan regions.

## Functionality

The HG region is widely recognized as the dominant functional region of pectin (Willats et al., 2006; Cameron et al., 2015; Kim et al., 2017) although the RG I and RG II regions also contribute (Sousa et al., 2015; Shi et al., 2017). Pectin functionality is largely dependent on its molecular weight, degree of methylesterification and the spatial distribution of charge within the HG region (Willats et al., 2001; Rolin, 2002). For some functionalities, such as water holding capacity, the distribution of the charge is more important than the DM (Willats et al., 2001). Considerable effort has been undertaken to map the distribution of charged (non-methylesterified GalAs) (Grasdalen et al., 1996; Daas et al., 1999; Neiss et al., 1999; Limberg et al., 2000; Ralet and Thibault, 2002; Kim et al., 2017) and neutral (methylesterified GalAs) domains within the HG region (Ralet et al., 2012; Remoroza et al., 2014; Cameron et al., 2015). The charged domains are required for crosslinking two or more pectin molecules via divalent cations (Powell et al., 1982; Luzio and Cameron, 2008) which is mandatory for gelation in the absence of sugar and low pH. Results typically show that the average number of charged blocks required per molecule must be greater than two and that some fraction of molecules in a given population must be trifunctional or more (contain three blocks or more) for a gel to form (Flory, 1941; Luzio and Cameron, 2008). These types of pectin (calcium sensitive pectin), commonly have a low DM (less than 50%). But in some instances, such as when pectin is used to stabilize acid dairy drinks, high DM pectins (greater than 50%) can also be made calcium sensitive (Rolin, 1994; Luzio et al., 2002; Tromp et al., 2004). Gelation of high DM, non-calcium sensitive pectins is a result of hydrogen bonding, dipolar and van der Waals interactions, and hydrophobic associations (Oakenfull and Scott, 1984; Evageliou et al., 2000). For this type of gelation it is the neutral, methylesterified domains of pectin HGs that are crucial.

Calcium sensitivity can be introduced into high DM, non-calcium sensitive pectins through the use of PME (Duvetter et al., 2006b; Cameron et al., 2011; Ngouémazong et al., 2012) and by cold temperature alkali demethylesterification. Plant and some bacterial PMEs that possess an alkaline isoelectric point are generally most active at neutral to alkaline pHs, whereas fungal PMEs generally have acidic isoelectric points and are most active at lower pHs. At least one plant PME is commercially available in a crude extract from papaya (Vasu et al., 2012). While fungal PMEs have a pseudo-random mode of action (Duvetter et al., 2006a) all plant PMEs have thus far shown the ability to hydrolyze GalA methyl esters with a processive, or blockwise, mode of action and the average sizes of the contiguous demethylesterified GalA blocks produced vary dependent on the enzyme and reaction conditions, such as pH, used (Cameron et al., 2008, 2011; Kim et al., 2013, 2014, 2017). Characterizing the inherent charge distribution, or that resulting from treatments to demethylesterify pectin, has been approached with several techniques including NMR (Grasdalen et al., 1996; Catoire et al., 1998; Kim et al., 2005), capillary electrophoresis (Williams et al., 2003) and enzyme-mediated structural characterizations (Daas et al., 1999; Cameron et al., 2008; Ralet et al., 2012; Kim et al., 2013).

The enzymatic methods developed by Cameron et al. (2008, 2011) estimate the average size of the charged blocks and their average number per molecule using a limited digestion with endo polygalacturonase (EPG). EPG excises the charged blocks from the parent molecules. Subsequently high performance anion exchange chromatography (HPAEC) coupled to an evaporative light scattering detector (ELSD) is used to visualize and quantify the charged oligomers excised by EPG (Cameron and Grohmann, 2005). An alternative enzymatic method developed by Daas et al. (Daas et al., 1999) relies on exhaustive EPG digestion. Products from this reaction are GalA monomers, dimers, trimers and undigested methylester protected domains of the HG. Since GalA monomer, dimer and trimer are commercially available their quantities can be estimated from standard curves produced by either a pulsed amperometric detector or an ELSD coupled to HPAEC (Daas et al., 1999; Cameron and Grohmann, 2005; Kim et al., 2013). The method calculates a parameter defined as Degree of Blockiness (DB) which estimates the amount of demethylesterified GalAs that are located in charged blocks large enough to be susceptible to EPG activity. Guillotin et al. (2005) introduced the parameter of Absolute DB ( $DB_{abs}$ ) which extends the method of Daas et al. (1999) to estimate the percentage of total GalAs that are in charged blocks large enough to be susceptible to EPG activity. Both of these methods, exhaustive and limited EPG digestion focus on charged blocks within the HG region. Other enzymatic methods have been developed to characterize the more neutral, methyl protected domains within the HG region. Ralet et al. (Ralet et al., 2012) coupled a pectin lyase digestion with an exhaustive EPG digestion to describe two new parameters related to HG charge distribution. They were DBMe and  $DB_{absMe}$ . Coupling both of these methods Ralet et al. (2012) were able to clearly differentiate between HGs that had been demethylesterified by chemical (random mode of action), fungal PME (pseudo-random mode of action) or a plant PME. Cameron et al. (Cameron et al., 2015) presented a method to characterize the methyl-protected domains of the HG region that are not susceptible to EPG attack due to the methyl ester of GalA. Cameron et al. (2015) defined methyl-protected HG domains as those that did not have four contiguous demethylesterified GalAs since EPG is presumed to require a minimum of four contiguous non-methylesterified GalA for cleavage (Chen and Mort, 1996). This method incorporated a cold (4 °C) alkaline demethylesterification following an exhaustive EPG digestion. The initial EPG digestion produced GalA monomers, dimers and trimers while the charged oligomers resulting from alkaline treatment of the methyl-protected domains were larger. These larger, charged oligomers were then separated and quantified using HPAEC coupled to an ELSD. Cameron et al. (2015) used the parameters of  $B_{ME}$  (average number of methyl-protected domains per molecule) and  $BS_{ME}$  (the average size of a methyl-protected domain) to describe these domains. Significant correlations between parameters used to describe methyl-protected domains and DM,  $DB_{abs}$ , and rheological properties were observed. Combining both exhaustive and limited EPG digests these analyses show that, based on Pearson's correlation coefficients, the average size of non-methylesterified blocks and the average number of methyl-protected domains per molecule may be the most useful for predicting pectin functionality.

The goal of being able to engineer, or tailor, the functionality of the HG regions in a population of pectin molecules has been a motivating factor behind much of this research. Kim et al. (2017, 2018) hypothesized that it is possible to control the size of

demethylesterified blocks within pectin HG regions with the use of different isoforms of processive pectin methylsterases or a combination of a pseudo-random fungal pectin methylsterase coupled to a processive plant pectin methylsterase (Kim et al., 2017). Values for all four charge distribution parameters (BS, BN, DB and DB<sub>abs</sub>) could be varied by manipulating the extent of an initial demethylesterification by a pseudo-random fungal PME, the total activity units of the processive plant PME and the reaction pH (Kim et al., 2018). When only processive plant PMEs were used for demethylesterification (Kim et al., 2017), and the charged block distributions produced by three different PME isoforms were compared, differences in the distribution pattern could be only be discerned using the results from a limited EPG digest (BS and BN) not from an exhaustive EPG digest (DB and DB<sub>abs</sub>).

## Pectin and Food Quality

Engineering the functionally important properties of pectin (i.e., molecular weight, total charge and distribution of charge) when used as an ingredient for food formulation or its *in-situ* modification in processed food has a long history. Pectin manufacturers routinely modify production conditions, blend different batches to obtain desired functionality and standardize pectins with additives to accommodate a customer's requirements (May, 1990; Rolin, 2002). When used as an ingredient for food formulation pectin is commonly classified as a high DM pectin (HM, DM > 50%) or low DM pectin (LM, DM < 50%) (Chan et al., 2017). If needed the DM can be reduced by an acid or enzyme treatment (Rolin, 2002). In general high sugar amounts are required for gelling with HM pectin (Yoo et al., 2003) while Ca<sup>2+</sup> is used to gel LM pectins (Yang et al., 2017). Calcium sensitivity is dependent on the HG regions having multiple charged, demethylesterified blocks ranging somewhere between 8–20 GalA residues per block (Luzio and Cameron, 2008). A calcium sensitive pectin is one in which two or more HG regions on different molecules can be coordinated to a middle layer of calcium ions (Grant et al., 1973; Kohn, 1975; Braccini and Perez, 2001). HM pectin is generally not calcium sensitive but calcium sensitivity can be introduced with a processive plant PME with a minimal (5%) reduction in DM (Hotchkiss et al., 2002). This calcium sensitive HM pectin is a critical component in acid dairy drinks where it serves to maintain protein suspension via ionic interaction with the positively charged protein surface via the negatively charged blocks of demethylesterified GalA in the HG regions (Glahn and Rolin, 1996; Tromp et al., 2004). The charged blocks within the HG region are not the only structural feature contributing to the stabilization of acid dairy drinks. Non-calcium sensitive pectin can also stabilize acid dairy drinks though not as well as calcium sensitive pectin (Laurent and Boulenguer, 2003). Calcium sensitive pectin also has use in potential applications where softer gels are preferred because they retain more water than LM gels and require less sugar (Joye and Luzio, 2000; Willats et al., 2001).

The *in-situ* modification of pectin in processed food products enables engineering food quality (Christiaens et al., 2015). Unit operations used by food processors such as thermal, high pressure and homogenization treatments alter pectin structure and the organoleptic qualities of the processed product. Texture is a major quality-associated property affected by changes in pectin structure. High temperature processing is the most common method to preserve food and make it microbiologically safe. An unwanted side effect of thermal processing is  $\beta$ -elimination reactions that lead to pectin depolymerization and solubilization. This action is the primary causes of texture degradation in many processed foods (Sila et al., 2006a; De Roeck et al., 2009). High pressure pasteurization is becoming a more common method for making foods microbiologically safe (Huang et al., 2017) with an additional benefit of having a reduced effect on texture. When high pressure pasteurization is coupled with high temperatures (>90 °C) it is believed that  $\beta$ -elimination is reduced due to increased demethylesterification of pectin (De Roeck et al., 2009) since the  $\beta$ -elimination reaction requires an adjacent methyl ester. The increased demethylesterification is believed to be due to increased activity of endogenous pectin methylsterase (Sila et al., 2006b). Additionally, the demethylesterified HG regions are now available for cross linking with Ca<sup>2+</sup> ions which has a positive effect on texture preservation. Ca<sup>2+</sup> soaking or infusion is often coupled to high temperature and high pressure treatments to improve firmness but Smout et al. (2005) concluded that factors in addition to demethylesterification, such as cell damage, are needed to account for the improved firmness.

Food formulation also uses vegetables and fruits that have been processed to disaggregate them into sauces, purees or suspensions (Blatt et al., 2011; Christiaens et al., 2015). Unit operations used to produce these disaggregated products can have a significant effect on their performance as an additive (Lopez-Sanchez et al., 2011). Thermal treatment may activate both pectin methylsterase and endo polygalacturonase (an enzyme that depolymerizes non-methylesterified HG regions leading to a reduction in molecular weight). This is especially important in tomato processing for juice, sauce, puree and paste (Anthon et al., 2008). A low temperature pre-treatment also affected the consistency and separation of pulp and serum in carrot and broccoli due to a decrease DM and an increase in Ca<sup>2+</sup> cross linking (Christiaens et al., 2011a, b).

The most recent innovation focused on pectin in food formulation is the work by Vancauwenberghe et al. (2017, 2018) in which pectin is incorporated into food inks (pumpable liquid or mashed foods that can be solidified) for 3D food printing. While the initial study (Vancauwenberghe et al., 2017) required a post printing incubation in a Ca<sup>2+</sup> bath to insure cross linking the second study (Vancauwenberghe et al., 2018) used a coaxial extrusion method in which both the pectin food ink and the Ca<sup>2+</sup> solution were simultaneously extruded from the print head so no post extrusion Ca<sup>2+</sup> incubation was required.

Pectin also influences quality of fresh fruit and processed juices. Investigations into the role of pectin in fruit softening have been ongoing for many years. Most recently it was reported that pectate lyase, an enzyme that depolymerizes non-methylesterified HG regions has a major role in tomato softening (Wang et al., 2018). Pectin methylsterase also is responsible for cloud loss in citrus juices and other cloudy juices (Cameron et al., 1998; Baker and Cameron, 1999). Galant et al. (2014) was able to demonstrate that

a very small decrease (74.7% to 68.3%) in DM in orange juice pectin was sufficient to initiate juice cloud destabilization, leading to juice clarification.

The targeted modification of pectin to provide precision functionalities as an ingredient or in fresh and processed fruits and vegetables is an area of growing interest. Continued studies on how to engineer pectin structure to produce defined functionality will provide an expanded toolkit for food chemists and food technologists to help feed a hungry world.

# Phospholipids

Meizhen Xie, Xi'an Jiaotong University, Xi'an, China

## Structure and Occurrence

Phospholipids (PL) are a group of polar lipids that consist of two fatty acids, a glycerol unit and a phosphate group which is esterified to an organic molecule (X) such as choline, ethanolamine, inositol, etc. The structure of a PL molecule is shown in Fig. 1. The phosphate group together with the X molecule is called the head group of PL. The common PL classes found in nature include phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidic acid (PA), phosphatidylserine (PS), and phosphatidylglycerol (PG).

PL are major components of cell membranes, and exist in all living organisms. The contents of PL in various sources are different. In foods, the content of PL range from 11 mg/100 g to 5433 mg/100 g. Good sources of PL include eggs, meats, fish, shellfish, cereal grains and oilseeds (Weihrauch and Son, 1983). The PL composition is different depending on its origin. For example, although PL from both animals and plants contain phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS) phosphatidylinositol (PI) and phosphatidic acid (PA), the content of PS in PL from animals is much higher than that in PL from plants (Guo et al., 2005). PG which is rarely found in plants and animals, is a major PL class in microorganism. Fatty acid composition of PL is dependent on the sources as well. PL from oilseeds contain fatty acids including palmitic acid (C16:0), stearic acid (C18:0), oleic acid (C18:1), linoleic acid (C18:2) and linolenic acid (C18:3); while PL from egg yolk does not contain C18:3, instead, arachidonic acid (C20:4), eicosapentaenoic acid (C20:5) and docosahexaenoic acid (C22:6) are present (Wang, 2007).

## Physiochemical Properties

### pH-Dependency of PL

Although various PL have a similar structure, there are differences in their properties due to the different head groups. For example, PC is positively charged at pH < 4, while at pH > 4, PC exists as a zwitterion, which is a neutral compound carrying electrical charge of opposite signs. Due to steric reasons, the negative phosphate group does not form an intramolecular salt with the positive quaternary amine group. Since the positive trimethylamino group remains isolated at all pH values, PC is hydrophilic at all pH values. As with PC, PE carries positive charge at pH < 4. PE turns into a zwitterion at 4 < pH < 10, and exists as an anion at pH > 10. Unlike PC, PE as a zwitterion can form an intramolecular salt due to the small ethanolamine group. As a result, zwitterion PE is weakly hydrophilic. PI carries no charge at pH < 4, and is negatively charged at pH > 4. PI is highly hydrophilic at all pH values due to the five free hydroxyl groups on the inositol moiety. PA carries no charge at pH < 4; at 4 < pH < 8, PA carries one negative charge; and at pH > 8 it carries two negative charges (Dijkstra, n.d).

**Figure 1** Structure of phospholipid. Adopted from Li et al. (2015) with permission.

## Phase Behavior

When dispersed in water, PL molecules aggregate to form two major structures: lamellar and hexagonal  $H_{II}$  phases (Fig. 2), which are interconvertible. The type of structures adopted depends on temperature, the saturation of the fatty acid chain, the nature of the head group, pH, water content, presence of divalent cations, etc. The increase in temperature usually induces the transition of the lamellar phase to the hexagonal phase, and the lamellar to hexagonal transition temperature varies with different PL classes. In general, PL with fully saturated fatty acid chains form lamellar phase at temperature range of 0–100 °C, regardless of pH and cations concentration. Unlike the other unsaturated PL classes that adopt the lamellar phase under physiological conditions (temperature, pH, salt concentration), the unsaturated PE adopts the hexagonal  $H_{II}$  phase under these conditions. Increase in the unsaturation of PE lowers the lamellar to hexagonal transition temperature. Increasing pH leads to the conversion of the hexagonal phase to the lamellar phase for unsaturated PE, which is uncharged at neutral pH. PS and PA carry negative charge at neutral pH, decreasing pH results in the transition from lamellar to hexagonal phase. In the presence of  $Ca^{2+}$ , PA adopts the hexagonal phase at neutral pH. For PC, lowering the water content induces hexagonal phase formation. As the membrane lipids, the phase preferences of different PL classes are of great importance to membrane functions (Cullis et al., 1990).

## Emulsifying Properties

PL are amphiphilic molecules containing both hydrophilic (the head group) and hydrophobic (acyl chains) moieties: they are natural emulsifiers with HLB values  $\sim 8$ . Since pH affects the association of the polar head groups of PL, the properties and stabilities of PL-stabilized emulsions are sensitive to pH change. At neutral pH, PC and PE exist as zwitterions. The stability of emulsions stabilized with these two PL are maintained mainly by hydration repulsion; while the stability of emulsions stabilized with PA and PI, which are anionic, are maintained by electrostatic repulsion, and are sensitive to changes in ionic strength and pH. PC has a tendency to favor the formation of oil-in-water (o/w) emulsions, while PE and PI facilitate the formation of water-in-oil (w/o) emulsions (McClements, 2005). PE and PA are sensitive to calcium, which could cause the loss of their function as surfactants. PL from egg yolk (contains mainly PC and PE) can form emulsions with great heat stability, and is usually used in the production of intravenously injectable emulsions. Interaction with proteins can improve the emulsifying properties of PL (Van Nieuwenhuyzen and Tomás, 2008).

## Oxidative and Antioxidative Properties

PL with unsaturated fatty acid chains are susceptible to oxidation. The nitrogen-containing moieties, ethanolamine and choline in PE and PC, respectively, can affect the oxidative stability of the corresponding PL (Corliss and Dugan, 1970). It is reported that PL can act as prooxidant, possibly by causing the decomposition of hydroperoxides which results in the formation of new radicals. However, PL has been demonstrated to exhibit antioxidant activities in various systems including vegetable oils (Doert et al., 2012; Hildebrand et al., 1984), marine oils (Olcott and Van Veen, 1963; Segawa et al., 1994), lard (Koga and Terao, 1994) and aqueous emulsion system (Cardenia et al., 2011.). There are four different mechanisms proposed to explain the antioxidant activity of PL:

1. Synergism between PL and other antioxidants. PL used alone in oil model show little primary antioxidant activities, however, PC, PE and PS work effectively as synergists to phenolic antioxidants such as tocopherol, vitamin C and ethoxyquin. There is no synergism observed between other antioxidants and PG/PI (King et al., 1992). The amino groups in PE and PS is believed to be involved in the regeneration of tocopherol from tocopheroxyl radicals, exerting the synergistic effect (Doert et al., 2012). PC and PE are reported to improve the radical-scavenging activity of tocopherol by making it more accessible to the radicals (Koga and Terao, 1995).
2. Binding of pro-oxidant metals. Acidic PL such as PA, PS and PG have been reported to show effective binding ability for the transition iron ion, which is a prooxidant for lipid oxidation. However, only PS exerts antioxidant activity (Dacaranhe and Terao, 2001).
3. Formation of Maillard-type products between PL and oxidation products

**Figure 2** Phase diagrams of phospholipid. Modified from Li et al. (2015) with permission.

The amino group of nitrogen-containing PL, PE specifically, may react with oxidation products of unsaturated fatty acids (aldehydes) to form Maillard-reaction products, which have been reported to show antioxidant activity (King et al., 1992).

#### 4. As non-radical peroxide decomposer

It is reported that PC can perform as free radical scavenger, and react with peroxy radicals to produce trimethylammonium oxides; while PE can decompose lipid hydroperoxides in a non-radical way to yield imines (Pokorny, 2002).

## Enzymatic Hydrolysis of PL

PL can be hydrolyzed by five different phospholipases: phospholipase A<sub>1</sub>, A<sub>2</sub>, B, C and D. The acting sites of these phospholipases are shown in Fig. 3. Phospholipase A<sub>1</sub> and A<sub>2</sub> specifically hydrolyze 1- and 2- acyl ester bonds of PL, respectively. The products of these enzymes are FFA and 1- or 2- LPL. Phospholipase B can hydrolyze both 1- and 2- acyl ester bonds, yielding FFA and water-soluble glycerophosphodiester (Merkel et al., 1999). Phospholipase C cleaves the phosphorus-oxygen bond between glycerol and phosphate, producing diacylglyceride and a phosphorylated head group. Phospholipase D hydrolyzes the phosphorus-oxygen bond between phosphate and the head group, and the products are phosphatidic acid and a free head group (Wang, 2001).

## Production of Phospholipid

Currently, PL is produced commercially in the form of lecithin, which is a mixture of different PL, glycolipids, triglycerides, and other minor components. Lecithin is a by-product of the degumming step in vegetable oil refining. Crude vegetable oils usually contain a certain amount (<3%) of PL, which need to be removed to ensure the quality of the final edible oil products. Degumming is the step designed to remove PL from the oil, where about 2.5% of water is added to the heated oil and mixed vigorously for about 30 min, the hydrated PL is then separated as gum from the oil by centrifugation. Other compounds such as glycolipids, free fatty acids, triglycerides and so on are also incorporated in the gum together with PL. The gum which contains about 50% of water is then dried to a water content of < 1%, resulting in a liquid-form of lecithin product. A liquid lecithin usually contains about 37% of neutral oil (triglycerides, free fatty acid, sterols, etc.), 45% of PL, glycolipids and carbohydrates. Washing the liquid lecithin with acetone would remove the neutral oil, yielding a de-oiled lecithin containing mainly PL (~74%), glycolipids (~17%) and carbohydrates (~5.5%), which are acetone insolubles (AI). Lecithin can be produced from various plant sources. At present, Soy bean is the main source for lecithin production. In food industry, lecithin is commonly used as emulsifier due to the emulsification properties of PL (Van Nieuwenhuyzen and Tomás, 2008).

Several methods are currently used to change the composition or chemical structure of PL in lecithin, in order to improve its emulsifying properties. Fractionation of lecithin with ethanol would yield ethanol soluble fraction enriched in PC and ethanol insoluble fraction enriched in PI. When compared to the parent lecithin, the PC-enriched fraction is a better emulsifier for oil-in-water emulsions, and PI-enriched is better for water-in-oil emulsions. Treating lecithin with peroxide or organic acid can result in the hydroxylation of the unsaturated fatty acids of PL, which can improve the hydrophilicity and emulsifying properties of lecithin. Treating lecithin with acetic anhydride would lead to the acetylation of the amino group in PE, producing acetyl-PE which can enhance the oil-in-water emulsifying properties of lecithin. Enzymatic treatment of lecithin with phospholipase A<sub>1</sub> or A<sub>2</sub> is a method

**Figure 3** Acting sites of phospholipases.

used to hydrolyze PL into lyso-PL (compounds with only one acyl chain compared to PL), which possess better emulsifying properties than PL (Van Nieuwenhuyzen and Tomás, 2008).

## Extraction and Analysis

The Folch extraction method is commonly used to extract PL from plant or animal or microorganism samples. In this method, chloroform/methanol 2:1 (v/v) is used as the solvent to extract all the lipids from samples including triacylglycerol, free fatty acid, PL, glycolipid, etc. PL is then separated from other neutral lipids by column chromatography or solid phase extract (SPE) before further analysis. For the past few decades, qualitative analysis of PL has been carried out through thin layer chromatography (TLC), which is only semi-quantitative. Nowadays, qualitative and quantitative analyses of PL are commonly performed by high performance liquid chromatography (HPLC) with various detectors. Silica columns are the most used stationary phase, but other columns are also used such as diol, cyano, amino, etc. Gradient elution of columns is usually applied with different mobile phases, which are mixtures of various solvents including chloroform, methanol, water, hexane, propanol, and so on. Several detectors can be used for HPLC analysis of PL. UV detector and evaporative light scattering detector (ELSD) are the two most commonly used ones. Although fluorescence detector are highly sensitive for PL, a derivatization of PL into fluorophore compound is required for the analysis, thus it is rarely used. Charge aerosol detector (CAD), which has greater sensitivity and better precision than ELSD, is a relatively new detector for PL analysis (Kielbowicz et al., 2013). <sup>31</sup>P-NMR is considered to be the ideal method for PL analysis. About 15 phospholipid classes (including lyso-phospholipid) can be separated and quantified by this method, while the HPLC method reported now can only separate less than 10 PL classes. However, the extremely expensive instrument required and the low sensitivity make it less popular than the HPLC method (Van Nieuwenhuyzen and Tomás, 2008).

### Introduction

Phosphates are derivatives of phosphoric acid ( $\text{H}_3\text{PO}_4$ ) with positively charged ions of elements, such as sodium, to form salts (inorganic phosphates), or with organic groups, such as phenyl, to form esters (organic phosphates). Phosphates irrespective of whether they are inorganic phosphates or constituents of phosphoproteins and membrane phospholipids, are found in most living organisms. Phosphates are an essential dietary requirement for humans. Organic phosphates from meat, grains, dairy products, and nuts, and inorganic phosphates (Pi) from food additives are readily absorbed in the small intestine, processed in the liver, stored in cells and bone, and reabsorbed in the kidneys (Takeda et al., 2004). Phosphate has many physiological, biochemical and cell signalling roles in the body. Phosphates are also used as additives to a range of food products where they serve as to aid processing, enhance organoleptic properties or improve safety and shelf-life. An appropriate balance between the use of phosphates as additives and possible ill effects associated with excessive consumption needs to be struck.

### Applications of Phosphates in Food

Phosphates are present in a range of foods typically including protein rich products such as meat, poultry, seafood and dairy products. Phosphates are used as additives to food to serve as preservatives on meats, as stabilizers and as melting salts for the processing of cheese products. These food grade phosphates aid in maintaining the structure and hydration of the meat products by enhancing the water holding capacity of muscle and assisting in the oxidative stability of the meat by chelating pro-oxidative metal ions (Lampila, 2013). In dairy products, phosphates are used as a protein dispersant in spray dried milk products. Potassium or sodium salts of phosphates are also used as emulsifiers in food such as processed meat and cheese. Processed food products tend to have a higher phosphate content than that naturally present on food. For instance, processed meat and poultry products were reported to have twice the amount of phosphate as compared to natural products (Sherman and Mehta, 2009). Levels of phosphates permitted for use in foods must be “generally be regarded as safe” by the Food and Drug Administration (FDA) (del Río et al., 2007; Ellerbroek et al., 1996).

### Poultry and Meat Products

Food grade phosphates are commonly used in the meat and poultry industry in the form of polyphosphates or pyrophosphates where they cause the sequestration of metal ions and dissociation of the acto–myosin complex (Fonseca et al., 2011). Application of phosphates on meat may increase the pH of meat, as the pH of most food grade phosphates ranges from 6.3 to 12.5, which will increase the ionic strength and water holding capacity of meat (Lampila, 2013; Vasavada et al., 2006). For this reason they are used as an aid in decreasing cooking loss, controlling pathogen growth, reducing drip loss and purge in chilled storage and improving textural properties (Lindsay, 2008; Lampila, 2013). They also prevent the discoloration of poultry and meat products. In addition, polyphosphates have been found to delay the rancidity of some products due to the sequestration of iron and copper (Coul-tate, 2009). Polyphosphate levels between 0.1% and 0.3% do not appear to pose a risk to health since they are broken down into pyrophosphates which is converted into orthophosphates in most meat products. The presence of phosphates in meat may result in high concentrations of salts, causing protein denaturation under frozen storage.

Sodium tripolyphosphate (STPP) ( $\text{Na}_5\text{P}_3\text{P}_{10}$ ) is commonly used in poultry and meat processing. This compound is used in blends with sodium hexametaphosphate [ $(\text{NaPO}_3)_n$ ,  $n = 10\text{--}15$ ] to improve the tolerance of calcium ions in brines for the curing of meat products. In brines, calcium may be complexed with hexametaphosphate which is soluble and prevents calcium phosphate precipitation. Previous studies have found that the combination of sodium phosphate and sodium chloride decreases the requirement of salt from 3% to 3.5% to 1.4% to 1.8% (Lindsay, 2008). A combination of these compounds solubilizes the myosin with the hydrophobic tail surrounding the fat and the hydrophilic end binds to the water molecule. These two compounds enhance the succulence of the cooked products and maintains the water holding capacity of the product (Lampila, 2013).

The strong antioxidant effect of phosphates against oxidation of lipids in cooked meat products occurs through the binding of metal ions that act as a catalyst for oxidation. Previous studies have reported that encapsulated phosphates enhances the stability and functionality of antioxidant activity and was able to inhibit lipid oxidation in ready-to-eat meat products as well as extend their shelf life (Kilic et al., 2014; Sickler et al., 2013). Sodium pyrophosphate (SPP) and STPP with and without encapsulation were reported to inhibit lipid oxidation in raw and cooked ground chicken and beef (Kilic et al., 2014). Excessive levels of phosphates use will incur higher costs and may affect the organoleptic qualities of the meat due to the amount of hydrogenated oil used in the encapsulation of the phosphate in addition to the high phosphate levels used.

## Dairy Products

Phosphates are added to dairy products, such as milk and cheese, for protein dispersion, acidification, gelation, supplementation of nutrients, chelating calcium and aiding in emulsification (Kapoor and Metzger, 2008). Tetrasodium phosphate is used in chocolate milk to maintain higher viscosity levels for the dispersion of cocoa powder (Lampila, 2013). Acidification by phosphoric acid is used to produce buttermilk. In addition, disodium phosphate is used in milk prior to drying to provide hydration and assist in protein dispersion. The use of trisodium phosphate in evaporated milk ensures that the butterfat is not separated from the aqueous phase (Lindsay, 2008).

There is a provision by the Codex Standards for the addition of low levels of polyphosphates in milk powders (Codex Alimentarius Commission, 2011), although milk powders do not usually contain polyphosphates. The use of polyphosphates such as sodium hexametaphosphate and sodium tripolyphosphate delays gelation via protein denaturation. Ultra-high temperature (UHT) processed milk is well known to gel upon storage. However, sodium hexametaphosphate was reported to enhance the shelf life of UHT milk products by delaying the onset of gelation due to observed proteolysis during the storage by milk proteases such as plasmin and exogenous enzymes from bacterial contamination (Anema, 2015). Another factor for the delay in gelation was the onset of gelation occurred without visible changes to proteins present in the milk (Datta and Deeth, 2001). Alkaline phosphatase is also used to determine if adequate pasteurization has been conducted in the dairy industry (Kilic et al., 2014).

As cheese aging involves proteolysis, it weakens the cheese emulsion. Heat treatment of cheese may separate the emulsion into coagulated protein and butter oil. The role of phosphates will be beneficial as it alters the proteins to form melting salts. During the process of cheese production, dicalcium phosphate and sodium caseinate is formed from disodium phosphate and calcium caseinate. Sodium caseinate generates a layer surrounding the fat droplet to form the desired characteristics of cheese (Lampila, 2013). In addition, sodium aluminium phosphate (SALP) is used as an emulsifier to process cheese and its associated products. The mode of action of SALP is it alters the protein in order to produce a smooth layer surrounding the fat droplets to prevent the separation of fat from the cheese product. SALP will assist in forming a soft texture and aid in easier melting characteristics of the cheese products (Yokel et al., 2008).

## Control of Pathogens Using Inorganic Phosphates

Among the inorganic phosphates, trisodium phosphate (TSP) is a well-recognised antimicrobial used in poultry processing facilities. Trisodium phosphate is formed by neutralizing phosphoric acid with sodium hydroxide as follows:  $\text{Na}_2\text{HPO}_4 + \text{NaOH} \rightarrow \text{Na}_3\text{PO}_4 + \text{H}_2\text{O}$ . Low reactivity of  $\text{Na}^+$  and  $\text{PO}_4^{3-}$  ions which are produced due to the dissociation of TSP when mixed with water causes extremely low by-product formation. This inorganic phosphate is an alkaline sanitizer and is used between pH 10–12. Gram negative bacteria such as *Campylobacter* and *Salmonella* are more susceptible to alkaline sanitizers including TSP at this pH range than Gram positive bacteria due to the presence of the thin peptidoglycan layer (Capita et al., 2002; Dickson et al., 1994). TSP is known for its surfactant properties which aid in preventing *Campylobacter* and *Salmonella* attachment to poultry. In addition TSP has the ability to remove some fat from the meat which indirectly aids in the removal of bacteria attached to the fat on the meat (Sarjit and Dykes, 2015). It is also able to remove the protective lipid layer on the meat enabling it to reach the entrapped pathogens thereby reducing the prevalence of these pathogens on meat (Capita et al., 2002).

TSP is regarded as safe for use on poultry at concentrations between 8% and 12% without hampering the organoleptic qualities of meat. At these concentrations, TSP has the ability to disrupt *Salmonella* spp. cell membranes due to the high pH resulting in the detachment of *Salmonella* cells from poultry and its associated surfaces through sequestration of metal ions (Sam-pathkumar et al., 2003). Effectiveness of TSP on both *Campylobacter* spp. and *Salmonella* spp. on poultry has been studied as indicated in Table 1. The occurrence of carryover of residues in the immersion chillers may alter the pH of TSP in water reducing its effect in reducing the numbers of pathogens in the chillers. To overcome this, air chilling may be used instead of immersion chilling (Buncic and Sofos, 2012).

## Regulations That Control the Use of Phosphates

At an international level, the World Health Organisms (WHO) and the Food and Agriculture Organisation (FAO) play leading roles in regulation of food additives. As both these organisations (WHO and FAO) have an interest in food regulation, they have set up different joint institutions that provide scientific information to United Nation member countries.

One of which is the Joint FAO/WHO Expert Committee on Food Additives (JECFA). This organisation lists over 100 different chemical forms of phosphate that can be used in food for different purposes, some of these applications include as flavouring agents. Phosphates can also be considered a food contaminant as some of its metal can contaminate food. Phosphates also make up the chemical structures of some mycotoxins and can be included in naturally occurring toxicants. They also make up the chemical structures of some veterinary drugs which can find its way into the food chain. The presence of toxicants, naturally occurring or otherwise and veterinary drugs are controlled by the maximum residual level regulations. Maximum residual level

**Table 1** Reduction of pathogens on poultry treated with trisodium phosphate

Sample	Pathogen	Concentration	Exposure time and temperature	Reduction (log units)	References
Chicken drumsticks	<i>C. jejuni</i>	12%	1 min dip at ambient temperature	$3.6 \pm 0.60$	Koolman et al. (2014)
Chicken legs	<i>S. Enteritidis</i>	12%	15 min dip at $20 \pm 1$ °C	$2.91 \pm 1.94$	Alonso-Hernando et al. (2013)
Chicken meat	<i>Campylobacter</i> spp. <i>Salmonella</i> spp.	12%	10 min at 4 °C	~1.81 to less than the limit of detection (<2.02) ~2.46 to less than the limit of detection (<2.02)	Sarjit and Dykes (2015)
Duck meat	<i>Campylobacter</i> spp. <i>Salmonella</i> spp.	8, 10, 12%	10 min at 4 °C	Less than the limit of detection (<2.02)	Sarjit and Dykes (2015)
Chicken legs	<i>S. Enteritidis</i>	12%	15 min at 20 °C	~2.0	del Río et al. (2007)

regulations controls the highest concentration of these chemicals that can be found in a food product that is meant for human consumption. If the concentrations are above this level then they cannot be legally sold as food.

The second WHO/FAO joint organisation is the Codex Alimentarius Commission, commonly known as the Codex. This organisation promotes the establishment of food regulatory frameworks within member countries that are compatible with Codex so as to promote international trade. Codex standard 192 (CODEX STAN 192-1995) is the General Standard for Food Additives which lists all of the food additives and their different chemical forms that can be used in human food. The standard has been revised over the years and the latest revision was in 2017. The Standard states that food additives can only be used when it has an advantage, such as preserving the product or maintaining its quality, and there is no known health risk to the consumer. Food additives cannot be used to mislead the consumer, in other words additives can be used only if it serves a technological function. The amount of a food additive added is controlled to the lowest quantity needed to achieve the required functional effect. The use of these additives are based on the risk assessments and exposure assessments. The JECFA carries out the risk assessment of all these chemicals and this information is provided to the Codex to be included in the evaluation process. The Codex standard (CODEX STAN 107-1981 Rev 2016) states that food additives need to be clearly labelled and must not lead to confusion or mislead the consumer. The Codex standard (CODEX STAN 192-1995) further states that only the food additives listed in it are recognised as suitable for human consumption and that these food additives must have an assigned acceptable daily intake and must be used considering these levels. The Codex lists 30 different chemical compounds of phosphates that are approved for human consumption as shown in **Table 2**. The FAO/WHO food standards not only lists the different chemical forms of phosphate that can be used but it also lists the different food products the chemical forms can be used in and their maximum concentrations. A food manufacturer (if within a Codex signatory country) is obliged to meet these requirements as a minimum level. Some countries or regions have their own maximum usage levels that form part of their regulations within that country.

### The United States of America

The Food and Drug Administration (FDA) of the US Department of Human Services is responsible for developing and administering food law within the United States (US) at a Federal level. The Food Additive Status List provides all of the additives that can be used in food and their different forms. This list needs to be read in conjunction with the different regulations. Some of the phosphate based compounds are listed as Generally Recognised as Safe (GRAS) and can be used considering Good Manufacturing Practises (GMP), which means there may be no regulation that controls its maximum usage levels but it can be used only at levels to achieve the required function. The FDA issues regulations that can be binding obligations and be enforced by law. Title 21 of the Code of Federal Regulations deals with food, Chapter I Subchapter B part 170 of the Federal law deals with Food Additives. Part 172 – Food Additives Permitted for Direct Addition to Food for Human Consumption gives the forms of phosphate that can be used in food for different purposes and the maximum levels that can be used at. For example, monosodium orthophosphate can be used to esterify starch where the residual phosphate in the food does not exceed 0.4% calculated as phosphorus. Part 173 – Secondary Direct Food Additives Permitted in Food for Human Consumption provides the concentrations of different forms of phosphate that can be used in material that may come in to contact with food, for example the concentration of phosphate esters that can be used in lye-peeling solutions, which must not exceed 0.2%.

### Australia

Food law in Australia at a Federal level is governed by the Food Standards Australia New Zealand (FSANZ). Each Australian state and territory has adopted the FSANZ standards as law within their jurisdictions and is enforced by a state government department and the local city councils. FSANZ recognizes that food additives play an important part in ensuring safety and quality required by

consumers. The Australian food standards, Standard 1.3.1 Food Additives and the Schedules published together with a list of all the different food additives can be found on the Federal Legislation Website. These schedules includes the different chemical forms of phosphate that can be used in food, the purposes that they can be used of and the maximum permitted levels.

The Australian food law, Standard 1.3.1 states that a food additive is a substance added to food for one or more technological or functional purposes as listed in Schedule 14. Schedule 14 lists the different technological functions that a food additive can perform, including their definitions. Schedule 15 and 16 list the substances that can be used as food additives, the food they can be used in and the maximum allowable levels. In these documents different phosphate compounds that can be added to different products at different maximum concentrations are listed. Schedule 7 lists the different classes of food additives which are to be included in the ingredient lists on food product labels. In Australia food additives must be listed on product labels by their class name followed by the name of the food additive or by its number.

## European Union

The European Commission's regulation EC 1333/2008 sets out the regulations on food additives that govern the rules within the different countries in the European Union. The aim of the regulation is to standardise the use of food additives within the different countries of the Union. It provides the different food additives that can be used in food and the maximum concentrations they can be used at, the functions that these can be used for and the labelling requirements. The safety of food additives are evaluated and approved for use within the Union by the Scientific Committee on Food (SCF) and/or the European Food Safety Authority (EFSA). Only additives that are approved by these two organisations can be used in food within the EU and that too only for the purpose(s) it was considered safe. Under Regulation No 1333/2008 Annex II the European Commission has a database of all food additives that are approved for use within the EU. It is designed as a tool to inform stakeholders of the approved food additives, their purposes of use and the maximum levels of usage. In this database there are 17 different phosphate containing phosphate based compounds listed. It also includes the functions for which they can be applied for and the maximum levels they can be included in food.

## Health Impacts Due to Phosphates in the Diet

As a biomolecule, the tetrahedral molecular geometry of phosphate allows it to form bonds with four other molecules and create complex molecular compounds such as nucleic acids, proteins, ATP and phospholipids (Azevedo and Saiardi, 2017). The importance of phosphate in the human body is evident by the fact that 80%–90% of filtered plasma phosphate is actively reabsorbed in the renal tubules in a healthy individual (Prasad and Bhadauria, 2013). However, the amount of phosphate additives in the average North American's diet has more than doubled since 1990, with an estimated half the population of the USA consuming in excess of the recommend ADI of phosphates (Ritz et al., 2012; Uribarri and Calvo, 2013). Elevated blood serum levels of phosphate has been linked to a wide range of cardiovascular diseases (Ritz et al., 2012). The link between elevated phosphate levels in the body and these diseases in at risk patients is a relatively new concept, and there are still many gaps in our understanding as to how they are associated (Selamet et al., 2015). However, it does appear from the evidence currently available that certain foods have a significant impact on homeostatic levels of phosphates which in-turn could be associated with an increased risk of mortality in patients unable to regulate phosphate levels (Moore et al., 2015).

## The Roles of Phosphates in the Body and Hypophosphatemia

The availability of phosphate on Earth when the first living organisms emerged was scarce. It is theorised that early metabolic pathways could have relied on biomolecules composed of ions such as iron and sulphur or carbon-based thioesters (Goldford et al., 2017). If these pathways existed in primitive cells, they have likely been replaced by molecules composed of phosphates suggesting that these phospho-molecules provided a selective metabolic advantage to the cells. Nucleotide molecules are composed of a 5-carbon ring, a nitrogenous base and phosphate groups. In DNA and RNA the phosphate groups bind the hydroxyl group on the 3' carbon and allow for the formation of genetic sequences. In energy-donating nucleotide molecules such as ATP and GTP, the electrostatic repulsive forces between phosphate groups can be released following phosphate hydrolysis and used to power energy dependent processes in the cell (Cooper, 2000).

The main structural component of the cellular membrane are phospholipids; carbon chains with a phosphate group on the extremity of one end of the molecule (Alberts et al., 2002). Phosphate is a polar anion and is therefore attracted to water, whereas the fatty acid tails of the phospholipids are hydrophobic. This configuration causes the phospholipid molecule to orientate itself with the phosphate heads facing the extra- or intracellular environment, whereas the fatty-acid tails aggregate with the fatty acid tails of other phospholipids, forming a membrane bilayer. This configuration allows the membrane to be selectively permeable, meaning it can allow for the passive diffusion of certain molecules into and out of the cell (Alberts et al., 2002).

Bone is comprised of an organic matrix of collagen fibres and an inorganic layer of the calcium phosphate salt, hydroxyapatite (Shaker and Deftos, 2000). Collagen fibres reduce the brittleness of bone so that it has a small degree of flexibility under tensile stress, whereas the hydroxyapatite gives bone structural rigidity. Bone growth is dependent on the maturation, death and subsequent mineralisation of chondrocytes. In addition to the structural roles of calcium and phosphate ions in bone, calcium also regulates the maturation and organisation of chondrocytes whereas phosphate induces apoptosis, resulting in mineralisation. Low calcium and phosphate levels in bone tissue results in the build-up of un-mineralized osteoid tissue characteristic of rickets (Penido and Alon, 2012). In addition to the metabolic and structural roles phosphates play in the body, phosphoric acid and dihydrogen phosphate are also used by the body to maintain the pH of blood within homeostatic ranges (Anderson, 2013).

Phosphate is primarily stored in the bones and teeth of the human body with the rest present as buffering ions or bound to proteins in the blood, or stored as biomolecules in cells. The three major hormones responsible for regulation of phosphate levels in the blood are calcitriol, parathyroid hormone (PTH), and fibroblast growth factor 23 (FGF-23). Broadly speaking, PTH and FGF-23 decrease phosphate levels in blood plasma by reducing the expression of the sodium/phosphate co-transport proteins (NaPiII) in the proximal convoluted tube of the nephron. FGF-23 also indirectly decreases absorption of phosphate in the gut by decreasing the expression of other sodium/phosphate co-transporter proteins. Conversely calcitriol, increases absorption of phosphate in the intestines and inhibits the release of PTH, indirectly increasing phosphate reabsorption in the renal tubules (Penido and Alon, 2012).

Hypophosphatemia is a drop in plasma phosphate levels below 2.5 mg/dL. This can be caused by a variety of different factors such as malnutrition, alcoholism, vitamin D deficiency or resistance to vitamin D, physical trauma, renal disorders, increased serum insulin concentrations, or hereditary factors (Pappoe and Singh, 2010). Hypophosphatemia is associated with general organ dysfunction, impaired bone growth, and structural abnormalities in blood cells (Alberts et al., 2002; Mozingo and Mason, 2007). Patients suffering acute hypophosphatemia have weakened skeletal, smooth and cardiac muscle contractions, which can lead to cardiomyopathy and respiratory problems (Pappoe and Singh, 2010). This is likely due to a drop in intracellular reserves of energy donating phospho-molecules such as ATP which are essential for muscle contractions. In rare cases, low serum levels of phosphate and ATP also increases the rate of haemolysis (Melvin and Watts, 2002).

## Chronic Renal Disease can Induce Hyperphosphatemia

Hyperphosphatemia is abnormally elevated serum concentrations of phosphate (>1.46 mmol/L) generally associated with negative health outcomes if experienced for a prolonged period of time (Shaman and Kowalski, 2016). It is most commonly associated with impaired kidney function but can also be the result of increased dietary phosphate intake, tumor lysis syndrome, and

hyperparathyroidism (Nguyen and Wang, 2012). There is mounting evidence that increased phosphate levels increases the risk of cardiovascular diseases such as atherosclerosis, although there are conflicting arguments over whether this is directly related to hyperphosphatemia (Lau et al., 2010; Nguyen and Wang, 2012).

In healthy patients, roughly 950 mg of phosphorus is absorbed from the gut into the blood stream every day. Being a water soluble ion, phosphorus readily passes through the filtration membranes of the kidney and the majority is actively reabsorbed in the proximal convoluted tubule. In patients with chronic kidney disease the glomerular filtration rate steadily decreases leading to a build-up of serum phosphate levels. PTH and FGF-23 levels are elevated to reduce the phosphate re-absorption NaPi-II molecules in the renal tubules. However, the water soluble phosphate molecules can still passively diffuse from the filtrate into the renal vascular network. Additionally, as the glomerular filtration rate decreases these compensatory mechanisms are insufficient to normalise serum phosphate levels (Shaman and Kowalski, 2016). Interestingly, although PTH decreases the amount of phosphate transporters in the kidneys, it also increases osteoclast activity which leads to bone resorption and elevated calcium and phosphate levels in the blood (Hruska et al., 2008; Shaman and Kowalski, 2016).

### Hyperphosphatemia Association With Cardiovascular Disease

Vascular smooth muscle cells (VSMC) are responsible for the vasomotor properties of the endothelium of blood vessels. However, the contractile phenotype of these cells can be switched to a bone cell-like calcifying state via altered expression of calcification promoter and inhibitor molecules. This switch causes the VSMC to secrete bone matrix proteins, and can induce apoptosis which creates nucleation sites for hydroxyapatite crystals to form (Askar, 2015). The resulting calcification of blood vessels stiffens the walls of the vessels, creates occlusions, and increases blood pressure.

Increased Pi serum levels are associated with increased incidence of vascular calcification (Adeney et al., 2009; Lau et al., 2010). Although the exact mechanisms are still unclear, studies have shown that exposure to concentrations of phosphate similar to serum concentrations of patients with hyperphosphatemia increased the expression and phosphorylation of certain proteins and signaling molecules in VSMC (Lau et al., 2010). For example, exposure to increased phosphate levels increased the expression of Runx2 and Cbfa1 transcription factors which induces the secretion in bone matrix constituents in VSMC (Speer et al., 2010). Increased phosphate levels increases phosphorylation rates of the Bcl2 and ERK1/2 proteins. Although their mechanisms are distinct from each other, phosphorylation of these proteins increases apoptosis of the cells (Lau et al., 2010; Speer et al., 2010). The remains of apoptotic cells provides an “anchoring” site for hydroxyapatite crystals to form, increasing calcification of the surrounding tissue (Lau et al., 2010).

### Glossary

**Blood cholesterol** Cholesterol concentration in the blood, which is used as a marker for the risk of coronary heart disease.

**Oleogel** Gel of a lipid phase, typically involving liquid triglyceride oils and gelling agents different from saturated triglyceride oils. Typically, oleogels can be considered a subclass of organogels, involving edible gelling agents and lipid phases.

**Triglyceride** Triacylglycerol, the main component of edible oils and fats.

**X-ray diffraction** Analytical technique to reveal long range translation order, typically in crystalline materials. The method uses x-ray radiation to probe the structure of the material.

### Sources of Plant Sterols

Steroids are triterpenes, organic compounds with a tetracyclic cyclopenta[*a*]phenanthrene structure (see Fig. 1) having two principal biological functions: signaling molecules that activate steroid hormone receptors, and components of cell membranes that affect the flexibility of the membranes in living cells. The present article concerns itself with sterols, a subclass of steroid alcohols.

Sterols of plant origin are usually referred to as phytosterols, and those of animal origin as zoosterols. These groups are not mutual exclusive, however. The most important zoosterol, cholesterol, can also be found in plant sources, sometimes in relative large quantities (for example in the nightshade and lily families). Further sterols are produced by yeasts and fungi, ergosterol being a common representative. Plant sterols on the one hand and zoosterols and sterols from fungi on the other hand differ in the common intermediate occurring in their biochemical synthesis. Plant sterol synthesis involves cycloartenol as an intermediate, whereas zoosterols and sterols from fungi are synthesized through a route involving lanosterol.

Phytosterols are naturally occurring steroid alcohols having the steroid structure with a hydroxyl group at position 3 and a side chain at position 17, usually containing one or more double bonds in the steroid skeleton. They can be obtained from many sources, but commercial sources include seed oils like corn, soybean and rapeseed oil at typical levels of 0.1%–1%. They are structurally closely related to stanols, which do not have any unsaturated bonds, and can be commercially obtained from hydrogenated sterols from e.g. woodpulp. In fact, stanols are usually considered to be part of the phytosterol group. Typically, sitosterol is the most abundant plant sterol, although stigmasterol and campesterol can often be found in substantial quantities too – depending on the particular source being used. Less common plant sterols include brassicasterol, avenasterol, and spinasterol (Akihisa et al., 1991).

The various phytosterols can be considered as closely related variations of the cholestanol molecule, a molecule with only saturated bonds in the triterpene ring system. Campestanol and sitostanol have an additional methyl or ethyl group respectively attached to the carbon at position 24 compared to cholestanol. Cholesterol, campesterol and sitosterol have an additional double bond between the carbons at position 5 and 6 compared to their stanol counterparts. Brassicasterol and stigmasterol have an additional double bond between carbons 22 and 23 compared to campesterol and sitosterol. Finally, ergosterol has an extra double bond between carbons 7 and 8 relative to brassicasterol (See Fig. 2). Obviously, we have restricted ourselves here to a limited number of well-known sterols, as the full list of sterols is much longer, having ~200 entries (Akihisa et al., 1991).

Figure 1 Steroid skeleton nomenclature.

**Figure 2** Structural relationships between selected sterols.

## Chemical Analysis

The official methods for sterol analysis are based on gas chromatography with flame ionisation detection (GC-FID), with an elaborate sequence of sample preparation steps: saponification to remove triglycerides from the sample, extraction of the phytosterol-rich unsaponifiables fraction by liquid extraction followed by fractionation using thin layer chromatography (TLC) or solid-phase extraction (SPE), derivatization to form phytosterol trimethylsilyl-ethers (TMS) or phytosterol acetates, before applying the GC-FID analysis ([International Organization for Standardization, 1999](#); [American Oil Chemists' Society, 2017](#); [Winkler-Moser, 2017](#)). In recent years, more rapid alternative methods have been developed which require a less extensive sample preparation method, often involving mass spectroscopic techniques ([Alberici et al., 2016](#)).

## Crystallization Behaviour

Sterols typically form  $\sim 3.8$  nm thick bilayers in their crystalline state ([Craven, 1986](#); [Argay et al., 1996](#); [Kawachi et al., 2006](#); [den Adel et al., 2010](#)). Depending on the temperature, three hydrated and anhydrous crystal forms are found. For sitosterol, dissolution takes place above  $110^\circ\text{C}$ , an anhydrous form is observed between  $80$ – $110^\circ\text{C}$ , a hemi-hydrate forms between  $45$ – $80^\circ\text{C}$  (1:2 M ratio water/sitosterol), and finally a monohydrate (1:1 M ratio water/sitosterol) occurs for temperatures below  $45^\circ\text{C}$  ([Christiansen et al., 2002](#)).

In x-ray diffraction, all crystal forms share wide-angle x-ray scattering peaks at  $d = 2\pi/q_i = 1.2$  and  $0.59$  nm (here  $d$  is the distance over which the crystal structure repeats itself, and  $q_i$  is the wave vector that characterizes the length scale probed in the scattering experiment). The various crystal forms can be distinguished by the small(er)-angle x-ray diffraction peaks at either  $d = 1.76$  and  $0.880$  and  $0.523$  nm (anhydrous), or  $1.88$  and  $0.481$  nm (hemi-hydrates), or  $1.76$  and  $0.503$  nm (monohydrates). Hydration of the sterols can also be inferred from the existence of an infrared feature at  $\sim 3450\text{ cm}^{-1}$ , which is best explained by the existence of an intermolecular hydrogen bond ([den Adel et al., 2010](#); [Rogers et al., 2010](#)).

The crystal structure of sitosterol in non-aqueous solvents confirm the presence of a bilayer structure and long-range order in three dimensions, with diffraction peaks indicating  $d = 3.76$  and  $1.88$  nm but not at  $0.50$  nm (powder and slurry in oil) and  $d = 3.59$  and  $1.79$  nm and a weaker peak near  $0.50$  nm (slurry in water) ([den Adel et al., 2010](#)). This suggests that the sitosterol exist as a mixture of anhydrous and hemi-hydrate crystals in powder and oil slurry, whereas the monohydrate form seems more abundant in slurries in water.

The infrared spectra show only a very weak band associated with intermolecular hydrogen bonding, around  $\sim 3420$ – $3440\text{ cm}^{-1}$ . The absence of characteristic hemi-hydrate and anhydrate peaks in aqueous slurry and in emulsion suggests the presence of the

mono-hydrate form, despite the surprising similarity of the infrared spectrum for the aqueous slurry and that of the powder (den Adel et al., 2010).

Mixtures of sterols can form mixed crystals. Small structural differences affect the concentration ratio ranges over which mixed crystal formation occurs. Mixed cholesterol + sitostanol crystals form only at a fixed 1:1 wt ratio, whereas cholesterol + sitosterol mixed crystals form over a much wider range around the 1:1 composition (Melnikov et al., 2004). The most likely explanation is that the ring system in the molecules, the sterane core, is more similar in cholesterol and sitosterol than in cholesterol and sitostanol (see Fig. 1).

## Physiological Effects of Plant Sterols

At modest concentrations, phytosterols (and stanols) are part of a normal human diet. Sterols have been added to various food products at enhanced concentrations in order to reduce blood cholesterol by as much as 8.8% at a daily intake of 2.5 g or more (Katan et al., 2003; Demonty et al., 2009). No evidence has been observed of over-consumption of phytosterols as a result of the intake of these fortified products (Lea and Hepburn, 2006), and phytosterols were found to be safe for human consumption - even at higher concentrations (Willems et al., 2013).

An increase in the intake of dietary cholesterol is compensated nearly perfectly in the body by balancing the cholesterol synthesis, leading to relatively constant blood cholesterol levels. For dietary plant sterols, however, the cholesterol synthesis response is weaker. The commonly accepted mechanism explains the effect by a combination of the competition between cholesterol and plant sterols for incorporation in intestinal mixed micelles and the poor intestinal absorption of plant sterols. The reduced uptake of cholesterol does not lead to a matching increase in cholesterol synthesis in the body, and leads to an overall decrease in blood cholesterol levels and an effective increase in fecal excretion of cholesterol (Lecerf and de Lorgeril, 2011).

In addition, there are emerging indications that plant sterol intake may result too in a modest reduction of blood serum triglyceride levels by about 6% for a ~2 g/day plant sterol intake (Demonty et al., 2013).

The large body of nutritional studies resulted in the approval of a number of health claims by major regulatory bodies, like the European Food Safety Authority (EFSA) and the Food and Drug Administration (FDA):

- Europe: Plant sterols have been shown to lower/reduce blood cholesterol. Blood cholesterol lowering may reduce the risk of coronary heart disease (EFSA, 2008).
- USA: Foods containing at least 0.65 g per serving of plant sterol esters, eaten twice a day with meals for a daily total intake of at least 1.3 g, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [name of the food] supplies \_\_\_ grams of vegetable oil sterol esters (FDA, 2016).
- Canada: [serving size from Nutrition Facts table in metric and common household measures] of [naming the product] provides X% of the daily amount of plant sterols shown to help reduce/lower cholesterol in adults (Health Canada, 2010)

Serving sizes are dependent on product format. Several related claims exist for stanols, and some additional supporting claims are approved as well.

## Derived Molecules: Sterol Esters and Bile Salts

Sterols can be esterified with other groups to form sterol esters. These occur naturally, like oryzanol, which is a well-known component in rice bran oil and which has a saturated ring systems like the stanols but with additional methyl groups at the 4 and 14 positions and a missing one at the 19 position (cf. Fig. 1). They can also be produced via traditional oil processing technology, like though interesterification of sitosterol with fatty acids obtained from liquid oils like rapeseed or canola (Bot and Flöter, 2011). Plant sterols are often added to functional foods in the form of sterol esters: this form is easier to handle because they are much more soluble in edible oils. However, hydrolysis in the digestive tract ensures that plant sterols become available as free sterols when required.

Bile salts (or bile acids) are steroid acids and act as powerful natural emulsifiers obtained from the cholesterol through enzymic oxidation of cholesterol, and bile salt-like molecules derived from plant sterols will show comparable behaviour.

## Mutual Interactions Between Plant Sterol and Derived Molecules

Mixtures of sterols and their derivatives show rich behaviour, often as a result of co-crystallization. The combination of cholesterol with bile salts, for example, can form helical ribbons in aqueous phases (Konikoff et al., 1992).

Quite a few derivatives of cholesterol have been demonstrated to show fibrillar aggregation in non-triglyceride fluids (Bot and Flöter, 2011). The similarities between cholesterol and plant sterols in terms of aggregation behaviour justify the prediction that analogues based on plant sterols will show the same behaviour.

Sitosterol, and most related plant sterols, self-assembles with oryzanol in triglyceride oil and several other organic solvents (Bot and Agterof, 2006; Sawalha et al., 2012). The molecules cannot stack perfectly parallel, and form curved one-dimensional

aggregates, also known as helical ribbons. These aggregates consisting of equimolar amounts of plant sterol and oryzanol appear as tubules of ~10 nm diameter on longer length scales (Bot et al., 2012; Matheson et al., 2017). The tubules tend to aggregate laterally, but sufficient cross-links are formed between bundles of tubules to establish a network at 3%–4% structurant. Macroscopically, such networks cause the oil to form a transparent or slightly hazy block of gelled oil which are stable for many months.

The presence of water destabilizes the oleogel, however, because the plant sterols have a higher affinity to water than to the oryzanol. The formation of sterol monohydrates can only be avoided if the water activity of the water phase is sufficiently low ( $a_w < 0.9$ ) or delayed if the solubility of water in the organic phase is low enough. The latter cannot be achieved with triglyceride oils (Sawalha et al., 2012).

## Plant Protein Ingredients

**Andrea K Stone<sup>a</sup>, Yun Wang<sup>a,b</sup>, Mehmet Tulbek<sup>b</sup>, and Michael T Nickerson<sup>a</sup>**, <sup>a</sup> University of Saskatchewan, Saskatoon, SK, Canada; and <sup>b</sup> AGT Food and Ingredients Inc., Saskatoon, SK, Canada

© 2019 Elsevier Inc. All rights reserved.

### Overview

The global protein ingredient market was valued at \$31.8 billion in 2016 and is expected to rise to \$46.4 billion by 2022 with a compound annual growth rate of 6.5% (Anonymous, 2017), with the greatest growth occurring in the plant protein ingredient sector. In 2054, it is estimated that  $\frac{1}{3}$  of all global protein consumed will be of plant origin (Anonymous, 2017). Overarching drivers leading to the market shift towards increased plant protein consumption include: a) population growth; b) increased need for sustainable agronomic practices with reduced water usage; c) changing demographics and lifestyles (Henchion et al., 2017); and d) emerging regulatory influencers, with countries, including China, the Netherlands, France and Denmark, moving to change dietary guidelines to restrict meat consumption in favor of other protein alternatives (Hosafci, 2017). North America represents the largest market for protein ingredient utilization and growth, followed by Europe and Asia Pacific. In these regions, market trends are also shifting towards lower cost, more abundant, plant-based alternatives (although markets are still dominated by animal-based proteins) due to rising costs of dairy-based ingredients, and growing dietary preferences based on religious, moral or ethical beliefs. Other market drivers include the rising demand in the functional food, beverage and breakfast food sectors as consumers move their purchasing power towards healthier ingredients/products. The leading emerging non-soy protein alternative comes from pea, however other legumes (e.g., lentils, faba beans, chickpeas, lupin, peanut and edible beans), oilseeds (e.g., canola/rapeseed, flax seed and hemp) and cereals (e.g., wheat, rice, sorghum, millet, barley, quinoa, amaranth and oats) are of substantial interest as well. Utilization of proteins from agriculture by-products such as from oilseed meals left over after oil extraction or dried distillers grain left over from ethanol fuel processing is also of importance in order to add value to their respective industries, especially based on the sheer volume of feedstock available. In terms of product development, the majority of plant protein research to date has focused on meat alternatives or meat/plant hybrids, sports nutrition bars, high protein non-dairy beverages and breakfast cereals/snacks. However, protein innovations are also occurring across all market segments. Despite experiencing market growth, the wide spread use of plant proteins has been hindered by their reduced solubility (and functionality) relative to animal-based products, in some cases allergenicity (e.g., soy and canola napin), the presence of certain bioactive compounds (e.g., vicine/convicine from faba bean), strong flavor compounds that can negatively affect consumer perception, and tendency to cause flatulence.

### Protein Fractionation

Processing of agriculture crops into flours (20%–30% protein), enriched flours (30%–50% protein), concentrates (50%–80% proteins) and/or isolates (>90% protein) can be accomplished by physical means or dry/wet fractionation processes. Depending on the raw material, dry processing may first involve seed cleaning, dehulling, sorting, and splitting followed by milling into a flour (Wood and Malcolmson, 2011). Milled flours with different particle sizes can be used for various purposes, as they display different functional attributes. Flours may or may not be defatted prior to use. Proteins, due to their size and density differences from starch, can be concentrated by air classification which is a dry separation technique that suspends milled flour in a flow of air allowing for the larger starch particles (known as the coarse fraction) to be collected from the bottom while the smaller protein particles (known as the fine fraction) leave the classifier from the top (Schutyser et al., 2015). The resulting protein concentrates (fine fraction) typically range in protein between 30%–60%. Protein concentrates (65%–80%) and/or isolates (>90% protein) produced by wet fractionation processes can be prepared using flours, enriched flours, defatted oilseed meals or dry fractionated protein concentrates. Alkaline extraction followed by isoelectric precipitation is the most widely used industrial wet extraction method. During this process, flours/concentrates are dispersed in water and pH adjusted to pH 8.0–9.0 to solubilize the proteins. The insoluble materials (e.g., insoluble fibre, carbohydrates and prolamin-type proteins) are removed via centrifugation, leaving a clarified supernatant which is then pH adjusted to the protein's isoelectric point (i.e., zero net charge) to precipitate the protein. The precipitated protein is centrifuged, washed and neutralized then spray dried into a powder (Boye et al., 2010). Alternatively to isoelectric precipitation, proteins can also be recovered from the supernatant using membrane separation technology. Other wet fractionation techniques include salt extraction (Martínez-Maqueda et al., 2013), micellar extraction (Stone et al., 2015), and alcohol washing (Cookman and Glatz, 2009). Depending on the mode of extraction, and the exact conditions used (e.g., flour slurry concentration, pH, temperature, salt concentration, etc.) different protein compositions are achieved leading to different functionality of the final powdered ingredient (Boye et al., 2010).

## Protein Functionality

Protein functionality is dependent on intrinsic factors relating to the protein (e.g., size, conformation, charge, hydrophobicity, amino acid profile and level of folding, etc.) environmental factors (e.g., presence of salt, temperature, solution pH, presence of other additives, etc) and processing factors (e.g., shearing, temperature, enzymatic modification, pressure, etc.). A brief description of the following important functional properties is given below: solubility, water/oil holding, foaming, and emulsification. Protein solubility is correlated with protein surface charge, where solubility tends to be greatest at pHs away from the isoelectric point where protein charge and electrostatic repulsion is highest, and lowest at pHs close to the isoelectric point where repulsion is minimal and aggregation is favored because of non-covalent attractive forces and hydrophobic interactions (Can Karaca et al., 2011). The presence of salts can improve solubility through the 'salting in' effect or decrease solubility through the 'salting out' effect or by charge screening to promote protein aggregation, based on the ionic strength of the solution (Martínez-Maqueda et al., 2013). Water hydration (WHC) and oil holding (OHC) capacities of protein ingredients refers to the amount of water or oil that can be held per g of protein (or protein ingredient) (Boye et al., 2010), and tends to be related to the amount of hydrophilic and hydrophobic amino acids, respectively, on the protein surface (Tiwari and Singh, 2012). These properties are also related to particle size, where smaller particles tend to bind more water (or oil) due to their greater surface area for wetting. The ability of a protein to hold water or oil helps to prevent cook loss from occurring within a product during processing or storage, and improves tenderness and moisture retention (Boye et al., 2010). Foams are described as air-in-water emulsions, where air represents inclusions in the continuous water phase containing the protein. Foams are generated through the addition of mechanical energy in the form of high shear from sparging, homogenization or whipping (Zayas, 1997). During this process, proteins migrate from the water phase to the air–water interface where they then reorient to position the hydrophobic moieties towards the gas phase and hydrophilic moieties towards the water phase to lower the interfacial tension (Boye et al., 2010). Proteins at the interface (also known as the lamellae in foams) form a viscoelastic film around the air bubbles generating a physical barrier between the bubbles (Zayas, 1997). Foam stability is usually the greatest near the isoelectric point of the protein, where the lack of electrostatic repulsion leads to a greater amount of protein–protein interactions and network formation in-between neighboring bubbles (Lam et al., 2017). This network also helps inhibit draining of the continuous phase, which would ultimately lead to foam breakdown. Foams are characterized by their foaming capacity, which refers to the volume of foam generated after mechanical shear for a given amount of protein, whereas foam stability refers to the ability of the foam to retain its structure and resist separation over time (Boye et al., 2010). An emulsion refers to a thermally dynamically unstable mixture of an oil and water phase, in which one phase becomes dispersed within the continuous phase of the other in response to mechanical shear (e.g., homogenization or ultrasonication) and in the presence of an emulsifier (e.g., protein) (Damodaran, 2005). During emulsion formation, proteins migrate in the water phase to the oil–water interface, where like foams, proteins re-orient such that the hydrophobic moieties are positioned towards the oil phase and the hydrophilic moieties are positioned towards the water phase. Protein–protein interactions then occur to form a viscoelastic film that protects against droplet coalescence (Kiosseoglou and Paraskevopoulou, 2011). Emulsions are most stable at pHs away from the protein isoelectric point due to significant electrostatic repulsion between droplets (McClements, 2004). The presence of salts, depending on the increase in solution ionic strength, can destabilize emulsions by screening charges on the protein's surface allowing for closer interactions and droplet flocculation and coalescence (McClements, 2004). Emulsion capacity measures the amount of oil that can be stabilized in an emulsion mixture per g of protein material, whereas emulsion activity index measures the total surface area of the oil droplets being stabilized in the emulsion (Tiwari and Singh, 2012). The stability of an emulsion over time is measured as emulsion stability index (Tiwari and Singh, 2012).

## Nutritional Properties

Protein quality refers to the amount of essential amino acids within the protein itself, as well as their bioavailability or ability for the protein to be uptaken into the metabolic process (Nosworthy et al., 2017a). Essential amino acids include histidine, isoleucine, leucine, methionine, lysine, phenylalanine, threonine, tryptophan and valine. They also include arginine, cysteine and tyrosine for immune compromised individuals and infants. Typically protein digestibility is measured using *in vitro* methods, such as the pH-stat titration method involving one or more digestive enzymes or by *in vivo* methods, such as the Protein Efficiency Ratio, Biological Value, Protein Digestibility Corrected Amino Acid Score (PDCAAS) or the Digestible Indispensable Amino Acid Score (DIAAS) (Nosworthy et al., 2017a). Although more accurate than *in vitro* methods, *in vivo* methods involve the use of animals (e.g., rats or pigs), are more expensive, labor-intensive and time-consuming. As such, *in vitro* methods tend to be favored. Currently, the PDCAAS method is approved for use by the FAO/WHO as the international standard, however, the DIAAS method is being considered for its replacement since it allows high-quality protein sources to be better differentiated (Nosworthy et al., 2017a). Soaked/boiled red kidney beans, green lentils, yellow peas and Kabuli chickpeas have PDCAAS values of 0.55, 0.63, 0.64 and 0.52, respectively (Nosworthy et al., 2017b), whereas raw flours from barley, wheat, oats and maize have PDCAAS values of 0.49, 0.45, 0.71 and 0.41, respectively (Boye et al., 2012).

Despite their nutritional properties, plant materials also contain bioactive compounds that can adversely affect protein and carbohydrate digestion as well as mineral absorption. For instance, phenolic compounds act to cross-link proteins to reduce their digestibility, whereas the presence of enzyme inhibitors (trypsin, chymotrypsin and amylase inhibitors) can reduce the activity of digestive enzymes for proteins and carbohydrates (Dahl et al., 2012). Phytates and oxalates can act as chelators to reduce mineral

absorption (Dahl et al., 2012), whereas lectins can cause diarrhea, vomiting, bloating and red blood cell agglutination (Roy et al., 2010). The presence of oligosaccharides can be fermented by bacteria within the gastrointestinal tract leading to the production of gas, abdominal pain and flatulence (Granito et al., 2005). And in the case of faba beans, the presence of vicine and convicine, which are glycosides, can be associated with favism in certain individuals (McMillan et al., 2001). In canola/rapeseed, glucosinolates can be converted to toxic metabolites (Campbell et al., 2016). Levels of bioactive compounds can be reduced via processing and breeding programs. However further research into specific bioactive compounds, also reveals health promoting effects such as their antioxidant activity, satiety (diet control), anticarcinogenic activity and cholesterol lowering effects (Güçlü-Üstündağ and Mazza, 2007; Chung et al., 1998).

## Tailoring Plant Protein Structure, Functionality and Quality Through Processing

Processing, such as extrusion, roasting, boiling, fermentation, autoclaving (Khattab et al., 2009), microwave, infrared heating and so on, can be used to improve protein digestibility and reduce or eliminate levels of bioactive compounds affecting digestion. Processing causing changes to the protein's quaternary and tertiary structures during partial denaturation to make them more susceptible to digestive enzymes (Park et al., 2010). This also induces changes in the functional properties of the protein/material. Various processes used to modify plant protein-based materials are given in Table 1. For instance, Coda et al. (2015) found that fermentation of a protein-rich faba bean flour, produced by air classification, significantly decreased the concentration of vicine and convicine by >90% and decreased the trypsin inhibitory activity by 86%, however the *in vitro* protein digestibility remained relatively unchanged. Not all conditions lead to a positive impact on protein quality and accordingly are process and material dependent. O'Sullivan et al. (2016) reported that ultrasound treated pea protein isolate produced emulsions with decreased droplet size and lowered the interfacial tension better than untreated pea protein isolate. This was attributed to the ultrasound treatment decreasing the pea protein size and increasing protein surface hydrophobicity, whereas these changes were not seen for a rice protein isolate and no change in the emulsion properties of the rice protein isolate was observed.

## Summary

Plant based protein ingredients have been consistently in the top global food trends as it relates to demand, health, product innovation, sustainability and food security. The nutritional and functional properties of these ingredients can be modified through a wide variety of processing methods with the subsequent induced changes being material and process dependent. Although not discussed in this review, other key areas of interest as it relates to plant protein ingredients are flavour reduction strategies, development of bioactive peptides, utilization of protein-rich waste streams, and ingredient-application specificity.

### Overview

Salt is the name commonly used for sodium chloride (NaCl), which consists of 40% sodium and 60% chloride by weight. In the body, sodium is essential for the maintenance of cellular membrane potential; its presence determines the volume of extracellular fluid and thereby maintains blood volume and blood pressure, [Fig. 1](#). Given its multiple functions in the body, an excessive consumption of sodium can have negative health effects, within the most alarming ones being cardiovascular diseases and elevated blood pressure ([Doyle and Glass, 2010](#)). In industrial countries, about 75%–80% of dietary salt is obtained through processed food consumption, 5%–10% is naturally occurring in the foods that make up the diet and the remaining 10%–15% comes from salt added during cooking or at the table ([Dotsch et al., 2009](#)). In contrast, in developing countries, salt used for seasoning plays a much more important role; In China, for example, this accounts for 76% of total salt intake ([He et al., 2012](#)). An assessment of processed foods in Australia revealed that sauces and spreads contain the most sodium (1280 mg/100 g) followed by processed meats (850 mg/100 g), snacks (800 mg/100 g), fish products (510 mg/100 g) and bread and bakery products (470 mg/100 g); however, a similar study performed in the UK detected lower sodium levels in bread and bakery products, followed by meats, sauces and spreads. These differences indicate that the sodium content of processed food can varies greatly between different markets and between countries ([Kloss et al., 2015](#)).

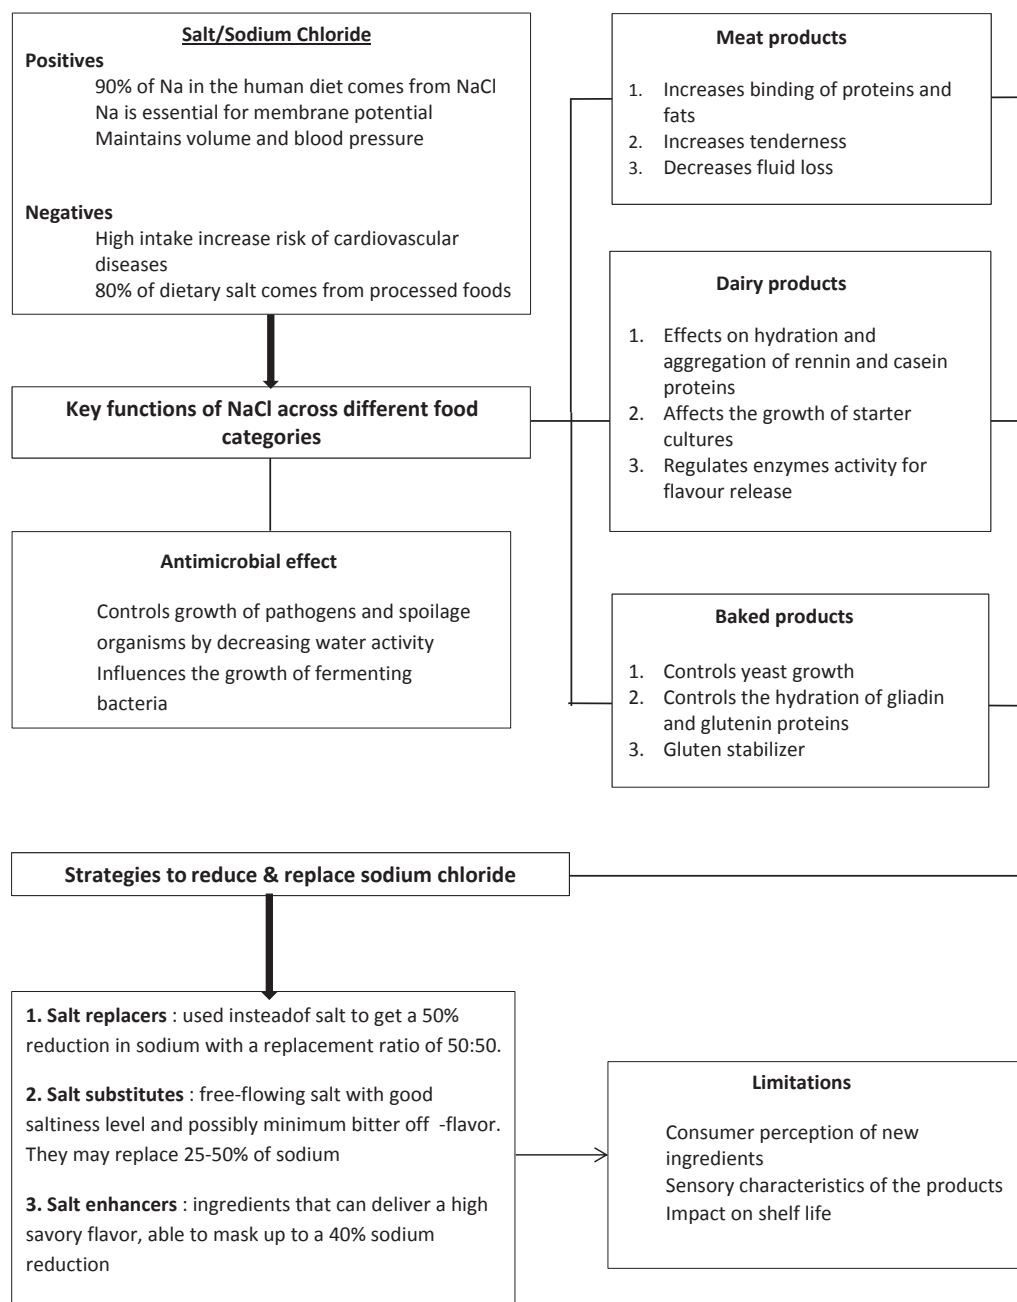

### Roles of Salt in Different Food Categories

#### Texture

Salt play a major role in the development of physical properties of foods that are expected by costumers, one of these being the texture of products ([Desmond, 2006](#)). For example, in **meat**, 1.5% to 2.5% (w/w) of salt can increase hydration and enhance the binding of proteins to each other and to fat; the mechanisms is given by the proteins actin and myosin that by swelling in the presence of salt, can bind more water and thereby increasing tenderness, decreasing fluid loss and allowing the formation of heat-stable emulsions in processed meat products ([Inguglia et al., 2017](#); [Man, 2007](#)). In **dairy products**, the use of salt in concentration of 5% to 6% (w/w), together with pH and calcium level, has a large effect on the degree of hydration and aggregation of the mammalian milk proteins rennin and casein; the mixture of salt and proteins called *para*-casein, precipitates with the calcium ion to form of insoluble curd. Is this that determine the water-binding capacity of the casein matrix, its rheological and textural characteristics and the changes that occur during cooking ([Guinee, 2004](#)). In pasteurized cheeses, emulsifying salts are added to aid in the hydration of the *para*-casein, to help the emulsification of fats, and its stability. Content and composition of emulsifying salts vary in different products, but a levels of about 1.5% are typically used ([Guinee and O'kenedy, 2007](#)). Yeast bread and some other **baked goods** require the addition of salt to control the growth of yeast and to develop an extensible gluten network. Salt in particular helps controlling the hydration of gliadin and glutenin proteins. The development of a robust gluten matrix in the dough is necessary to trap small air bubbles, critical for the production of high-quality bread ([Hutton, 2002](#)). Optimal salt concentrations stabilize gluten and prevent stickiness in dough. Too little salt however allows excessive growth of yeast, resulting in oversized bread with poor texture ([Vetter, 1981](#)). Moreover, it has been shown that salt has a plasticizing effect during heating of cereal products which improves the mobility of reactants and enhances Millard reactions, producing a darker colored product ([Moreau et al., 2009](#)).

#### Flavour

Sodium chloride is the saltiest sodium compound available; it affects the taste of specific foods by providing the flavor of saltiness, by enhancing or masking other flavors, and by controlling the growth of specific microbes that produce flavorful compounds. For example, during cheese ripening, salt significantly affects the growth of starter cultures and activities of lipolysis and proteolysis enzymes that produce important characteristic flavor compounds ([Guinee and O'kenedy, 2007](#)). Growth and metabolic activities of cheese starter cultures and yeast and sourdough starters for bread are also stimulated or depressed depending on sodium chloride levels ([Man, 2007](#)). Moreover, depending on the nature of the food matrix, the use of different particle's sizes may influence the overall perceived saltiness. In general, smaller salt particles showed to have a faster dissolution rate in the saliva resulting in a higher salt perception ([Desmond, 2006](#)). Experiments on fried potato crisps suggested that in a controlled chewing environment with controlled mixing, smaller crystals of NaCl could give a faster delivery of sodium into the saliva, influencing the timing of the maximum perceived saltiness ([Rama et al., 2013](#)).

**Figure 1** Overview of salt functions and salt reduction in different food categories.

### Microbial Safety

A major reason for the use of salt in food products has always been its function to reduce the water activity ( $a_w$ ) in foods and thereby acting as a critical hurdle to control growth of pathogens and spoilage organisms. Available water is a critical factor affecting microbial growth. By definition low water activity foods (dry foods) are those with  $a_w < 0.70$ , while fresh foods, soft cheeses, and low-salt meat products have a high  $a_w$  (0.95–1), as do highly perishable foods such as fresh meat and fish ( $a_w > 0.99$ ) (Blessington et al., 2013; Christian, 2000). Given the abundance of water in these products, the absence of salt would quickly lead to the over growth of bacterial pathogens and spoilage organisms, shortening the shelf life and stability of the products. Most shelf-stable products, processed meats, and hard cheeses rely in fact on salt for safety and preservation. Moreover salt commonly plays a central role in food fermentation. Fermentation is another accepted method use to preserve food due to the action of beneficial types of microbes that by growing inhibit the growth of undesirable spoilage bacteria and fungi (Doyle and Glass, 2010). The presence of lactic acid

bacteria is in fact responsible for distinguish characteristics of fermented foods such as pickles, sauerkraut, some cheeses and fermented sausages.

## Salt Replacers: Functions and Compositions

The link between high sodium intake from the diet and its consequences on the overall cardiovascular health in the population, has led to the development of methods and formulation to help achieving sodium reduction; salt replacers, salt substitutes and salt enhancers have been one of the key strategies used in order to maintain the functional properties of sodium salt with minimal effect on the taste of the product (Doyle and Glass, 2010; Pietrasik and Gaudette, 2014). Salt replacers are used in place of salt to get a 50% reduction in sodium with a replacement ratio of 50:50. Salt substitutes are free-flowing salt with good saltiness level and possibly minimum bitter off-flavor. They may replace 25%–50% of sodium in products like sauces, gravies, dressings, snack seasonings and spices (Desmond, 2006). Salt enhancers are ingredients that can deliver a high savory flavor, able to mask up to a 40% sodium reduction (Brandsma, 2006). However, as already described, sodium chloride influence many steps in the formulation of processed foods, including growth of starter cultures, moisture levels, fat binding properties, flavor of other additives, as well as processing conditions. Reducing sodium chloride levels may require alterations in other parameters to ensure that foods retain acceptable flavors and textures for the specific market.

## Salt Replacers: Taste and Flavor

Generally, sodium and lithium are the only cations with a taste that is primarily salty; lithium however, is toxic in amounts that would be needed as salt substitutes. Potassium and calcium compounds have some component of saltiness but they have other flavors, often described as “metallic” or “bitter” (Grummer et al., 2013). Potassium chloride (KCl), for example, can replace up to about 30% of sodium chloride in many foods but beyond that concentration, foods may become unpalatable (Israr et al., 2016; Inguglia et al., 2017; Grummer et al., 2013). The use of calcium chloride ( $\text{CaCl}_2$ ) and magnesium chloride ( $\text{MgCl}_2$ ) to reduce sodium in Cheddar-style cheese resulted in flavor differences (bitter, metallic, earthy, unclean, soapy, and numbing) compared with full-sodium control. Cheese made with NaCl + KCl and NaCl + modified KCl were similar to cheeses made with NaCl in most respects. Thereby, in products such as cheddar cheese, KCl can be used successfully to achieve large reductions in sodium when replacing a portion of the NaCl (Grummer et al., 2012). Magnesium sulfate or other ammonium compounds, amino acids, and peptides from hydrolyzed proteins have also a salty taste but, their use would need extra additives to mask off-flavors and bitter tastes (Institute of Medicine, 2010). One recommended additive that allows reduction of sodium content of foods, is monosodium glutamate, well known for providing the umami flavor (Kilcast and den Ridder, 2007). However, in the past monosodium glutamate has been claimed to be toxic and potentially leading to adverse effects in humans and animals (Fernstrom, 2007). Sea salts is also a good alternative to high sodium refine salts as it contain different percentages of calcium, potassium, and magnesium compounds that contribute to the different existing varieties and to the different flavors (Kilcast and den Ridder, 2007).

## Salt Replacers: Texture and Quality Characteristics

### Meats and Meat Batters

Formulation of low-salt meat batters is technologically challenging because a reduction in sodium chloride levels requires other ionic compounds to replace the water-holding, protein-binding, and fat-binding functions of the salt that is eliminated (Desmond, 2006). Potassium, calcium, and magnesium chlorides, along with polyphosphate compounds can be used to stabilize meat emulsions in reduced-sodium meats. Since KCl and NaCl, have an equal ionic strengths, this salts can interact identically with the meat proteins; calcium and magnesium chlorides however given their different chemical nature are not as effective (Gordon et al., 1992). Potassium phosphates can bind water and improve stability as well as their sodium counterparts, but high levels of potassium compounds may adversely alter taste. Restructured items such as sausages or deli-style meats are products in which lower-sodium ingredient options have been successfully produced. Here, the structural functions of salt-soluble proteins have been replaced by the addition of soy or milk proteins, gums and starches (Fellendorf et al., 2016). An alternative strategy that does not involve addition of other compounds is the use of different physical forms of salt. Salt companies, such as Morton and Cargill, produce fine flake and dendritic salts whose crystals have a larger surface area and dissolve more rapidly. There have been reports that such salts have the potential to improve water and fat binding in some meat batters and emulsions at lower salt concentrations but further research are needed in the area (Inguglia et al., 2017).

### Baked Products

Sodium chloride in baked products controls the growth of yeast and promotes the development of gluten structure. Therefore, a reduction in salt may cause the yeast to growth to quickly affecting the final texture (Belz et al., 2012). These effects may be mitigated to some extent by decreasing the amount of yeast used and by adjusting mixing and other mechanical processes during manufacture (Cauvain, 2007). Reduced resistance of the dough to extension, extensibility and no changes in the liquid to solid ratio, were observed in wheat bread formulated using decreasing salt concentrations (0.6%, 0.3%, and 0% NaCl). Despite a reduction in the

salt content resulted in no major structural changes compared to the customary level of 1.2% NaCl, complete omission of salt however, produced unpleasant flavors and a significant reduction in structural quality of dough and bread (Lynch et al., 2009).

### Cheeses and Dairy

KCl has been recognized as a potential salt substitute in various food categories given the similarity between the cation of these two salts. In particular this role seems to be the most promising in cheeses. In processed cheese, the replacement of NaCl by KCl has been successfully reported in various research works (Guinee and Sutherland, 2011; Grummer et al., 2013, Guinee, 2004). Most of the functional and microbiological properties of the cheese were not substantially affected as a result of this replacement. Recently, processed cheese was successfully manufactured at full replacement of NaCl by KCl (EL-Bakry et al., 2011). There were no adverse effects on functional properties of the cheese, which included textural, rheological and microstructural properties. However, the microbiological stability of the product was substantially reduced. Other experiments with cheese products where NaCl was substituted with compounds such as  $\text{CaCl}_2$  and  $\text{MgCl}_2$  were however observed to be really soft and crumbly (Guinee and O'Kennedy, 2007).

### Effects on Safety

Whenever changes in the formulation or in the processing method are made, it is necessary to test that the organoleptic and safety of the products are not been altered. The effectiveness of alternative salts relative to sodium chloride seems to vary based on the pathogen of interest (Barbut et al., 1986). KCl seems to be really similar in the way it affect microbes in foods when used at the same molar concentration (Bidlas and Lambert, 2008). Compounds, such as potassium chloride and mixtures of potassium lactate and sodium diacetate, that might be used to replace salt and other sodium-containing preservatives have been also shown to be somewhat effective at retarding growth and toxin production by pathogens (Barbut et al., 1986; Devlieghere et al., 2009; Taormina, 2011). Organic acids are commonly used as chemical preservatives in some foods (Doores, 2005). A list of the chemical compounds that are typically used along with the amount of sodium contributed by sodium salts and the type of products where they are used is presented in Table 1. The majority of the organic acids contain much less sodium than NaCl at the normal concentration used. Potassium, sodium, and calcium lactates are being shown to be equally effective in controlling growth of bacteria in meat packaged in modified atmospheres (Devlieghere et al., 2009). However, many salts of organic acids have strong flavors on their own which is a limitation to their use above certain concentration. Partially replacing salt with other compounds, such as potassium chloride and calcium chloride, may also be possible in fermented products. However, these alternatives may be less effective than salt so, once again, formulations with a higher concentrations may be needed to achieve the same functionality (Bautista-Gallego et al., 2008).

### Conclusion

A comprehensive strategy to reduce salt intake to 6 g/d (from around 8.6 g/d) has been undertaken in the UK in an effort to reduce rates of hypertension and cardiovascular disease. Voluntary salt reduction targets for different categories of manufactured food were first proposed in 2006. Information on current target values can be found at the Food Standards Agency website (<http://www.food.gov.uk/multimedia/pdfs/consultation/consultsalttargets.pdf>). Target levels were set with an eye on effects related to flavor, texture, and safety of foods and are periodically reconsidered in light of experiences to date with these reformulations. Despite the step

**Table 1** Amount of sodium contributed by some common sodium-containing additives and the relative concentrations used in food products

<i>Sodium compound</i>	<i>Amount of sodium contained (%)</i>	<i>Concentration used in foods (%)</i>	<i>Food to which the compound is added</i>
Benzoate	15.95	0.1	Beverages, fermented vegetables, jams, salad dressings
Diacetate	16.18	0.1–0.4	Condiments
Lactate	20.51	1.5–3	Meat products
Propionate	23.93	0.3	Bakery products
Sorbate	17.14	0.3	Cheeses, meats, ketchup, mayonnaise and marmalades
Nitrite	33.32	0.012	Cured meats
Acid pyrophosphate (SAPP)	20.72	0.35	Baked products
Triphosphate (STPP)	31.24	0.35	Seafood, meats, poultry
Pyrophosphate (TSPP)	34.57	0.35	Chicken nuggets, pudding, crab meat, canned tuna and soy-based meat alternatives
Hexametaphosphate (SHMP)	22.55	0.35	Cheese powders and dips, whipped topping, meats and canned fish, frozen desserts, salad dressings, herring, breakfast cereal, and bottled beverages

Modified table from Doyle and Glass (2010) and Institute of Medicine (2010).

forward which has been done in finding ingredients to reduce sodium content, the major limitation in their use used are still the consequences on sensory properties. A number of challenges have to be faced in order to satisfy consumers' opinion about low-salt meat products: taste, colour, flavour, texture, aroma, etc., all parameters which can become unacceptable if too much sodium is removed. Salt replacers and other ionic compounds used needs to be effective at maintaining product safety while being also practical and financially affordable during food formulation.

# Seaweed Polysaccharides (Agar, Alginate Carrageenan)

Katerina Alba and Vassilis Kontogiorgos, University of Huddersfield, Huddersfield, United Kingdom

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Red seaweeds or macro-algae (*Rhodophyceae*) are phylogenetically the oldest division of marine macrophytes. They contain sulphated galactans, such as carrageenan and agar as the main structural materials of cell walls and intercellular matrices that are commercially exploited across food industry. Carrageenan-containing seaweeds (carrageenophytes) are mainly collected from natural sources around the globe (Table 1). Initially, the production of agar was limited only to several locations where *Gelidium* species grow that produce agars with superior gelling properties. However, alkaline pre-treatment of alternative seaweed species (*Gracilaria*) was introduced later and resulted in expansion of agar industry. Brown seaweeds (*Phaeophyceae*) are primarily used for production of alginates that are also harvested in both northern and southern hemispheres (Table 1). The differences in compositional characteristics and conformational arrangement in solution of carrageenan, agar and alginates produce a set of polysaccharides with a wide spectrum of physical and chemical properties that are utilized in a large number of foods. The focus of the present chapter is on the structure, extraction, physicochemical properties, and food applications of seaweed polysaccharides with major industrial interest.

## Structure – Extraction

### Carrageenan

Carrageenan is a linear, sulphated galactan that is composed of alternating 3-linked  $\beta$ -D-galactopyranose and 4-linked  $\alpha$ -D-galactopyranose or 4-linked 3,6-anhydro- $\alpha$ -D-galactopyranose, thus forming their disaccharide repeating unit (Fig. 1) (Knutsen et al., 1994). Besides galactose and sulphate groups, other carbohydrate residues (e.g., xylose, glucose, or uronic acids) and substituents (e.g., methyl ethers, and pyruvate groups) may also be present (Van De Velde et al., 2002). These negatively charged polysaccharides are typically classified into six basic forms, namely *iota*- ( $\iota$ ), *kappa*- ( $\kappa$ ), *lambda*- ( $\lambda$ ), *mu*- ( $\mu$ ), *nu*- ( $\nu$ ), and *theta*- ( $\theta$ ) carrageenan based on the number and position of sulphate groups, and the presence of 3,6-anhydro-bridge in galactose residues (Knutsen et al., 1994).  $\kappa$ -,  $\iota$ -, and  $\lambda$ -carrageenan have one, two, or three ester-sulphate groups per repeating disaccharide unit, respectively (Rochas et al., 1986). The most industrially relevant types of carrageenan are *kappa*-, *lambda*-, and *iota*- whereas *mu*- and *nu*-are biological precursors of  $\kappa$ - and  $\iota$ -carrageenan, respectively, and their food applications are limited. The chemical composition of carrageenan varies between red seaweed species and depends on the extraction method. The  $\kappa$ - and  $\iota$ -carrageenan are predominantly extracted from *Kappaphycus alvarezii* and *Eucheuma denticulatum*, whereas  $\lambda$ -carrageenan is primarily sourced from *Gigartina skottsbergi* and *Sarcothalia crispata* (Imeson et al., 2009).

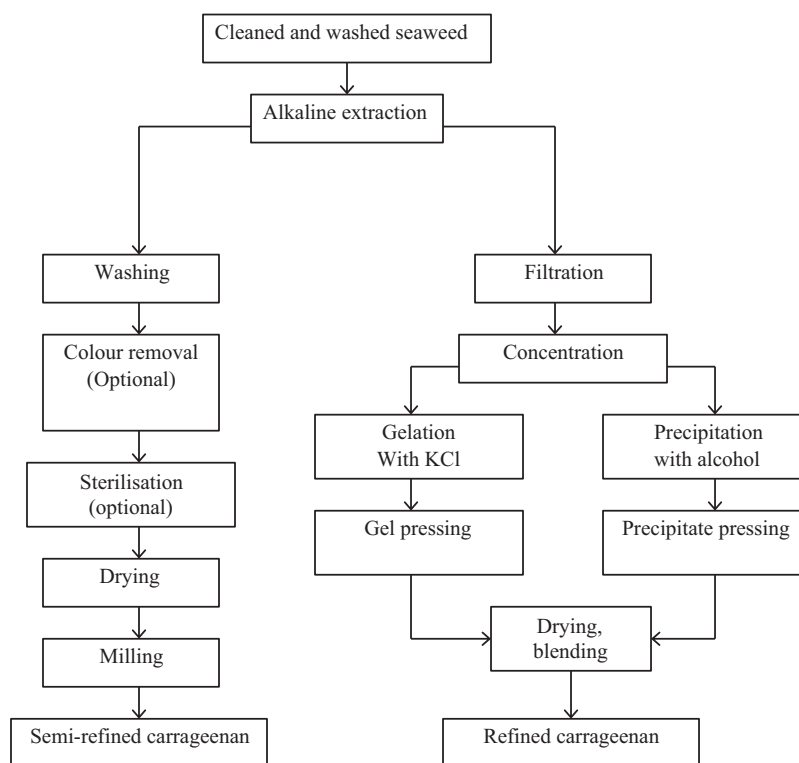

Carrageenan is produced using two extraction methods resulting in isolation of semi-refined or refined powders (Rudolph et al., 2000). During the isolation process of semi-refined carrageenan, hot KOH solution reacts with the sulphate esters of carrageenan precursors ( $\mu$ - and  $\nu$ -) resulting in increase of 3,6-anhydrogalactose (3,6-AG) and production of  $\kappa$ - or  $\iota$ -carrageenan, respectively (Fig. 2). In addition, potassium cations promote gel formation thus preventing carrageenan from dissolving in the hot alkaline

**Table 1** Species and locations of industrially relevant hydrocolloid-producing seaweeds

Species	Location
<b>Carrageenophytes</b>	
<i>Kappaphycus alvarezii</i> , <i>Eucheuma denticulatum</i>	Indonesia, Philippines
<i>Gigartina skottsbergi</i> , <i>Sarcothalia crispata</i>	Central Chile, Argentina
<b>Agarophytes</b>	
<i>Gelidium</i>	Spain, Portugal, Morocco, France, Japan, Republic of Korea, Mexico, Sumatra, Indonesia, lower harvests in Chile, China and South Africa
<i>Gracilaria</i>	Chile, Indonesia, Argentina, Atlantic coast of Canada, China, Vietnam, Namibia
<b>Alginophytes</b>	
<i>Ascophyllum nodosum</i>	Ireland, Scotland, Norway
<i>Laminaria digitata</i>	France, Norway, Iceland
<i>Laminaria hyperborea</i>	Ireland, Scotland, Norway
<i>Macrocystis pyrifera</i>	USA, Mexico, Chile
<i>Laminaria japonica</i>	China, Japan, Russia, France

**Figure 1** Structural features of carrageenan.  $\beta$ -D-Galactopyranose residues in  $\kappa$ - and  $\iota$ -carrageenan are sulphated at C-4, whereas in  $\lambda$ -carrageenan at C-2 position.

**Figure 2** Generalized extraction strategy of semi-refined and refined carrageenan.

solution. At this stage, seaweed extract is in a gel form that is finally dried and milled into a powder (Fig. 2). This method is only applicable for red seaweed species that contain mainly  $\kappa$ - and  $\iota$ -carrageenan because they form gels with potassium salts, as opposed to  $\lambda$ -carrageenan-containing seaweeds that do not gel in the presence of potassium and would therefore be lost during the alkali treatment. Extraction of refined carrageenan starts with seaweed heating in NaOH solution followed by precipitation with alcohol or by inducement of gelation with potassium salts (e.g., KCl) (Fig. 2). Alcohol-precipitation method can be used for any type of carrageenan, whereas the gel method is only applicable to  $\kappa$ -carrageenan.

## Agar

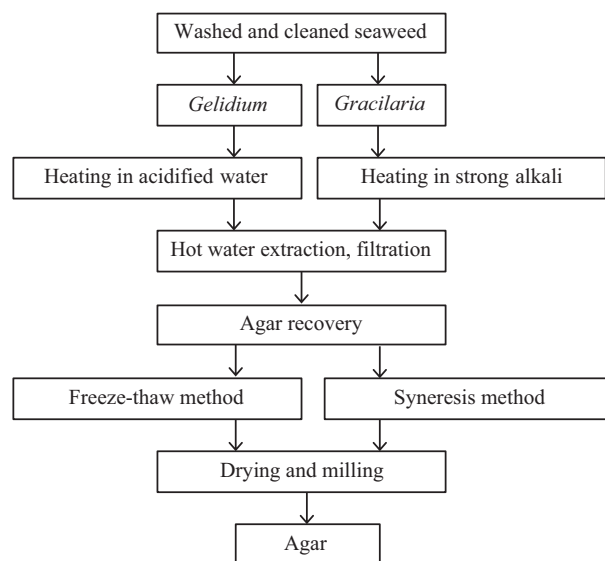

Agar is also a linear galactan with backbone comprised of  $\beta$ -D-galactopyranose and 3,6-anhydro- $\alpha$ -L-galactopyranose linked *via* alternating  $\alpha$ -(1 $\rightarrow$ 3) and  $\beta$ -(1 $\rightarrow$ 4) glycosidic linkages. The two alternating disaccharide units forming the backbone are agarobiose and neoagarobiose (Fig. 3) (Duckworth and Yaphe, 1971). Agar is a heterogeneous complex mixture of related polysaccharides with comparable backbone structure, but differences in the level of substitution of hydroxyl groups of sugar residues (e.g., ester sulphate, methoxyl, etc.) (Duckworth and Yaphe, 1971; Lahaye and Rochas, 1991). Agar is composed of two major polysaccharide fractions,

**Figure 3** Backbone structure of agarose. The repeating disaccharide units are called agarobiose and neoagarobiose. 3,6-anhydro-galactose residues in agar are L-enantiomers, whereas in  $\kappa$ - and  $\iota$ -carrageenan are D-enantiomers.

namely agarose that is a neutral, low sulphate/methoxyl substituted fraction that exhibits high gelling capacity, and agarpectin that is charged, heterogeneous, highly-substituted, and has low gelling capacity (Araki and Arai, 1967). The ratio of agarose to agarpectin varies depending on the seaweed species and isolation conditions. In contrast to carrageenan, agar is only lightly sulphated (<0.15%) (Armisen et al., 2009).

The major agar-producing red seaweeds (agarophytes) belong to genera *Gelidium* and *Gracilaria*. The extraction strategies of food-grade agar generally include a washing step followed by pre-treatments and hot water extraction. The pre-treatment stage is performed either with strong alkali (NaOH) for *Gracilaria* seaweed species or with acidified water for *Gelidium* species (Fig. 4). The alkali pre-treatment is a critical step in agar production from *Gracilaria* seaweed species since it results in conversion of the precursor porphyran (sulphated galactose) into the 3,6-anhydro-galactopyranose that is responsible for the gelling capacity and mechanical properties of agar gels (Knutzen et al., 1994). In the hot-water extraction stage, seaweeds of *Gelidium* species are typically extracted under pressure whereas seaweeds of *Gracilaria* species are treated with hot water and the mixture is filtered to remove the residual seaweed (McHugh and Food and Agriculture Organization of the United Nations, 2003). Cooled filtrate forms a gel that contains around 1%–2% of agar and which is later dehydrated using either a freeze-thaw process or by pressing water out (“syneresis” method). The freeze-thaw method results in production of gels that contain 10%–12% of agar, whereas syneresis method yields higher purity gels (~20%) (Armisen et al., 2009). After this treatment, isolated agar is dried in hot-air oven and milled to the desired particle size.

**Figure 4** Generalized extraction strategy for food-grade agar.

**Figure 5** Idealized structure of alginates. Alginates are composed of  $\beta$ -D-mannuronic acid (M) and  $\alpha$ -L-guluronic acid (G). Backbone consists of sequences of blocks of mannuronic acid (M-blocks) or guluronic acid (G-blocks), and regions of alternating sequences (MG-block).

## Alginates

Alginate is the term used for the salts of alginic acid, but it also refers to all derivatives of alginic acid and alginic acid itself. Alginates are structural components of brown micro-algae (*Phaeophyceae*) cell walls that are present in the form of divalent salts of alginic acid and form the intercellular gel matrix. Alginates are linear polysaccharides that are composed of  $\beta$ -D-mannuronic acid (M) and  $\alpha$ -L-guluronic acid (G) residues linked via 1→4 glycosidic linkages (Fig. 5). Accordingly, alginate backbone consists of sequences of blocks of mannuronic acid (M-blocks) or guluronic acid (G-blocks), and regions of alternating sequences (e.g., MG, MMG, GGM) (Grasdalen et al., 1979, 1981). The M-blocks are linked via  $\beta$ -1,4 linkages adopting  ${}^4C_1$  chair conformation that imparts flexibility to the chain, whereas G-blocks are stiff structures of buckled shape due to the  ${}^1C_4$  conformation of guluronate residues linked via  $\alpha$ -1,4 linkages (Atkins et al., 1970; Grasdalen et al., 1977; Penman and Sanderson, 1972). As a result, the stiffness of the blocks on the backbone follows the order (from most to least stiff): GG > MM > MG (Smidsrød et al., 1973).

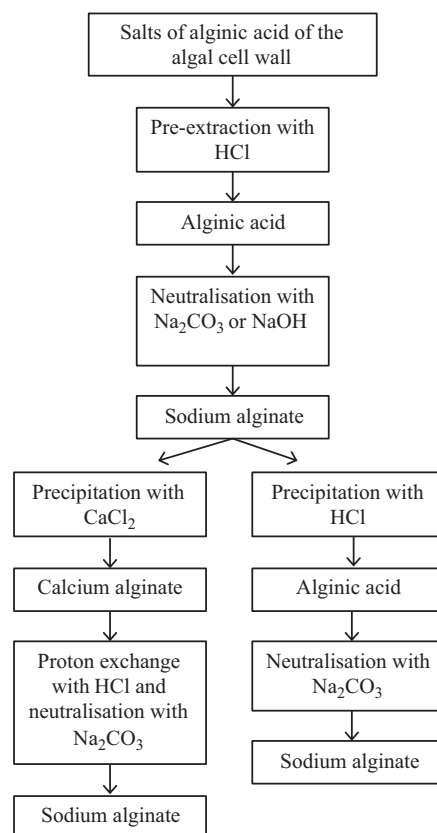

The main brown seaweed species used for commercial alginate production are *Laminaria hyperborea*, *Macrocystis pyrifera*, *Laminaria digitata*, *Ascophyllum nodosum* and to a lesser extent from *Laminaria japonica*. The ratio of mannuronic to guluronic acid, sequence of monomers, length of blocks, and molecular weight of the chains vary with the source and consequently impact the physical properties of alginates (Penman and Sanderson, 1972; Smidsrød and Haug, 1972; Haug et al., 1967). Alginates isolated from *L. hyperborea* typically have the highest guluronic acid content (M/G ratio ~0.62), whereas those extracted from *L. japonica* (M/G ratio: 2.34–3.18) and *A. nodosum* (M/G ratio: 1.29–1.85) are low in guluronic acid and therefore exhibit weak gelling properties (Grasdalen et al., 1979; Penman and Sanderson, 1972; Draget et al., 2006; Haug and Larsen, 1962; Minghou et al., 1984).

Alginate extraction is based on conversion of all insoluble salts of alginic acid that are present within the cell wall of brown seaweed to the soluble ( $\text{Na}^+$ ) salt of alginic that is subsequently recovered as alginic acid or calcium alginate. Isolation of alginates can be divided into three major stages that is pre-extraction, neutralization, and precipitation (Fig. 6). Initially, proton exchange with a strong acid (e.g., HCl) converts salts of alginic acid into free alginic acid. In the next step, insoluble alginic acid is solubilized by neutralization with alkali to form water-soluble sodium alginate, which is consequently recovered from the extraction solution by precipitation with hydrochloric acid, calcium chloride, or alcohol, and finally dried and milled (Fig. 6). Sodium alginate is the major commercial form of alginate, however, there are other forms of soluble alginates such as alginic acid and its calcium, ammonium, and potassium salts, or esters of alginic acid, such as the propylene glycol alginate (PGA).

## Physical Properties

### Carrageenan

All forms of carrageenan are soluble in water and the type of carrageenan, temperature, pH, ionic strength of the medium and the presence of cations are the factors that influence its aqueous solubility. Their hydrophilic character originates from sulphate and hydroxyl groups whereas hydrophobicity from the 3,6-AG units resulting in differences of water solubility between different types of carrageenan. For instance,  $\lambda$ -carrageenan has three sulphate groups and no 3,6-AG content and, therefore, is easily soluble under most conditions. Water solubility of carrageenan follows the order (from most to least soluble):  $\lambda$  >  $\iota$  >  $\kappa$ -carrageenan. The presence of cations in the solution induces aggregation between carrageenan helices resulting in alterations in solubility. For instance, all salts of  $\lambda$ - and sodium salts of  $\kappa$ - and  $\iota$ -carrageenan are soluble in cold water, whereas potassium salts of  $\kappa$ - and  $\iota$ -carrageenan are soluble only in hot water. The viscosity of carrageenan solutions decreases at pH values below 4.3 and in particular at high temperatures (70–120 °C) due to backbone depolymerisation (Imeson et al., 2009). Carrageenan solutions exhibit shear-thinning flow behavior and gel at certain temperatures and cation concentrations. Gelation of  $\kappa$ - and  $\iota$ -carrageenan is comprised of two consecutive steps: a coil-to-helix transition upon cooling and cation-induced aggregation of helices (Fig. 7). First, carrageenan dispersions are heated to about 80 °C. At this stage, chains attain random coil conformation due to the electrostatic repulsions between adjacent polymer chains. On cooling to approximately 40–60 °C, carrageenan solutions demonstrate pronounced increase in viscosity and undergo coil-to-double helix conformational transition. The final sol–gel transition occurs in the presence of cations that leads to the helix–helix aggregation of the adjacent spiral chains that contain sulphate groups and formation of a stable three-dimensional network (Piculell et al., 2006).  $\lambda$ -Carrageenan does not gel, but forms polyelectrolyte

**Figure 6** Generalized extraction strategy of alginates.

solutions and is utilized as a thickening agent in dairy products.  $\kappa$ - and  $\iota$ -carrageenan form thermo-reversible gels at concentrations as low as 0.5% and cation concentrations between 0.2%–0.8%. The strength of carrageenan gels depends on the biopolymer concentration, type of the salt (e.g., KCl, CaCl<sub>2</sub>, NaCl) and concentration of the gelling cation. For instance,  $\kappa$ -carrageenan in the presence of K<sup>+</sup> forms firm, brittle gels, whereas  $\iota$ -carrageenan require Ca<sup>2+</sup> and forms soft, and elastic gels (Kara et al., 2006).  $\kappa$ -Carrageenan has lower gelation temperature (35–65 °C) as opposed to  $\iota$ -carrageenan (40–70 °C) at equivalent gelling conditions (Imeson et al., 2009; Nishinari et al., 1990). Typically, the higher the cation concentration, the greater the gelling temperature and gel strength (Michel et al., 1997). The presence of co-solutes, such as sucrose also increases gelation and melting temperatures of

**Figure 7** Gelation mechanism of carrageenan. Carrageenan dispersions are heated to about 80 °C and chains attain random coil conformation. On cooling to approximately 40–60 °C, they undergo coil-to-double helix conformational transition. The final sol–gel transition occurs in the presence of cations that leads to the helix–helix aggregation of the adjacent chains that contain sulphate groups. Gels are thermoreversible and melt on heating.

carrageenan solutions (Nishinari et al., 1990). Carrageenan gels are thermally reversible (melt at temperatures  $\sim 5\text{--}20^\circ\text{C}$  above the gelling temperature and re-gel on cooling) and also exhibit hysteresis (difference between gelling and melting temperatures).

Textural properties and applications of  $\kappa$ -carrageenan gels can be improved by addition of other hydrocolloids (e.g., galactomannans or xanthan) (Williams et al., 1993). Hot solutions of  $\kappa$ -carrageenan and galactomannans form strong and elastic gels with low syneresis in contrast to brittle  $\kappa$ -carrageenan gels. The synergistic effects between  $\kappa$ -carrageenan–galactomannan systems depend on the mannose/galactose ratio of the galactomannan backbone (Dea and Morrison, 1975). The mannose-free regions of the galactomannans, particularly of locust bean gum, are able to associate with carrageenan helices resulting in gel formation (Fernandes et al., 1991). Another notable synergistic interaction of carrageenan is with milk proteins, primarily with casein micelles where carrageenan forms weak gels in the aqueous phase and adsorbs at the surface of casein micelles through interactions with positively charged amino acids (Langendorff et al., 2000).

## Agar

Agar is insoluble in cold water and for dissolution requires heating at temperatures of above  $\sim 85^\circ\text{C}$ . The viscosity of agar solutions at  $45^\circ\text{C}$  is not affected by ionic strength or pH in the pH-range between 4.5–9.0 (Stanley et al., 2006) and it depends on history, as when they are cooled and reheated back to initial temperature, they exhibit higher viscosity (Armisen et al., 2009). Agar is potent gelling agent, as it forms networks at concentrations as low as 0.1%–0.2% w/v in the absence of any cross-linking ions in contrast to carrageenan. Their gelling capacity arises from the agarose fraction and is stabilized exclusively by hydrogen bonding between the 3,6-anhydro- $\alpha$ -L-galactopyranose residues of the chains. The gelation of agar commences with a heating step ( $\sim 85\text{--}95^\circ\text{C}$ ) where chains adopt random coil conformation. Cooling the system to gelling temperature ( $\sim 33\text{--}45^\circ\text{C}$ ) results in the sol–gel transition that proceeds in two steps (Armisen et al., 2009; Normand et al., 2000). Initially, randomly distributed, single agarose coils join to form a double helical association *via* intra-molecular hydrogen bonding. This is followed by aggregation of double helices *via* inter-molecular hydrogen bonding into a three-dimensional gelled network (Fig. 8).

Agar forms thermo-reversible gels, that melt by heating and gel again upon cooling showing considerable hysteresis (melting  $\sim 85\text{--}95^\circ\text{C}$  and gelling  $\sim 33\text{--}45^\circ\text{C}$ ). Agar gels have the most pronounced hysteresis values among gelling polysaccharides that are typically in the range of  $40\text{--}60^\circ$  depending on the source of seaweed. For instance, hysteresis values of  $\kappa$ -carrageenan are in the range of  $15\text{--}27^\circ$ , whereas the lowest values are reported for  $\iota$ -carrageenan ( $2\text{--}5^\circ$ ) (Rees et al., 1969). The gelation temperatures of agar increase with the degree of methoxylation (Guiseley, 1970; Falshaw et al., 1998). Agar gels are susceptible to “syneresis” that is separation of water from the system during ageing. This is attributed to the contraction of the network by slow further aggregation of double helices that reduces the interstitial space available for water. The rate of syneresis is lower for agar gels that contain high ester sulphate content (Lahaye, 2001).

Agar typically forms transparent, stiff gels; however, their rheological properties can be modified by addition of sugars (e.g., sucrose, glucose, trehalose) or incorporation of other polysaccharides (e.g., locust bean gum, xanthan, alginates). The addition of sugars to the agar solutions promotes formation of helices and results in increased gel strength and higher gelation temperatures (Rees et al., 1969; Watase et al., 1990; Vilgis, 2015). This is attributed to the “exchange” of free water by sugar molecules that leads to increased hydrocolloid concentration and decreased distance between polymer chains thus favouring intermolecular polymer–polymer interactions. Agar–locust bean gum mixtures show the most notable synergistic interaction that results in formation of stronger gels and improved mouthfeel making the texture of agar gel similar to gelatin, a property that is widely utilized in food

**Figure 8** Gelation mechanism of agar. The gelation of agar commences with a heating step ( $\sim 85\text{--}95^\circ\text{C}$ ) where chains adopt random coil conformation. Cooling the system to gelling temperature ( $\sim 33\text{--}45^\circ\text{C}$ ) results in the sol–gel transition and formation of double helical associations. This is followed by aggregation of double helices into a three-dimensional network. Double helices of agar are more compact than carrageenan due to the smaller amount of sulphate groups.

formulations (Armisen et al., 2009; Stanley et al., 2006; Sousa and Gonçalves, 2015). Multicomponent gel systems of agar, xanthan and alginate are also formulated and typically aim to expand the range of textures and mouth-feel of agar gels (Russ et al., 2013).

### Alginates

Alginates have a wide range of molecular weight distribution and are charged polysaccharides with electrostatic forces originating from the carboxylic groups within the biopolymer backbone. Therefore, its solubility depends strongly on the pH and ionic strength of the solvent, and the presence of ions in the solution (Mackie et al., 1980). Alginates are soluble in aqueous solutions at pH above its dissociation constant ( $pK_a$ ). The  $pK_a$  of mannuronic and guluronic acids are 3.38 and 3.65, whereas the  $pK_a$  of the global alginate structure varies within this range (Haug et al., 1967). An abrupt decrease of pH results in protonation of carboxyl groups leading to precipitation of alginate, whereas a slow and controlled release of protons results in formation of alginic acid gel. The pH range at which precipitation of alginates occurs is controlled by chemical composition, molecular weight and sequence of M-, G-, and MG-blocks of the backbone. For instance, alginates that contain more MG-blocks will precipitate at lower pH values as opposed to those that contain homogeneous M- and G-blocks. Change in the ionic strength of alginate solution has considerable impact on alginate solubility and viscosity due to the decrease of electrostatic interactions between the biopolymer chains. Monovalent metal ions (e.g.,  $Na^+$ ) form soluble salts with alginate whereas divalent or multivalent cations form gels. Alginates form highly viscous solutions due to the highly extended conformation of the chains and large hydrodynamic volume. The viscosity of alginate solutions depends the length of M and G blocks on the backbone, and on external factors such as pH and ionic strength of the solution.

The most prominent physical property of alginates is the selective binding of divalent and multivalent cations that determines their ability to form gels. Cations have different affinity for alginates, although the extent of cross-linking may be also influenced by the chemical composition (M/G ratio). For instance, alginates with high content of G-blocks form tightly held junction zones in the presence of divalent cations (e.g.,  $Ca^{2+}$ ) and form gels of considerably higher strength compared to alginates rich in M- or M-G-blocks that exhibit lower affinity towards divalent cations (Morris et al., 1978; Wang et al., 1993). In contrast, trivalent cations (e.g.,  $La^{3+}$  and  $Pr^{3+}$ ) bind to both M- and G-blocks of alginate backbone (Deramos et al., 1997). The affinity of alginates towards divalent ions decreases in the following order:  $Pb > Cu > Ba > Sr > Ca > Zn > Mn$ , however,  $Ca^{2+}$  is the most commonly utilized to induce gelation. Gelation of alginates is described by the “egg-box” model, according to which alginate chain-chain interactions are induced by the presence of cross-linking divalent cations (Stokke et al., 2000; Donati et al., 2005). Alginate blocks show different mechanisms of interactions with cross-linking cations. For instance, G-blocks integrate cations into pocket-like structures formed between adjacent chains of guluronate residues, whereas M-blocks bind cations externally near the carboxylate groups. In MG blocks, cations are preferentially located in a concave structure formed by MG pairs (Emmerichs et al., 2004). The strongest interactions between junction zones occur in guluronic acid residues, as the buckled chain conformation enables strong gel formation (Donati et al., 2005; Grant et al., 1973). Ionotropic gelation of alginates can be performed by two ion-dependent methods: “diffusion” (sometimes referred as “dialysis”) and “internal setting” method. In the “diffusion” method, alginate solution is dripped into the solution of cross-linking ion (e.g., soluble calcium salts,  $CaCl_2$ ). Calcium ions diffuse into the alginate solution and alginate beads are formed (Fig. 9).

This method is characterized by fast gelation kinetics, heterogeneous distribution of alginate and widely utilized in the production of restructured food products and encapsulation of bioactive compounds. In “internal setting” method, inactive form of cross-linking ion (e.g., insoluble calcium salts,  $CaCO_3$ ,  $CaSO_4$ ) is mixed with alginate solution. Then, a slowly hydrolyzing agent (e.g., D-glucono- $\delta$ -lactone, GDL) is added to the mixture of alginate and inactive cross-linker. The hydrolysis of GDL to gluconic acid results in gradual decrease of the pH of the system and production of protons that convert inactive cross-linker (e.g.,  $CaCO_3$ ) into its active form (e.g.,  $Ca^{2+}$ ). Slow release of cross-linker in the alginate solution leads to the formation of homogeneous gels. Alginates also gel following cation-independent gelation mechanism. In this method, pH of alginate solutions is gradually lowered below the  $pK_a$  of the uronate residues leading to the reduction of electrical repulsion between biopolymer chains and consequently formation of alginic acid gels though intermolecular hydrogen bonding. Alginic acid gels are typically produced either by addition of a hydrolyzing lactone (e.g., GDL) or by conversion of ionically cross-linked (pre-formed) gel to the acid gel by addition of mineral acids. The M/G ratio and length of those blocks in the alginate backbone have a considerable impact on the mechanical properties of the resulting gels. Alginates with low M/G ratios produce strong and brittle gels with good heat stability but with pronounced syneresis after freeze-thaw processing, whereas alginates with high M/G ratios produce more elastic gels with good freeze-thaw stability (Grant et al., 1973; Braccini and Pérez, 2001). The strength of alginate gel increases when the average length of guluronate blocks changes from 5 to 15 leading to a formation of mechanically strong, stable, and porous gel. However, gel strength is relatively unaffected by molecular weight values greater than  $200 \times 10^3 \text{ g mol}^{-1}$ .

## Food Applications

### Carrageenan

Carrageenan is utilized mainly as gelling agent, thickener, and stabilizer at concentrations between 0.005% and 2.0% w/w. Carrageenan is weaker gelling agent than agar, however, their ability to produce gels with a wide variety of textures is highly valued. Food applications of carrageenan depend on whether they are added to dairy or aqueous systems (e.g., water-based dessert gels) (Table 2).

**Figure 9** Gelation mechanism of alginates. G-blocks integrate divalent cations into pocket-like structures formed between adjacent chains of guluronate residues leading to formation of a network. This is known as the “egg box” model.

**Table 2** Food applications of seaweed polysaccharides (Stanley et al., 2006; Hambleton et al., 2009; Fabra et al., 2012)

Applications	Functionality	Seaweed polysaccharide
Desserts (e.g., dessert jellies, low-energy jellies, non-dairy puddings, sorbets)	Gelation, emulsion stabilization, emulsification	$\kappa$ - and $\iota$ -carrageenan, $\kappa$ -carrageenan with galactomannans, alginates, agar
Seasonings (e.g., relishes, sauces, vinaigrette salad dressings)	Gelation	$\kappa$ - and $\iota$ -carrageenan, alginates
Meat (e.g., low fat meats, cooked hams, meat preserves, canned meat, restructured meat and fish products, pet food)	Gelation, thickening, fat stabilization and reduction	$\kappa$ -Carrageenan and galactomannans, $\iota$ -carrageenan and konjac gum, alginates, agar
Beverages (e.g., fruit drinks, beer, wine)	Emulsion stabilization, foam stabilization, flocculating agent	$\kappa$ - and $\iota$ -carrageenan, Na-alginates, agar
Bakery (e.g., gluten-free breads, pastry fillings, pie fillings, icings and glazes)	Improve loaf volume, gel formers/binders, moisture barrier, antistaling agent	$\kappa$ -Carrageenan, alginates, agar
Milk gels (e.g., custard, pudding) and whipped dairy products	Gelation, syneresis control, thickening, emulsion stabilization	All forms of carrageenan and their mixtures
Milks (pasteurized, sterilized)	Suspension, mouthfeel, emulsion stabilization	Combinations of $\kappa$ -, $\iota$ - and $\lambda$ -carrageenan
Frozen desserts (e.g., ice cream, ice milk)	Prevents whey separation, prevents formation of ice crystals	$\kappa$ -Carrageenan, alginates, agar
Processed cheeses (e.g., cheese slices, cream cheese)	Gelation, moisture binding, improve slicing, texture improver	$\kappa$ -Carrageenan with locust bean gum, agar
Food films and coatings	Extended shelf-life	Alginates, all forms of carrageenan
Foods with encapsulation technology	Aroma encapsulation, controlled release of aroma compounds	$\iota$ -Carrageenan, alginates

All forms of carrageenan are utilized at concentrations  $<0.3\%$  in dairy formulations (Anderson et al., 2002; Langendorff et al., 1999). Carrageenan interacts with milk proteins and forms a network that prevents whey separation and aggregation, and stabilizes particles such as cocoa suspensions in chocolate milk. Water-based desserts are the typical non-dairy carrageenan applications, in which  $\kappa$ -carrageenan or  $\kappa$ -/ $\iota$ -carrageenan blends are used at concentrations  $>0.3\%$ . The synergistic interactions of carrageenan with galactomannans are also widely utilized in the production of fruit sorbets, poultry and meat products. The thixotropic nature of  $\iota$ -carrageenan gels is applied in salad dressings formulations to stabilize suspended herbs and vegetable particles. In drink industry, they are used at low concentrations ( $\sim 0.2\%$ ) to stabilize suspensions (e.g., fruit juices) and colloidal systems (e.g., soft drinks) or increase the viscosity and add palatability to liquid food products (Piculell et al., 2006). Recently, carrageenan is also explored in bread making industry with particular interest in improvement of dough proofing characteristics and formulation of gluten-free breads (Rosell et al., 2001; Sciarini et al., 2010).

## Agar

Food applications of agar rest on its high gelling capacity, high hysteresis, and perfect gel reversibility. Agar is largely utilized in the baking industry due to the ability to withstand high temperatures as opposed to carrageenan, and is effective in retarding staling of cakes and bread. In confectionary products (e.g., cakes or doughnuts), agar is primarily utilized (0.2%–1.0% w/v) to prevent the dehydration of the product and maintain the integrity of the icing during storage. Agar is also important in fruit jelly confections, due to its ability to gel without high sugar concentrations. In meat industry, agar is used at levels of 0.5% to 2.0% in gelled canned meat products, fish, poultry and boiled sausages as a structuring and fat reducing agent (Stanley et al., 2006).

## Alginates

Alginates are used as thickeners, gelling agents, and stabilizers of aqueous mixtures, dispersions, and emulsions. Alginates are polyelectrolytes and therefore can interact electrostatically with proteins in mixed systems resulting in increase in viscosity. These types of interactions can be utilized to stabilize and enhance the mechanical properties of gelled networks in some restructured food products. The process of food restructuring is based on binding together sectioned, chunked or milled food components (e.g. meat cuts with high connective tissue content, or homogenized fruits and vegetables) to make them resemble the original or formulate novel food products (Draget et al., 2006). Gelation of alginates is independent of temperature and therefore can be used in the restructuring of foods that may become damaged or oxidized at high temperatures (e.g. meat products, fruits and vegetables). Common restructured foods produced using alginates are reconstituted onion rings, pimento olive fillings, and cocktail berries (Draget et al., 2006; Mancini and McHugh, 2000; Manjunatha and Gupta, 2006). Synergistic interactions between G-rich alginates and pectins with high degree of esterification result in formation of thermo-reversible gels that are commonly utilized in the production of jams (Walkenström et al., 2003; Toft et al., 1986). The advantage of alginate-pectin gels is that they are independent of sugar content and therefore can be utilized in low-calorie food products. PGA is the most common alginate derivative used in food formulations acting simultaneously as surface-active and gelling agent and finds applications in foams (e.g., desserts, beer froth) and emulsions (Nilsen-Nygaard et al., 2016; Jackson et al., 1980). PGA has also high tolerance to  $\text{Ca}^{2+}$  and low pH and is suitable for applications in fermented milk-based products and salad dressings. In food industry, alginate matrices (e.g., alginate, alginate with xanthan gum, chitosan, or pectin) may also be used for encapsulation and delivery of live cells (probiotics) to the large intestine and colon and in immobilization of reactive or volatile molecules (e.g., enzymes, flavours, etc.) (Cook et al., 2012; Desai and Park, 2005). Alginates have been also used as edible coatings in meat products and a number of fresh fruits and vegetables where the coating maintains texture, reduces the rate of browning, inhibits the growth of yeast and molds, decreases weight loss, and provides color and moisture retention (Rojas-Graü et al., 2007; Azarakhsh et al., 2014; Jiang et al., 2013; Sipahi et al., 2013; Robles-Sánchez et al., 2013).

## Conclusions

Seaweed polysaccharides are widely utilized in the food industry and are of particular technological importance due to their broad spectrum of functionality. The physical properties (e.g., gelling, viscosity enhancement etc.) are tunable by controlling molecular properties of the chains and the environmental conditions (e.g., pH, ionic strength, etc.). This results in hydrocolloid systems with remarkably wide spectrum of physical properties that find applications across food industry. The most industrially relevant types of carrageenan are kappa-, lambda-, and iota-that are sulphated anionic galactans. Agar is also a linear galactan with backbone of two alternating disaccharides, agarobiose and neoagarobiose consisting of two major polysaccharide fractions, namely agarose and agarpectin.  $\kappa$ - and  $\iota$ -types of carrageenan are able to form gels ( $\lambda$ -does not form gels) assisted by the presence of cations most commonly potassium. In contrast to carrageenan, agar forms networks in the absence of any cross-linking ions and is more potent gelling agent. Gelling capacity of agar arises from the agarose fraction as agarpectin does not play central role in the process. Alginates are linear polysaccharides that are composed of mannuronic acid (M) and guluronic acid (G) residues. Accordingly, alginate backbone consists of sequences of M- or G-blocks, and regions of alternating sequences (e.g., MG, MMG, GGM). Consequently, the length of sequence of M and G blocks in the alginate backbone controls its physical properties. The most prominent physical property of alginates is the selective binding of divalent cations and in food industry gels are usually formed in the presence of calcium. Use of seaweed polysaccharides in foods is well established and future technologies should focus on their potential applications beyond food industry (e.g., biomedical, pharmaceutical, or drug industries) with the overall aim to create advanced formulations with tailored functionality (e.g., for nutrient and drug delivery, or wound healing).

# Sequestrants as a Food Ingredient

Benjamin M Bohrer, University of Guelph, Guelph, ON, Canada

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Chelation** a type of bonding of ions or molecules to metal ions; involves the formation or presence of two or more separate coordinate bonds between a polydentate ligand and a single central atom.

**Food additives** substances (synthetically produced or naturally occurring) incorporated in the formulation of a food product with the purpose to contribute in the processing, storage, preparation, or quality of foods.

**Ligand** a molecule, ion, or atom that is bonded to the central metal atom of a coordination compound.

**Sequestrant** a type of a food additive which improves the quality and stability of foods through the formation of chelate complexes.

## Overview

Sequestrants (chelating agents) offer food processors a valuable tool to be used to ensure integrity of whole and processed foods. The reaction caused by sequestrants protects food products from chemical, oxidative, and enzymatic reactions that promote deterioration during processing, storage, or preparation of foods through chelation. Sequestrants form chelate complexes with polyvalent metal ions (i.e. copper, iron and nickel), which can serve a variety of purposes in maintaining food quality (Aamoth and Butt, 1960). The term chelate comes from the Greek word “claw”, and they often resemble a claw with the metal ion clutched between the pincers of the organic molecule (Bessman and Doorenbos, 1957). As a food additive that has been around and used for over 75 years, the mechanistic action and purposes of sequestrants as a food additive are relatively well understood (Bessman and Doorenbos, 1957; Albert and Serjeant, 1984). This book chapter will help readers understand the mechanistic action of sequestrants, provide insight to common examples of sequestrants, and describe the use of sequestrants in foods.

## Mechanistic Action of Sequestrants

The reaction of a sequesterant with metallic and alkaline ions causes new metal complexes to be formed. In the newly formed complex, the metallic or alkaline ion is bound with a charged or uncharged electron donor referred to as the ligand (Damodaran et al., 2007; Furia and Furia, 1972; Yoe, 1958). By definition, the sequesterant is the molecule with the ligand properties (binding sites) that enable the newly formed metal complex to be formed (Furia and Furia, 1972).

Two general conditions must be satisfied for a sequesterant to be effective (Furia and Furia, 1972). First, the sequesterant must have the proper steric and electronic configuration in relation to the metal ion that is being acted upon, and secondly the environmental conditions (pH, ionic strength, solubility, etc.) must be conducive to the formation of the new complex.

## Examples of Sequestrants

While a great number of sequestrants are known to be highly effective as metal complexing agents, a great concern of food processors and government regulatory agencies continues to surface regarding their safety (Furia and Furia, 1972). Thus, most sequestrants used in the food industry are naturally occurring substances such as polycarboxylic acids, hydroxycarboxylic acids, polyphosphoric acids, amino acids, and various other macromolecules (Furia and Furia, 1972). Once safety and efficacy are established, the other determining factors determining the usefulness of a sequesterant is the effect on product quality and sensory attributes (color, flavor, etc.). Depending on the food product being manufactured, other considerations when choosing a sequesterant includes the substrate capability and the particular metal(s) in the food matrix that warrants chelation. Common examples of sequestrants in foods can be broken into three major categories, which will be discussed in the succeeding subsections.

### Ethylenediaminetetraacetic Acid

Likely the most commonly recognized of all sequestrants, EDTA is widely used with great success as a chelating agent in both food and non-food applications (Yoe, 1958; Gardiner, 1976; Branen and Davidson, 2004). EDTA is colorless, water soluble solid that is typically used in the food industry in a di-sodium salt form, a di-ammonium form, a chelated ferric sodium form, or a ferric

ammonium salt form. EDTA contains six donor groups (hexadentate) and has the ability to bind six times, at two nitrogen positions and at four oxygen positions (**Fig. 1**). Examples of food applications of EDTA salts include beverages (beer and malt beverages), condiments (salad dressing and sauces), canned meats and seafoods, and many others (**Table 1**). Overall, EDTA forms very stable complexes with most metal ions (particularly calcium and magnesium), and has been proven to be safe at low inclusion levels in food products ([Lanigan and Yamarik, 2002](#); [Heimbach et al., 2000](#); [Wedeen et al., 1983](#)).

## Phosphates

Phosphates are the naturally occurring form of the mineral phosphorus and the salt-forming anion of phosphoric acid. Many different types of phosphate salts are approved for use including sodium phosphates, calcium phosphates, and potassium phosphates (**Table 2**). Common food applications include processed meat products, ice cream, and frozen dairy products. With particular inference to meat processing, phosphates offer multi-functional roles with direct effects on water retention and improved binding properties ([Sindelar, 2015](#)). The meat industry has been attempting for several years to replace phosphates with more “natural” ingredients to meet clean label requirements, yet no direct substitutes have been discovered nor are any complete substitutes being used at the present time.

**Figure 1** The chemical structure of Ethylenediaminetetraacetic Acid (EDTA) with potential binding sites depicted with an asterisk (\*).

**Table 1** List of permitted EDTA substances permitted uses according to United States Food and Drug Administration (FDA) and Canadian Food Inspection Agency (CFIA)

<i>Name of compound</i>	<i>Permitted uses</i>
Calcium disodium EDTA	<p>Ale; Beer; Malt liquor; Porter; Stout</p> <p>Unstandardized dressings; Unstandardized sauces; French dressing; Mayonnaise; Salad dressing</p> <p>Potato salad; Unstandardized sandwich spreads</p> <p>Canned shrimp; Canned tuna; Canned crabmeat; Canned lobster; Canned salmon</p> <p>Margarine</p> <p>Canned clams; Canned sea snails; Canned snails</p> <p>Canned legumes except canned green beans, canned peas and canned wax beans</p> <p>Unstandardized beverage concentrates, except unstandardized dairy beverage concentrates and unstandardized alcoholic beverage concentrates</p> <p>Pasteurized sous-vide potatoes</p> <p>Beans; Beans with pork</p>
Disodium EDTA	<p>Dressing and sauces</p> <p>Unstandardized sandwich spreads</p> <p>Canned legumes except canned green beans, canned peas and canned wax beans</p> <p>Dried banana products</p> <p>Aqueous suspensions of color lake preparations for use in coating confectionery tablets</p> <p>Pasteurized sous-vide potatoes</p> <p>Edible coating for sausages</p> <p>Beans; Beans with pork</p>

**Table 2** List of permitted phosphates with sequestration activity and their permitted uses according to United States Food and Drug Administration (FDA) and Canadian Food Inspection Agency (CFIA)

<i>Name of compound</i>	<i>Permitted uses</i>
Calcium phosphate, monobasic	Unstandardized dairy products; Ice cream mix; Ice milk mix; Sherbet
Calcium phosphate, tribasic	Ice cream mix; Ice milk mix
Potassium phosphate, monobasic	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Ice cream mix; Ice milk mix; Sherbet
Potassium phosphate, dibasic	Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers
Potassium phosphate tetrabasic	Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Canned seafood
Potassium tripolyphosphate	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Canned seafood
Sodium acid pyrophosphate	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Canned seafood; Ice cream mix and milk mix
Sodium hexametaphosphate	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Canned seafood
Sodium phosphate, monobasic and dibasic	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Ice cream mix; Ice milk mix; Sherbet
Sodium potassium hexametaphosphate	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Canned seafood; Ice cream mix; Ice milk mix; Liquid whey products
Sodium potassium tripolyphosphate	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Canned seafood
Sodium pyrophosphate, tetrabasic	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers; Ice cream mix; Ice milk mix; Sherbet
Sodium pyrophosphate, tribasic	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers
Sodium tripolyphosphate	Unstandardized foods; Injection or cover solution for the curing of poultry or poultry meat; Pumping pickle for the curing of pork, beef and lamb cuts; Prepared meat; Solid cut meat and poultry; Meat tenderizers
Calcium Phytate	Glazed fruit
Phosphoric acid	Mono- and di-glycerides

Information sourced from regulatory webpages of the United States Food and Drug Administration (FDA) and Canadian Food Inspection Agency (CFIA).

### Citric Acid

Citric acid and other forms of citrate (derivatives of citric acid) occur naturally in citrus fruits (lemons, limes, oranges, etc.; [Table 3](#)). In addition to the acidic properties that citric acid elicits in terms of flavor, preservation, and emulsification – citric acid and other forms of citrate are fairly effective sequestrants by binding metals into water soluble complexes ([Mehlretter et al., 1953](#); [Soccol et al., 2006](#)).

### The Role of Sequestrants in Foods

Newly formed complexes formed by sequestrants exhibit unique properties in terms of their ability to function in a food matrix. Sequestrants have been adopted as common food additives for a variety of purposes in foods; yet the major reason would be to ensure product quality after extended periods of storage and/or shelf time. Sequestrants can contribute an important part in the stabilization and sustainability of fat/oil quality. Sequestrants do not directly contribute to the inhibition of oxidation; however, play a role in the delay of lipid oxidation by chelating trace metals that are pro-oxidant catalysts. Metal chelation slows or even eliminates the ability for pro-oxidant activity of some metals in food products ([Furia and Furia, 1972](#); [Labuza and Dugan, 1971](#)). The synergistic effects of sequestrants and antioxidants have been established for a lengthy period of time in a variety of food applications ([Furia and Furia, 1972](#)). Vitamins tend to be unstable components in food products, and sequestrants have been used (along with antioxidants) for preventing and inhibiting the decomposition of oil soluble vitamins. The use of sequestrants in produce prone to enzymatic browning (i.e. fruits, vegetables, potato, and dairy products) has been well-established for decades ([Furia and Furia, 1972](#)).

**Table 3**      List of permitted citric acids and derivatives with sequestrant activity and their permitted uses according to United States Food and Drug Administration (FDA) and Canadian Food Inspection Agency (CFIA)

<i>Name of compound</i>	<i>Permitted uses</i>
Citric acid	Pumping pickle, cover pickle, and dry cure employed in the curing of preserved meat or preserved meat by-product Unstandardized foods Frozen seafood (clams, crab, crustaceans, fish, lobster, marine mammals, minced fish, molluscs, shrimp; Prepared fish or prepared meat; Preserved fish or preserved meat; Other Frozen marine invertebrates
Ammonium citrate, monobasic or dibasic	Unstandardized foods
Calcium citrate	Unstandardized foods
Sodium citrate	Unstandardized foods Ice cream mix; Ice milk mix; Pumping pickle, cover pickle and dry cure employed in the curing of preserved meat or preserved meat by-product; Sherbet Frozen clams; Frozen crab; Frozen crustaceans; Frozen fish; Frozen fish fillets; Frozen lobster; Frozen marine mammals; Frozen minced fish; Frozen molluscs; Frozen shrimp; Glaze of frozen fish; Prepared fish or prepared meat
Stearyl citrate	Margarine

Information sourced from regulatory webpages of the United States Food and Drug Administration (FDA) and Canadian Food Inspection Agency (CFIA).

Another key role that sequestrants have is their ability to aid in water retention during processing and product storage (Shults *et al.*, 1972; Hellendoorn, 1962; Thorarinsdottir *et al.*, 2001). This example may be observed to the greatest extent with the use of phosphates in processed meat products. Phosphates are a common ingredient in many processed meat products and have direct roles on sensory attributes and processing techniques that are implemented in the meat industry. Similar to the chelation in metals found in water, phosphates may also chelate divalent cations in meat. A classical theory claims that phosphates bind divalent cations away from the protein cross-bridges, allowing the protein structure to unravel and hold more water through capillary activity (Knipe, 1983). Some research even suggests that phosphates may only affect free cations with limited to no effects on cations already bound to proteins (Knipe, 1983). The cation chelation by alkaline phosphates protects cooked meats from “warmed-over” flavors, while also stabilizing cured color, and improving retention during thawing of frozen products (Knipe, 1983).

## Conclusions

Sequestrants provide food processors a valuable tool in the food additive toolbox with a wide range of purposes and uses. The integrity of whole and processed foods can be improved with sequestrants with particular inference on slowing of lipid oxidation and improvement of water retention properties. In general, sequestrants approved for use in food products are considered to be safe and effective at inclusion levels established by governing agencies such as the United States Food and Drug Administration and the Canadian Food Inspection Agency.

## Introduction

Starch is a plant polysaccharide that is predominantly found in cereal grains, roots and tubers such as potatoes, cassava and manioc, and legumes such as peas, chickpeas and beans (Table 1). The diversity in starch granule structure and properties is appalling. Even cereal starches widely vary in properties (Tables 1 and 2). Starch occurs in intracellular granules and does not have any function as structure-building molecule in plant cells, but rather functions as a storage polysaccharide. Starch is produced in plant leaves through photosynthesis in the chloroplasts. It is stored in these green plant parts as small granules. This (poorly investigated) assimilation starch is then hydrolysed at night and transported as sucrose to those parts of the plant which either require the energy or serve as energy storage organs (*e.g.*, grains for cereals and roots for tubers). In these storage organs, starch is deposited in amyloplasts as water-insoluble granules. Starch gradually accumulates in these granules and is eventually used as energy source during germination. One amyloplast can either hold one starch granule or a cluster of starch granules. The different morphological characteristics of the starch granules, such as size, shape and architecture, depend on their botanical origin, which makes it relatively easy to microscopically gain insights in the source of the starch (Table 1). In contrast to what is the case in plants, starch does function as a major structure-building and -stabilizing carbohydrate in the human diet. In what follows, focus will be laid on starch structure, chemistry and functionality in food systems.

## Structure

Depending on the botanical source, the diameter of starch granules varies between a few to above 100  $\mu\text{m}$  (Table 1). When observing a starch granule under the regular light microscope, it is easy to recognize the hilum of the granule (Fig. 1). This spot is easy to find as it contains a higher amount of water than the rest of the granule. During drying or wetting of the kernels, the hilum slowly disappears. At this specific hilum site, starch biosynthesis is started and granules, hence, grow 'out of' their hilum, layer after layer of starch building blocks are then added on the outside of the growing granule. The ease with which these layers or shells can be observed is dependent on the plant source.

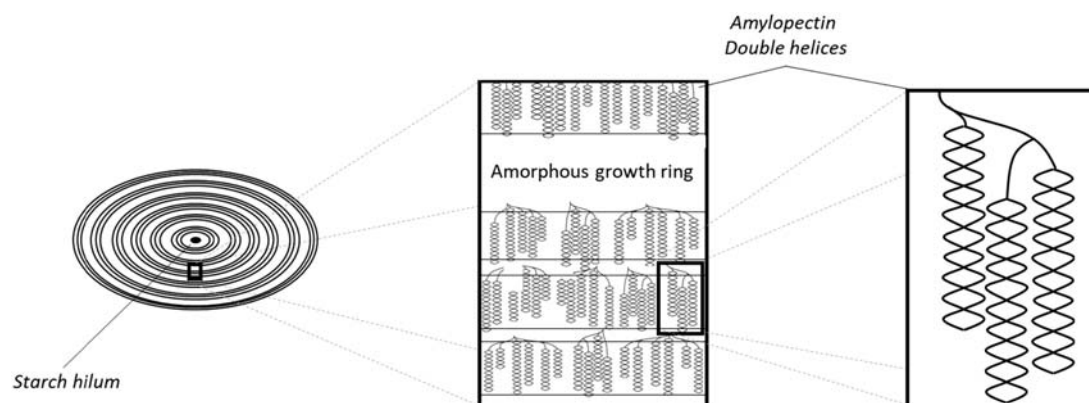

In starch granules, besides the growth rings, different levels of organization can be distinguished at different length scales: blocklets (20–400 nm), lamellae ( $\sim 10$  nm) and lattice spacings (0.1–2 nm). Growth rings can either be more amorphous or crystalline in nature. Amorphous growth rings have a radial thickness of 120 to 400 nm and are less dense and relatively rich in amylose and less ordered amylopectin. The semi-crystalline shells are composed of alternating amorphous and crystalline lamellae of about 9–10 nm. The crystalline lamellae are built of amylopectin double helices which are tightly parallel packed (Fig. 2). The amorphous lamellae are made of the amylopectin branching regions. For a more in-depth discussion on starch granule architecture, the reader is kindly referred to the review by Tester and colleagues (Tester *et al.*, 2004).

**Table 1** Characteristics of starch from different botanical sources (Hoover, 2001; Lasztity and Lasztity, 2009; Gomand *et al.*, 2010; Moorthy, 2002; Delcour and Hosney, 2010; Delcour *et al.*, 2010; Sivoli *et al.*, 2012; Santana and Meireles, 2014)

Plant source	Starch content (% dm)	Starch morphology	Granule diameter ( $\mu\text{m}$ )
Wheat	72	Lenticular Spherical	15–40 1–10
Barley	74	Lenticular Spherical	20–40 2–10
Oats	56	Polyhedral (compound starch)	2–10 (single granules)
Rye	72	Lenticular spherical	25–40 5–10
Corn	80	Polyhedral to spherical	5–30
Rice	76	Polyhedral (compound starch)	3–6 (single granules)
Triticale		Spherical	20
Sorghum	65	spherical	4–25
Potatoes	10–25	Lenticular	10–110
Cassava	25–30	Oval to round (some built as compound granules)	3–43
Peas	25–35	Kidney-shaped	5–20
Chickpeas	35	Oval to round	20
Beans (Carioca)	30	Oval to round	20

**Figure 1** Schematic representation of starch granule structure and polarization microscope image of native starch. The hilum of the starch granule is indicated. Starch granules grow out of this hilum and the hilum is at the crossover point of the Maltese cross visualized under polarization microscopy.

**Figure 2** Schematic representation of starch granule internal structure.

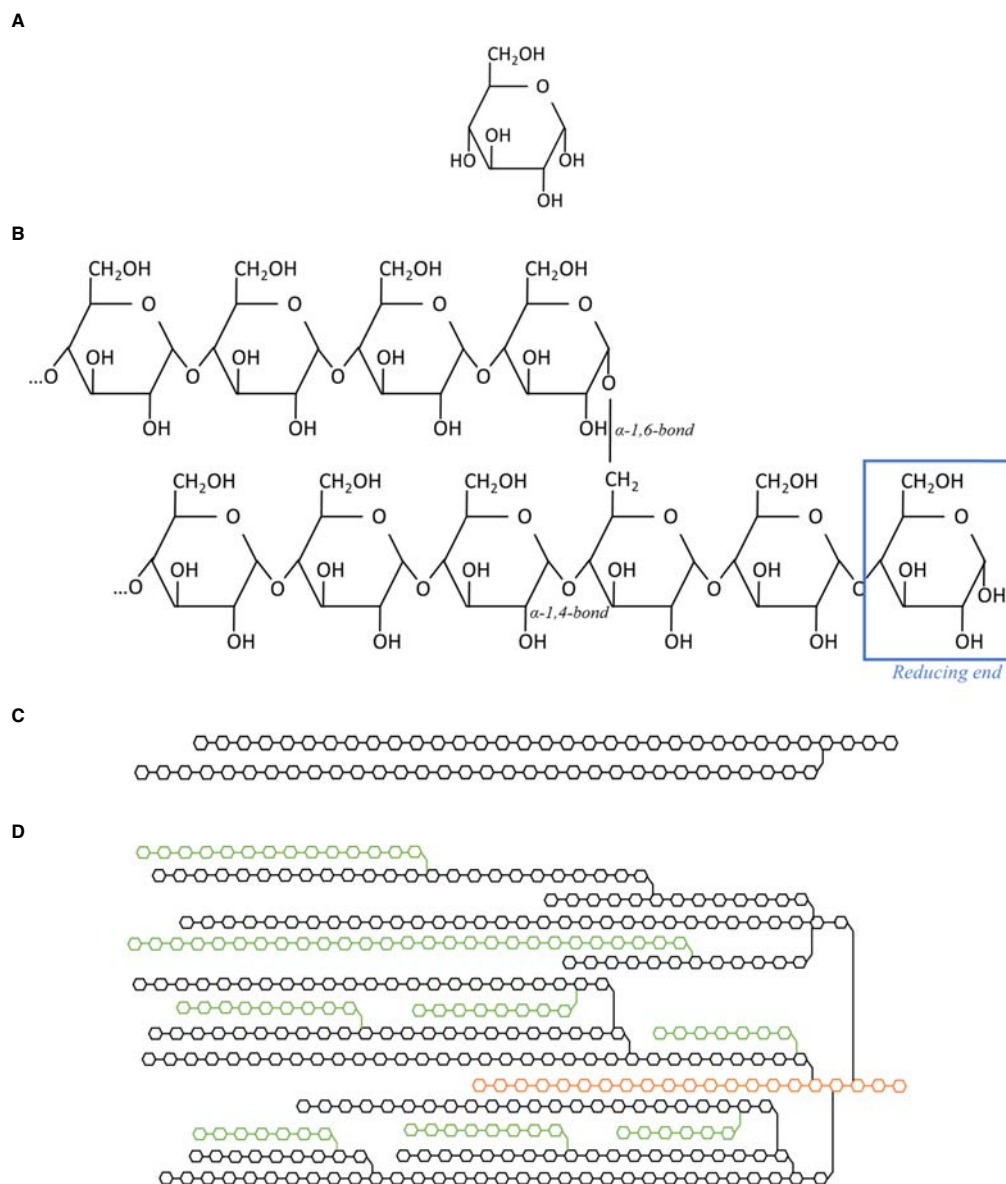

The 'crystallinity' or high degree of order in the starch granules makes them light up under a polarized light microscope as a result of their birefringent character. The typical Maltese cross that is observed for native starch granules (Fig. 3) stems from the radial orientation of the macromolecules in the granules. Amylopectin double helices are responsible for this semi-crystalline character and are organized perpendicular to the starch granule surface (Fig. 2) (Tester et al., 2004). The intersection of the two arms of the Maltese cross coincides with the hilum of the granule (Figs. 1 and 3).

## Composition

Starch granules consist of about 98% polymeric carbohydrate material. The carbohydrate is composed of  $\alpha$ -D-glucopyranosyl units (Fig. 4A). Each individual starch molecule has one hemiacetal group, *i.e.*, the reducing end (Fig. 4B). Starch granules, hence, have

**Figure 3** Polarization microscopy images of (A) potato and (B) pea starch. Image courtesy of Dr. Liu Qiang, Agriculture and Agri-Food Canada.

**Figure 4** Structure of (A)  $\alpha$ -D-glucose unit, (B)  $\alpha$ -1,4 and  $\alpha$ -1,6-linked D-glucose units, (C) amylose and (D) amylopectin. C, B and A chains in amylopectin are shown in orange, black and green, respectively.

minor reducing power. The glucopyranosyl units are connected through either  $\alpha$ -1,4 or  $\alpha$ -1,6 bonds (Fig. 4B). In starch, two main polymers are found, *i.e.*, the (predominantly) linear amylose and the highly branched amylopectin. For most starches, amylose accounts for about 18% to 33% of the starch carbohydrate weight (Table 2) (Buleon et al., 1998). Mutant genotypes exist which have much higher amylose contents (up to 70%; *e.g.*, maize, barley, rice and potato) or do not contain amylose (less than 1%; *e.g.*, corn, rice, sorghum, barley, wheat, potato and cassava). These starches are referred to as amylotypes or waxy starches, respectively.

### Amylose

Amylose is a linear polymer of D-glucose residues linked through  $\alpha$ -1,4 bonds (Fig. 4C). The molecular weight range of amylose (*i.e.*, 80000–1000000) is quite broad and varies in between plant species, varieties and maturity of the starch under study. Amylose can be considered as a linear polymer, but nevertheless contains a very low number of  $\alpha$ -1,6 branching points (less than 1.0%, Fig. 4B). The side branches in amylose are very long and of a high molecular weight, which, from a practical point of view, makes that amylose behaves and can be considered as an unbranched linear polymer. Amylose molecules tend to adopt a natural helical structure. Amylose is also known to interact with iodine, organic alcohols and fatty acids. The formed complexes are usually referred

**Table 2** Amylose content and typical gelatinization temperature range of starches of different botanical origin (Delcour and Hosney, 2010; Sivoli et al., 2012; Buleon et al., 1998; Belitz et al., 2009; Sanchez-Arteaga et al., 2015)

<i>Plant source</i>	<i>Amylose content (%)</i>	<i>Gelatinization temperature range (°C)</i>
Wheat	26–31	58–62
Barley	22–29	51–60
Oats	~27	53–59
Rye	22–28	57–70
Corn	25–28	62–87
Rice	0–33	62–79
Triticale	22–31	55–62
Sorghum	21–34	68–78
Potatoes	19–23	62–66
Cassava	18–25	60–65
Common beans	20–35	76–80

to as helical inclusion complexes. In case fatty acids are enclosed, the formed complex is referred to as an amylose–lipid complex (Putseys et al., 2010). Amylose can relatively easily be extracted using hot water.

### Amylopectin

The building blocks of amylopectin are also  $\alpha$ -D-glucose units, but in this case a considerable part of the linkages are actually  $\alpha$ -1,6 bonds (5%–6%), which gives the molecule a branched structure (Fig. 4D). Amylopectin has a very high molecular weight (up to  $10^8$ ), and clearly behaves as a branched molecule. To better describe amylopectin structure, the different chains in amylopectin have been named A, B, and C according to their position in the molecule (Fig. 4D) (Peat et al., 1952). The C-chain contains the only reducing group in the molecule and every amylopectin molecule, hence, only contains one C-chain. B-chains are side chains which themselves are carrying side chains. The outer sidechains that are not carrying branching points are referred to as A-chains. The intrinsic complexity of amylopectin structure has been stepwise resolved by using very specific hydrolytic enzymes such as  $\beta$ - and  $\alpha$ -amylases.

### Minor Constituents

As outlined above, about 98% of starch weight is carbohydrate material. However, the other 2 wt%, although minor levels, can have a big effect on the behaviour of starch in the plant and during food processing. The most prevalent minor constituents in cereal starches are lipids. These make up about 0.5 to 1.0 wt% of the starch weight. The most prevalent lipids are lysophospholipids and free fatty acids. The most abundant fatty acids in cereal starches are linoleic and palmitic acid. Starch may also be ‘contaminated’ by surface lipids, stemming from the amyloplast membrane (Tester et al., 2004). Non-cereal starches, on the other hand, contain virtually no lipids. The lipids in starch may occur as amylose–lipid complexes. In amylose–lipid complexes, free fatty acids occupy the inner apolar core of single amylose helices. These amylose–lipid complexes are naturally present in starch, but additional ones can be formed during starch gelatinization.

Phosphorus levels in starch can be rather high and phosphorus is either present as lysophospholipids (e.g., in cereal starches), inorganic phosphates (Tester et al., 2004) or directly esterified to the starch molecules. Potato starch is known for its high levels of phosphorus (up to 200–1000 ppm monoesterified phosphorus), while the levels in cereals and roots only go to about 0–20 ppm and 40–150 ppm, respectively. Nitrogen can also be found in starch, either originating from the lipids or stemming from proteins. Starch synthase, the starch synthesizing enzyme can often still be found associated to its product.

### Starch in Food

About 70% to 80% of the calories consumed by humans worldwide originate from starch. Apart from being inherently present in the main ingredients of a lot of food products, starch is sometimes also deliberately added for its adhesive, binding, film forming, foam strengthening, gelling, moisture holding, stabilizing, texturizing and thickening properties. Its unique properties in food processing stem from the changes discrete starch granules undergo during hydrothermal treatments.

### Hydrothermal Treatment of Starch

In what follows, the main transitions a starch suspension (starch in excess water) undergoes in function of heat will be discussed (Fig. 5). Most of these changes are non-chemical transformations.

**Figure 5** Changes in starch size and shape during hydrothermal treatment and storage.

### Starch Swelling at Low Temperatures

When starch is dispersed in water, the discrete starch granules will slightly swell (around 5 v%). The swelling rate is highly dependent on the temperature of the water. As long as this temperature does not exceed the gelatinization temperature, starch swelling is a completely reversible process. Intact starch granules will not swell as fast as their damaged counterparts (starch damage may be induced by, *e.g.*, milling of cereal grains). Without extensive heating, starch can bind up to 30% of its dry weight of water. When the starch granules are dried following this soaking step, no changes in their granule morphology or crystallinity are observed. Swelling at these low temperatures does not involve the solubilization of starch.

### Starch Gelatinization and Pasting

When starch is heated in an excess water to a temperature exceeding the gelatinization temperature, starch swelling continues, but irreversible structural changes to the granules are introduced. As a result of the higher temperature, hydrogen bonds which existed within and in between molecules weaken and the granules absorb more water and swell more obviously. A first sign of the loss of the internal structure in the starch granules is the loss of semi-crystallinity of the granules, which can be visualized through the loss of birefringence of the starch granules under polarization microscopy. The temperature at which this occurs is referred to as the gelatinization temperature and is dependent on the starch source (Table 2). In DSC measurements, gelatinization is visualized as a relatively broad gelatinization peak. Together with the loss of birefringence, the transparency of the suspension will decrease, while its viscosity will steadily increase. Gelatinization is also dependent on the availability of water. Water will first penetrate the more accessible amorphous zones in a starch granule and make these swell. The swelling of these intermittent amorphous layers puts an enormous stress on the surrounding crystalline layers (Fig. 2). These crystalline layers are believed to break under this pressure, which speeds up the loss of semi-crystallinity in the starch granules. If not enough water is present (typically less than 30% moisture content) to rip the internal starch granular structure apart, the loss of order is often just acquired through regular melting of the crystals, which would typically occur at higher temperatures. Besides the moisture content, the presence of other molecules in the aqueous phase of the starch suspension also affects the gelatinization temperature. Sucrose addition, *e.g.*, is known to, above a certain concentration (30 w/w%), drastically increase the gelatinization temperature (Kweon et al., 2012). Also, input of energy (*e.g.*, through mixing of the suspension) leads to a better and more efficient distribution of heat in the system, also resulting in a faster gelatinization process. After the loss of molecular order, the starch granules keep on swelling through further absorption of water. Crystals melt and part of the starch solubilizes. These irreversible transitions go hand in hand with a sharp increase in viscosity. The raise in viscosity is initially caused by further swelling of the granules, followed by the generation of granule remnants and leaching out of amylose molecules. Further heating leads to further opening of the starch structure and water molecules being bound at the starch chains that are freed from the structure. This viscosity increase after gelatinization is referred to as starch pasting. Under continuous stirring and when holding the starch granules suspension at a high temperature, a decrease in viscosity is observed: the starch paste displays time-dependent shear thinning or thixotropic behaviour. This shear thinning behaviour is caused by alignment of the leached out amylose molecules with the stirring direction and the diminution of the swollen starch granules (and remnants) under prolonged mixing.

### Starch Gelation

Upon cooling of a gelatinized starch suspension, an increase in viscosity is observed which is indicative of the formation of new non-covalent bonds in between the starch granules. These bonds are predominantly formed between the leached out amylose

molecules which associate with each other and hence form a matrix around the starch granule remnants, leading to an increased viscosity of the system. At high enough starch concentrations, a gel will be formed which can be visualized as a network of amylose molecules in which amylopectin enriched granules are embedded (Fig. 5).

### Starch Retrogradation

Upon storage of a gelatinized starch gel or suspension, the starch polymers associate more tightly in function of time. The reassociation and recrystallization of amylopectin is referred to as retrogradation. Strictly speaking, only amylopectin can recrystallize as amylose does not occur in crystalline form in the starch granules, and, hence, a term like retrogradation, literally meaning 'to go back', is only used to refer to the reassociation and crystallization of amylopectin. A partially crystalline system is, hence, reformed. In function of time, the association of the polymers may become more tight, eventually leading to expulsion of water entrapped in the gel structure. This is referred to as syneresis.

### Starch Analysis

The behaviour of starch during hydrothermal treatments can be monitored using visualization as well as rheological methods. Visualization methods focusing on starch swelling, loss of molecular order and granule disintegration include regular light and polarization microscopy (Fig. 3). The change in viscous properties of the starch suspension can be monitored through rapid viscoanalyzer and amylograph measurements. Gelatinization temperatures, retrogradation degree and the presence of amylose-lipid complexes can be studied through Differential Scanning Calorimetry.

### Applications in Food

As a result of the above behaviour of starch under hydrothermal treatments, starch often acts as a structuring agent in a range of food products. When starch is added as such, starch addition is often aiming at providing body and bulk to the food product. The extent of starch gelatinization in baked goods affects product properties such as storage behaviour and rate of digestion. In low moisture foods, starch usually does not gelatinize, while it does gelatinize in higher moisture food products.

Examples of food products in which structure is built by starch that is naturally present in one of the ingredients is bread, cake, pasta, cooked potatoes and vegetables. In these food products, starch is heated without shear and this results in clearly identifiable starch granules. The degree of gelatinization in these products will determine the product acceptability. Undercooked potatoes, *e.g.*, will have an undesirable texture. In cookies, characterized by high sugar levels, starch will not gelatinize during baking, while for bread and cake systems, the majority of the starch granules will be gelatinized. Initial bread crumb firmness, *e.g.*, is highly dependent on amylose gelation, while during storage crumb hardening (and bread staling) can be partially explained by starch retrogradation.

Examples of food products to which starch is added in order to build 'structure' are sauces, soups and puddings. In these products, starch plays a water binding, viscosity increasing and/or gelling role. These products, usually also undergo some shear during starch heating, resulting in granule degradation and more pronounced amylose leaching.

In most food products, instead of using unmodified 'natural' starches, modified starches are used. These starches have undergone a physical or chemical treatment to change their properties. This will be discussed in section **Starch Modification**.

### Enzymatic Hydrolysis

Starch is readily hydrolysed by a wide range of amylases once it has been gelatinized. These amylases target the hydrolysis of the  $\alpha$ -1,4 bonds connecting the glucose units and create new reducing ends upon every hydrolysis. Two well-known amylases with widely differing hydrolysis patterns are  $\alpha$ - and  $\beta$ -amylases. While the latter is an exo-amylase, *i.e.*, it cuts maltose units from the non-reducing ends of the starch granules,  $\alpha$ -amylase typically hydrolyzes  $\alpha$ -1,4 bonds that are more centrally positioned in the starch molecular structure.  $\alpha$ -amylases, hence, also have a much more pronounced effect on the molecular weight of the parent molecule containing the original reducing end and on the overall starch suspension viscosity.  $\beta$ -amylase usually does not get past  $\alpha$ -1,6 branching points and will, hence, only have a minor effect on the amylopectin molecular weight. When only  $\beta$ -amylase would be present, amylopectin would only be degraded for about 55%, generating a lot of maltose and one amylopectin residue, *i.e.*, the  $\beta$ -limit dextrin, containing the 'original' reducing end. Hydrolysis of  $\alpha$ -1,6 bonds can be achieved by pullulanase. This enzyme can release all A and B amylopectin chains and each of these released chains will have a reducing end, increasing the reducing power of the carbohydrate system. The concerted action of  $\beta$ - and  $\alpha$ -amylase and pullulanase enables the complete hydrolysis of amylose and amylopectin.

### Digestibility of Starch

After ingestion, starch is claimed to be very quickly degraded by human amylases. The hydrolysis products, small sugar molecules, serve as an important source of energy. However, it is clear that some of the starch will not be readily digested. Depending on the rate of starch digestion, starch is classified as rapidly (RDS) and slowly digestible starch (SDS), and resistant starch (RS).

### **Rapidly and Slowly Digestible Starch**

Rapidly digestible starch is readily digested as the polysaccharide chains are accessible to starch hydrolysing enzymes. This starch is usually amorphous or dispersed and can be found in high amounts in freshly cooked starch foods. This type of starch is completely converted to glucose in about 20 minutes of enzyme digestion. Conversely, slowly digestible starch is also digested completely in the small intestine, but much more slowly. This starch is usually physically inaccessible amorphous starch or starch which has a more accessible structure. This starch is defined as the starch which is converted within 100 min of enzyme digestion ([Sajilata et al., 2006](#)).

### **Resistant Starch**

Resistant starch, as it is not digested in the upper parts of the human intestinal tract, is assumed to have health benefitting physiological effects similar to those ascribed to dietary fibre. Resistant starches have been subdivided into different categories according to the underlying molecular reason for their digestion resistance:

- Resistant starch category I resists digestion because it is physically entrapped in cellular structures, making it less susceptible for hydrolytic enzymes. Products in which whole grains or shredded cereal grains appear often contain this physically inaccessible starch.
- Resistant starch category II is a native crystalline, hence, ungelatinized starch. Native starch is very poorly digested by human amylolytic enzymes due to its semi-crystalline and compact structure. Examples are starches found in raw potatoes and green bananas.
- Resistant starch category III is retrograded starch. Recrystallization of amylopectin and crystallization of amylose reduces the susceptibility of starch towards hydrolysis. Resistant starch category III is the starch in cooked and cooled potatoes and stale bread.
- Resistant starch category IV is resistant because it has been chemically or thermally modified to reduce its digestibility. During these treatments, other glycosidic bonds can be formed besides  $\alpha$ -1,4 and  $\alpha$ -1,6 bonds which are resistant against amylolytic enzymes.

The interested reader is referred to the review by [Sajilata et al. \(2006\)](#).

## **Starch Modification**

Granular starch is sometimes modified in order to change the properties and functionality. This modification can either be physical or chemical. The diversity in starch properties from different sources already offers a range of functionalities, but the degree and type of modification can further extend this functionality range.

### **Physically Modified Starches**

#### **Annealing of Starch**

Annealing is a heat treatment of starch which takes place in either an excess of water ( $>60$  w/w%) or intermediate (40–55 w/w%) water levels ([Jacobs and Delcour, 1998](#)). This hydrothermal treatment changes the physicochemical properties of starch, but does not affect and destroy its granular structure. The starch systems are heated above the glass transition temperature but kept below the gelatinization temperature. During annealing, the starch molecules are physically reorganized in the granular structure. It has been suggested that amorphous regions become more glassy during annealing and the amylopectin double helices are more ordered ([Tester and Debon, 2000](#); [Stute, 1992](#)). This would decrease the penetrability of the granular structures for water. Strictly speaking, gelatinization may not occur during annealing, which makes that the gelatinization enthalpy after annealing may not be lower than for the native starch. In practice, however, annealing is often accompanied by partial gelatinization. Annealing is intended to increase the gelatinization temperature and sharpen the gelatinization range. Annealing also leads to less pronounced starch granule swelling power. The effect of annealing on starch pasting are less clear as both lower and higher consistencies of the annealed starch paste relative to the native starch paste have been reported ([Hoover and Vasanthan, 1994](#)). On an industrial scale, starch annealing is not considered an economically viable process as there exist (cheaper) chemical modifications of starch which result in similar effects. Annealing may occur unintentionally, however, during for example the isolation of starch (e.g., wet milling of corn).

#### **Heat-Moisture Treated Starch**

This process is related to starch annealing, but is usually carried out at a lower moisture content ( $<35$  w/w%) ([Jacobs and Delcour, 1998](#)). Similar to what is the case for starch annealing, the starch systems are kept at a temperature between the glass transition temperature of starch and its gelatinization temperature. Sometimes, the term 'heat-moisture' treatment is also used for temperature treatments of starch at temperatures that exceed the gelatinization temperature. The lower moisture contents at which heat-moisture treatments of starch occur also allow for physical reorganization if the temperature is raised higher than what is customary for

annealing. Similar structural changes have been suggested for heat-moisture treated starch as were described for annealed starch (Tester and Debon, 2000; Stute, 1992). The temperature must exceed the glass transition temperature to allow for molecular mobility and the molecular reorganization. Heat-moisture treatments of starch are industrially performed to alter the quality and properties of starch.

### **Ethanol Treated Starch**

Although this treatment uses a chemical, it is, strictly speaking, not a chemical modification as there is no formation or hydrolysis of covalent bonds, but only involves a physical rearrangement within the starch granules. Native starch granules are heated in alcohol-water mixtures (Dries et al., 2016). As a result, the crystals will melt, but the granules themselves will not or only sparsely swell as there is not enough water available for swelling. After removal of the solvent and drying, the starch granules can be added to cold water and will swell (Delcour and Hoseney, 2010).

## **Chemically Modified Starches**

### **Acid Modified Starches**

Treatment of starch with acid is probably the oldest type of starch modification. Acid-treated starch is nowadays called lintnerized or Naegeli starch, after its 'inventors'. A common way to do this modification is suspending starch in a 1%–3% hydrochloric acid medium for 12 to 14 h at temperatures ranging between 25 and 55 °C. An alternative is using sulphuric acid. After the treatment, the starch slurry is neutralized and washed. Acid treatment of starch predominantly leads to hydrolysis of glycosidic bonds in the amorphous regions of the starch granules (Hoover, 2000). The crystalline regions are largely unaffected (depending on the acid hydrolysis time). The overall effect is a drastic reduction of the starch molecular weight as the connecting amorphous regions are etched away. These starches swell less and disintegrate more during hydrothermal treatments. As only the crystalline parts remain, the gelatinization temperature usually also increases and the starch becomes more soluble as a result of the molecular weight reduction. This also comes with a reduced viscosity of the starch paste (even vs. viscosity obtained for native starch suspensions). Upon cooling, a more rigid gel is formed due to the shorter chain length leading to more easy association of the chains (Delcour and Hoseney, 2010). However, reports describing a less rigid and more elastic gel can also be found (Hoover, 2000). These starches are usually used for gum candy (Hoover, 2000).

### **Cross-linked Starches**

Starch can be cross-linked by forming diesters in between the different starch chains/molecules. This can be achieved by either using phosphoryl chloride ( $\text{POCl}_3$ ) or epichlorohydrin (Majzoobi et al., 2009; Jyothi et al., 2006). Cross-linking can decrease the swelling power of starch, increase the starch gelatinization temperature and lead to lower viscosity upon pasting (Majzoobi et al., 2009). Cross-linked starches, however, are less prone to shear thinning, which may be desirable for food that needs to be pumped. It is even possible to produce starch that does not gelatinizes when boiled (Delcour and Hoseney, 2010). However, for food applications this is often not desired and moderate degrees of substitution (*i.e.*, on average there is one substituent attached to every 100 or 10 anhydroglucose residues) are aimed for. Next to viscosity control of the paste, cross-linking also increases the viscosity of starch systems in acid conditions. Cross-linking restricts starch swelling and prevents starch from falling apart, hence, maintaining a higher viscosity. Cross-linked starches usually also lead to shorter pastes, delayed crystallization and retrogradation and an increased freeze-thaw stability (Delcour and Hoseney, 2010). The reduced viscosity increase in function of heating is desirable for the production of jam, baby food, soups and salad dressing (Majzoobi et al., 2009).

### **Substituted Starches**

Starch can also be substituted by addition of monoesters of phosphoric acid. The bulky and charged phosphate groups will make the chains in the starch to repel each other. This leads to more outspoken swelling behaviour, a lower gelatinization temperature and a better solubilization during gelatinization (Liu et al., 1999). The resultant starch paste viscosity is higher (Liu et al., 1999), but displays more shear-thinning behaviour. Substitution also retards or even nullifies retrogradation and pastes turning opaque. It also improves the freeze-thaw stability of starch. In case the degree of substitution is very high, starch can be produced that gelatinizes at room temperature (Delcour and Hoseney, 2010).

### **Oxidized Starches**

Starch can be oxidized with hypochlorite (Kuakpetoon and Wang, 2001). An alternative to hypochlorite would be hydrogen peroxide (Parovuori et al., 1995). When using sodium hypochlorite, the resulting starches are referred to as 'chlorinated starches' although there is no actual incorporation of chlorine atoms in the structure. The oxidation leads to the formation of carbonyl- and carboxyl groups and a minor depolymerization. Oxidation reduces the swelling power, pasting temperature and the paste viscosity (Kuakpetoon and Wang, 2001; Zhou et al., 2016). After gelatinization of this starch, less pronounced retrogradation is usually observed (Garrido et al., 2014). Oxidized starch has only few applications in food such as increasing the adhesion to meat of bread-formulations.

## Sugar Alcohols

**Małgorzata Grembecka**, Department of Bromatology, Faculty of Pharmacy with Subfaculty of Laboratory Medicine, Medical University of Gdańsk, Gdańsk, Poland

© 2019 Elsevier Inc. All rights reserved.

### Introduction

Sugar alcohols (polyols, polyhydric alcohols) are hydrogenated forms of mono- (erythritol, xylitol, sorbitol, mannitol), di- (lactitol, isomalt, maltitol), or polysaccharides (maltitol and sorbitol syrups). During hydrogenation process, aldehyde or ketone group is replaced by the hydroxyl one. There are seven sugar alcohols approved for use in food products in Europe but also other countries, i.e. sorbitol (E420), mannitol (E421), isomalt (E953), maltitol (E965), lactitol (E966), xylitol (E967) and erythritol (E968) ([Regulation \(EC\) No 1333/2008](#)) ([Table 1](#)).

Their presence in food products must be accompanied with the notice on the package stating that excessive consumption might result in laxative effect ([EFSA, 2011](#); [Grabitske and Slavin, 2008](#); [Livesey, 2003](#)). Such warning is due to incomplete digestion of polyols, which can undergo fermentation process in the intestines and the gastrointestinal effects such as noisy bowels, flatulence or diarrhea can be observed. However, their occurrence depends on consumer's tolerance and can be improved by regular polyols' consumption ([EFSA, 2011](#); [Grabitske and Slavin, 2008](#); [Livesey, 2003](#)). Moreover, products of their fermentation have beneficial effect on colon health as they positively influence the growth of gastrointestinal flora, which consists of glucidolytic and acidforming organisms ([Grembecka 2015, 2018](#); [Livesey, 2003](#)). Slower and incomplete absorption also influence the caloric value of sugar alcohols, which varies from 0 (erythritol) to 2.6 kcal/g (sorbitol) ([Table 1](#)) ([Evrendilek 2012](#); [de Cock 2012](#), [Grembecka, 2015](#); [Grembecka, 2018](#); [Livesey, 2003](#); [Regulation \(EC\) No 1333/2008](#)). Therefore, they can be used as sugar alternatives with low glycemic index (GI) ([Table 1](#)) in calorie-reduced foods and products suitable for diabetics ([Grembecka 2015, 2018](#)). Based on literature data, it can be concluded that mixtures of polyols, fats, starch- and protein-based foods yield lower GI than cumulative GI of the components ([Livesey, 2003](#)). They all characterize with sweet taste, which strength varies from 0.3 to 1 as compared with sucrose ([Table 1](#)). Moreover, their negative heat of solution, i.e. energy needed to dissolve crystals, creates cooling sensation in the mouth. However, such cooling effect can be observed just when the heat of solution is lower than  $-20$  cal/g ([de Cock, 2012](#)). All sugar alcohols are white odorless crystalline powders (except for syrups), and can play various technological roles, i.e. sweetening, texture, filling, preservative and retaining moisture ([Barbieri et al., 2014](#); [Evrendilek, 2012](#)). They all can be used as bulking agents that can substitute sugar in 1:1 ratio and eliminate improper taste of intense sweeteners ([Grembecka, 2015](#)). Polyols can influence spread, volume, texture, shelf life and mouthfeel of various food products due to their physicochemical properties. In general, these properties greatly depend on sugar alcohols' molecular weight, and with its decrease osmolality increases, freezing point decreases, viscosity decreases and boiling point increases ([Nabors and Hedrick, 2012](#); [Grembecka, 2018](#)) ([Table 2](#)). They characterize with high thermal, chemical and pH stability as well as do not undergo Maillard-type browning reaction. Besides, they have high microbial stability and solubility in water ([Table 2](#)).

Sugar alcohols are not fermented by mouth bacteria, thus, are non-cariogenic and non-acidogenic substances. What is more important, they were found to help in tooth mineralization as well as neutralize plaque acids and reduce tooth demineralization ([EFSA, 2011](#)). US FDA and European Commission allow on placement on a product with polyol of a health declaration "does not promote tooth decay" ([EFSA, 2011](#)). They were thoroughly investigated in trials conducted on animals and humans and no health risk was found, thus, no ADI have been specified for whole group ([WHO, Koivistoinen, 2007](#); [Lawson, 2007a](#); [Ly et al., 2006](#); [WHO](#)) ([Table 1](#)). Their usage in food industry is approved in most countries, except for maltitol, which awaits the approval of Food and Drug Administration (FDA), but it can be used as the petition regarding this compound has been already accepted ([Kearsley and Deis, 2012](#)).

### Characteristics of Particular Polyols

#### Erythritol

It is a four-carbon polyol ((2R,3S)-Butan-1,2,3,4-tetrol) ([Fig. 1](#)), which is widely found in nature in such products as wine (130–300 mg/L), soy sauce (910 mg/L), vegetables, fruits (melons – 22–47 mg/kg; pears – up to 40 mg/kg), but is also present in human body in semen, lens, cerebrospinal fluid, serum and human urine (10–30 mg/L) ([Barbieri et al., 2014](#); [den Hartog et al., 2010](#); [Evrendilek, 2012](#); [Ortiz et al., 2013](#); [Oku and Okazaki, 1996](#); [Regnat et al., 2018](#)). Due to such occurrence and levels in food products, erythritol consumption reaches 25 mg/person/day in the United States and 106 mg/person/day in Japan ([de Cock, 2012](#)).

#### Metabolism

Although, erythritol is rapidly and well absorbed (60%–90%) in the small intestine, it is not fermented, but excreted intact in urine within 24 hours ([Bernt et al., 1996](#); [de Cock, 2012](#); [den Hartog et al., 2010](#); [Friedman, 2008](#); [Grembecka, 2015](#); [Livesey, 2003](#); [Munro et al., 1998](#); [Regnat et al., 2018](#)). Therefore, the usual side effects of polyol consumption, i.e. laxative effects, are rarely observed in case of consumption of this substance ([Bernt et al., 1996](#); [de Cock, 2012](#); [den Hartog et al., 2010](#); [Friedman, 2008](#); [Livesey, 2003](#); [Munro et al., 1998](#)). However, it was found that women are less prone to suffer from diarrhea after erythritol

**Table 1** General characteristics of polyols (Grembecka 2015, Grembecka 2018, Livesey 2003, Regulation (EC) No 1333/2008)

Sugar alcohol	Synonyms	E number (according to EU legislation)	Functional classes	ADI	Sweetness (Sucrose = 1)	Glycemic index (Glucose = 100)	Caloric value [kcal/g]

**Figure 1** Chemical structure of erythritol.

consumption (up to 1000 mg/kg body) than men (Bernt et al., 1996; Oku and Okazaki, 1996). What is more, according to EFSA scientific opinion this polyol's metabolism route is independent of consumer's age (EFSA, 2015). Owing to intact excretion, erythritol is a non-caloric substance, which was attributed 0 kcal/g by international legislations (de Cock, 2012; Evrendilek, 2012) (Table 1).

### Production

There are two methods of erythritol production, i.e. chemical synthesis (from 2-butene-1,4-diol) and biotechnological (by yeast or fungi), but only one is actually used on an industrial scale. High cost of the substrate as well as complexity of the chemical procedure, resulted in application of various microorganisms that produce this polyol by fermentation in quite large quantities. Most useful are osmophilic species of yeast as *Moniliella pollinis* (Barbieri et al., 2014; Chattopadhyay et al., 2014; de Cock, 2012; Embuscado and Patil, 2001; Evrendilek, 2012; Lin et al., 2010), but the most productive according to literature data are *Trichosporonoides megachiliensis* and *Pseudozyma tsukubaensis* (Park et al., 2016). Besides these microorganisms, there are also applications of *Oenococcus oeni*, *Leuconostoc mesenteroides*, *Lactobacillus sanfranciscensis* and *Yarrowia lipolytica* MK1 (Carly et al., 2017; Liu et al., 2017; Mironczuk et al., 2015; Rakicka et al., 2017; Regnat et al., 2018; Richter et al., 2001; Stolz et al., 1995; Tomaszewska et al., 2014; Veiga-da-Cunha et al., 1993; Yang et al., 2014). The starting material is usually starch or sucrose, but glycerol was also found useful (Carly et al., 2017; Mironczuk et al., 2015; Tomaszewska et al., 2014; Yang et al., 2014).

### Properties and Applications

It is a white non-hygroscopic powder that have sweetness lower than sucrose (0.6%–0.8%, Table 1), which can be increased (up to 30%) when blended with other polyols or intense sweeteners (Barbieri et al., 2014; Boileau et al., 2012; de Cock, 2012). Erythritol is mainly used as a sweetener, flavor enhancer and humectant. Among its advantages, there is also inability to take part in the Maillard-type browning reactions, stability in various pH conditions and high temperatures (up to 160 °C) (de Cock, 2012). Besides giving a strong cooling effect when dissolving, it also has no aftertaste and is able to mask the taste of intense sweeteners (Barbieri et al., 2014; Boileau et al., 2012; Chattopadhyay et al., 2014; de Cock, 2012; INCHEM, Friedman, 2008; Oku and Okazaki, 1996; Regnat et al., 2018). As erythritol is not metabolized and freely circulates in the body, it can act as a radical scavenger with membrane-protecting properties (de Cock, 2012; den Hartog et al., 2010). With the lowest among polyols molecular weight, it provides higher osmotic pressure and lower activity in solution (Lawson, 2007a). Moreover, it supports microbiological safety as it inhibits the growth of *mutans streptococci*, which results in reduced plaque growth (Runnel et al., 2013). That makes it a very desirable low-calorie, tooth-friendly, bulk sweetener, which finds its application in such products as tooth-friendly chewing gums, candy products, ice creams, ipocaloric beverages, tabletop sweeteners and calorie reduced beverages (Barbieri et al., 2014; de Cock, 2012). When mixed with maltitol it can be useful in production of bakery products (Grembecka, 2015). It is also suitable for use in foods for diabetics as it does not influence blood glucose or insulin levels (Lawson, 2007a). It has very high digestive tolerance and its safety has been comprehensively tested all around the world.

### Isomalt

It is composed of equimolar amounts of two disaccharides (Fig. 2), i.e. 6-*O*- $\alpha$ -*D*-glucopyranosyl-*D*-sorbitol (1,6-GPS) and 1-*O*- $\alpha$ -*D*-glucopyranosyl-*D*-mannitol dihydrate (1,1-GMP dihydrate) and produced exclusively from sucrose (Joint Expert Committee on

**Figure 2** Chemical structure of isomalt.

Food Additives, [Sentko and Bernard, 2012](#)). It is an odorless, non-hygroscopic, crystalline substance, which finds its application as anticaking, bulking and glazing agent as well as stabilizer, sweetener and thickener ([Grembecka, 2015](#)) ([Table 1](#)).

### Metabolism

Due to its stability, isomalt is hardly hydrolyzed and absorbed in the intestine (10%) ([Grembecka, 2015](#); [Livesey, 2003](#); [Sentko and Bernard, 2012](#)). The remaining unabsorbed part is transported to the large intestine, where is fermented to volatile short-chain fatty acids, CO<sub>2</sub>, CH<sub>4</sub> and H<sub>2</sub> ([Dehghan et al., 2013](#); [Livesey, 2003](#); [Sentko and Willibald-Ettle, 2012](#)). As one of the products is butyrate, thus, this polyol exhibit prebiotic effects (increase of the *Bifidobacteria* growth) ([Sentko and Bernard, 2012](#)). However, when consumed in large quantities, and especially in liquid form, the gastrointestinal effects occur, which also depend on the moment and frequency of consumption ([Sentko and Bernard, 2012](#)).

### Production

Isomalt is not found in the nature but was developed and patented by BENEOPalatin GmbH, which is owned by Südzucker AG (Germany) ([Sentko and Bernard, 2012](#)). The substrate is sucrose, which undergoes two-stage process that is enzymatic transformation into more stable isomaltulose (6-*O*- $\alpha$ -*D*-glucopyranosyl-*D*-fructose) and then hydrogenation in the presence of metal catalyst ([Sentko and Bernard, 2012](#); [Sentko and Willibald-Ettle, 2012](#)).

### Properties and Applications

Isomalt characterizes only with about the half sweetening power of sucrose ([Table 1](#)), but it resembles disaccharide in a similar sweetness profile. The intensity of the sweetness depends of isomalt type, concentration and temperature, but can be also increased though blending with intense sweeteners ([Ferguson et al., 2007](#); [Sentko and Willibald-Ettle, 2012](#)). Isomalt also blends with any flavor and has no cooling effects (the highest heat of solution, [Table 2](#)) so it can enhance flavor transfer ([Ferguson et al., 2007](#); [Sentko and Willibald-Ettle, 2012](#)). Isomalt is also used as decorative material as it crystallizes slowly. Its high temperature of melting results in resistance to boiling, baking and extrusion process, while very low hygroscopicity in ability to be stored for long periods ([Table 2](#)) ([Sentko and Bernard, 2012](#)). These properties allow on isomalt usage for coatings (chewing gum pellets) and chocolate applications as a glazing agent. Moreover, it can act as a sweetener, bulking agent and anticaking agent (FAO-WHO Food Standards). Isomalt is also anti-cariogenic and enhance teeth remineralization so can be used in products safe for teeth (EFSA, 2011; [Takatsuka et al., 2008](#)). Moreover, it can be found in hard candies, toffees, chewing gum, chocolates, baked goods, nutritional supplements, cough drops and throat lozenges (FAO-WHO Food Standards, [Grembecka, 2015](#)). It can be also recommended for diabetic people as it characterizes with a low glycemic index ([Table 1](#)) ([Grembecka, 2015](#)).

### Lactitol

This disaccharide polyol with a systematic name 4-*O*- $\beta$ -*D*-galactopyranosyl-*L*-glucitol, consists of sorbitol and galactose ([Fig. 3](#)). Lactitol is an odorless white crystalline powder with a mild sweet taste. It has similar to sucrose technical and handling properties and can substitute sugar in almost every application ([Koivistoinen, 2007](#)). Anhydrous form is especially applicable in case of moisture-sensitive products. Moreover, it can be used as an emulsifier, sweetener and thickener ([Table 1](#)) ([Grembecka, 2015](#)). Commercially, it is sold in two forms, i.e. monohydrate and anhydrous ones ([Koivistoinen, 2007](#); [Zacharis, 2012a](#); [Zacharis and Stowell, 2012](#)).

**Figure 3** Chemical structure of lactitol.

### Metabolism

Lactitol is hardly absorbed in the small intestine (only in 2% by passive diffusion) and mainly is fermented in the large intestine, where it is transformed into biomass, short-chain fatty acids, carbon dioxide, a small amount of hydrogen and organic acids (Chattopadhyay et al., 2014; Koivistoinen, 2007; Zacharis, 2012a; Zacharis and Stowell, 2012). Short-chain fatty acids are then utilized by human organism to produce energy (2–2.4 calories per gram) (Table 1). Lactitol acts as a prebiotic stimulating *Lactobacilli* and *Bifidobacteria* growth (Ballongue et al., 1997; Koivistoinen, 2007; Zacharis and Stowell, 2012). The gastrointestinal effects, i.e. laxative ones are dependent on the person's diet, age, general gut health and the mode and frequency of digestion, but they are unlikely to observe when less than 20 g of lactitol is consumed per day (Grembecka, 2015; Zacharis, 2012a; Zacharis and Stowell, 2012).

### Production

It is a polyol that cannot be found in nature and was firstly synthesized in 1920 (Zacharis and Stowell, 2012). The chemical process is based on a catalytic hydrogenation of 30%–40% lactose solution using Raney nickel as the catalyst (Koivistoinen, 2007; Zacharis, 2012a; Zacharis and Stowell, 2012).

### Properties and Applications

Although it characterizes with a relatively low mild sweetness with no aftertaste (Table 1), it can be increased through blending with intense sweeteners such as alitame, aspartame or acesulfame K (Zacharis and Stowell, 2012). Lower melting temperature of lactitol results in lower costs of production of food products (Koivistoinen, 2007; Zacharis, 2012a). This polyol can be also used as a sucrose 1:1 substitute and characterizes with high stability in various conditions (pH and temperature), good solubility and low hygroscopicity (Zacharis, 2012a). Due to the low heat of solution (Table 2) it has a very small cooling effect, which is useful for particular applications (i.e. in chocolates). Similarly to sucrose, it can be also used as a cryoprotectant for surimi. Lactitol is also a substance known for its positive prebiotic effects on the intestinal microflora, i.e. *Bifidobacteria* and *Lactobacilli* (Ballongue et al., 1997; EFSA, 2011; Finney et al., 2007; Koivistoinen, 2007; Ouwenhand et al., 2009; Zacharis, 2012a). Simultaneously, it inhibits the growth of intestinal putrefactive bacteria, lowers pH, production and absorption of ammonia (Ballongue et al., 1997; Finney et al., 2007; Koivistoinen, 2007; Ouwenhand et al., 2009; Zacharis, 2012a). Being not fermented in the mouth it does not contribute towards dental caries (EFSA, 2011; Koivistoinen, 2007). Besides, it characterizes with very low glycemic index, so it is useful for diabetic people (Table 2). This substance was found to be helpful in treatment of encephalopathy and constipation (Cammà et al., 1993; Chen et al., 2007; Kummel and Brokx, 2001; Mas et al., 2003; Morillas et al., 2014; Salerno et al., 1994).

### Maltitol

This disaccharide polyol (4-O- $\alpha$ -D-glucopyranosyl-D-glucitol) is composed of glucose and sorbitol in equal parts (Fig. 4) (Grembecka, 2015; Kearsley and Boghani, 2012; Lawson, 2007b; Livesey, 2003). Maltitol is a white crystalline powder that acts as a bulking agent, an emulsifier, a humectant, a stabilizer, a sweetener and a thickener (Table 1) (Grembecka, 2015).

**Figure 4** Chemical structure of maltitol.

### Metabolism

There is no active transport mechanism of this compound, thus, before absorption, this polyol must be enzymatically hydrolyzed to glucose and sorbitol as maltitol molecules are too large to be absorbed by diffusion (Lawson, 2007b; Livesey, 2003). As the process is quite slow, so the absorption rate varies between 5% and 80% (Livesey, 2003). The intact molecules of maltitol are moved to lower gut, where undergoes fermentation, which can result in osmotic laxation (Grabitske and Slavin, 2008; Kearsley and Deis, 2012). However, the laxative effects were noted for doses higher than 25–30 g/kg body weight (Lawson, 2007b).

### Production

The industrial process of maltitol production is mainly based on a catalytic hydrogenation (100–150 °C; 100–150 bar) of glucose syrup with high maltose levels, obtained by enzymatic hydrolysis of starch (Kearsley and Boghani, 2012). However, the reaction product is maltitol syrup of different grades, i.e. with 50%–55%, 72%–77% and 80%–90% of maltitol, which can be subjected to crystallization process, thus, leading to maltitol powder. European Union legislation requires the maltitol powder to contain at least 98% of this polyol (on a dry basis), whereas according to American regulations maltitol concentration should be within 92% and 100.5% (on a dry basis) (Kearsley and Boghani, 2012).

### Properties and Applications

Maltitol properties such as sweetness and taste resemble those of sugar (Kearsley and Boghani, 2012; Kearsley and Deis, 2012). It can be used as a fat substitute as it gives food creamy structure and has very small cooling effect (Kearsley and Boghani, 2012; Kearsley and Deis, 2012; Lawson, 2007b). It characterizes with high melting point as well as medium hygroscopicity (Table 2). Moreover, the insulin response after its consumption is reduced as compared to sucrose (EFSA, 2011; Livesey, 2003). Decrease in postprandial glycemic response was observed when maltitol was used with shortchain fructo-oligosaccharides (Respondek et al., 2014). Its non-cariogenic properties allow on its application in many sugar-free foods (Evrendilek, 2012; Kearsley and Boghani, 2012; Lawson, 2007b), as well as a variety of reduced-calorie, reduced-fat foods (Evrendilek, 2012; Kearsley and Boghani, 2012; Lawson, 2007b).

### Mannitol

This 6-carbon polyol can be found in nature, i.e. bacteria, fungi, brown seaweeds and some higher plants (Fig. 5) (Jacobsen and Frigaard, 2014; Ruperez and Toledano, 2003). It is a white, crystalline, odorless, non-hygroscopic substance that is stable in high temperatures (>160 °C) (Table 2). Mannitol is an isomer of sorbitol, with the difference in the planar orientation of the OH group. It can be used as an anticaking and bulking agent, humectant, stabilizer, sweetener and thickener (Table 1) (Grembecka, 2015).

### Metabolism

Only 25% of consumed mannitol is absorbed in the small intestine by passive diffusion. This part of this sugar alcohol is converted by mannitol dehydrogenase to D-fructose, which enters the normal fructose pathway. The unabsorbed mannitol reaches the colon, where is fermented to produce short chain fatty acids (Ghoreishi and Shahrestani, 2009; Livesey, 2003; Wisselink et al., 2002). It is one of the least well-tolerated polyols, which should be consumed in amounts less than 20 g per day in order to prevent side effects (Friedman, 2008).

### Production

Industrial production of mannitol is based on the catalytic hydrogenation of glucose/fructose (1:1) mixture, obtained from invert sugar or starch. The process is carried out at high temperatures and pressure and yields both sorbitol and mannitol, which are later separated based on their solubility (Ghoreishi and Shahrestani, 2009; Makkee et al., 1985; Song and Vieille, 2009). As hydrogenation characterizes with rather low efficiency (25%) and purity of the products, thus, fermentative processes are researched. Application of heterofermentative lactic acid bacteria as well as cyanobacteria is being considered (Akinterinwa et al., 2008; Jacobsen and Frigaard, 2014; Soetaert et al., 1995; von Weymarn et al., 2002; Wisselink et al., 2002). Extraction from natural sources is also investigated as mannitol can be found in many natural sources such as exudates of certain trees (Manna ash, *Fraxinus ornus*), figs, olives, larches, edible fungi, yeasts and seaweed (Deis and Kearsley, 2012; Ghoreishi and Shahrestani, 2009; Ruperez and Toledano, 2003; Song and Vieille, 2009; Wang et al., 2013; Wilson, 2007). Such approach is applied commercially in China, where mannitol is extracted from certain species of seaweed (Deis and Kearsley, 2012).

**Figure 5** Chemical structure of mannitol.

### Properties and Applications

Mannitol can positively modify taste, texture and keeping properties of food products. Its low solubility affects the strength of cooling effects (Table 2) (Ghoreishi and Shahrestani, 2009; Livesey, 2003; Ortiz et al., 2013). Mannitol characterizes with lower sweetness than sucrose, thus, can be combined with other sweeteners in order to increase sweetness and create better taste (Grembecka, 2015). Owing to its very low hygroscopicity, it can be applied as a dusting powder, preventing gums from sticking to wrappers and equipment (Table 2) (Ghoreishi and Shahrestani, 2009; Grembecka, 2015; Gombás et al., 2003; Jamieson, 2012). Its physicochemical properties and non-cariogenicity allow on its usage in production of nutritional tablets, chocolate-flavored coating agents for ice cream and confections or "breath-freshening" and "sugar-free" products (Grembecka 2015, 2018). Mannitol also characterizes with glycemic and insulinemic indexes amounting to 0, which allows on its consumption by diabetic people (Livesey 2003, 2012; Song and Vieille, 2009; Wisselink et al., 2002). Besides food and pharmaceutical industry, it is also known for its medical activities, such as prebiotic, antioxidant and diuretic effects (Gaspar et al., 2004; Ghoreishi and Shahrestani, 2009; Jagannatha et al., 2016; Kassim and Esmat, 2016; Monedero et al., 2010; Saha and Racine, 2010; Shawkat et al., 2012; Wisselink et al., 2002). Moreover, it helps to get rid of mucus and cough in asthmatics and other hypersecretory diseases (Daviskas et al. 2010a, 2010b). It was found that combined with hydration during endovascular aortic aneurysm repair might improve renal function (Kalimeris et al., 2014).

### Sorbitol

This sugar alcohol, called d-glucitol, is an isomer of mannitol (Fig. 6), but characterizes with different properties. It can be found in nature in various fresh and dried fruits, i.e. apples, pears, peaches, prunes, dates and raisins, as well as in some vegetables (Barbieri et al., 2014; Budavari et al., 1996; Deis and Kearsley, 2012; Gutierrez and Gaudillere, 1996; Lawson, 2007c; Milala et al., 2013; Silveira and Jonas, 2002). It is a white, hygroscopic, well soluble, crystalline powder that is stable in high temperatures (Grembecka, 2015).

### Metabolism

Sorbitol is slowly absorbed (25% to 80% of the consumed dose) in the gut by facilitated diffusion and later metabolized in the liver (Livesey, 2003). The unabsorbed part is moved to colon, where fermentation takes place (Deis and Kearsley, 2012; Ghoreishi and Shahrestani, 2009; Jamieson, 2012; Livesey, 2003; Wisselink et al., 2002). The side effects such as laxation can occur as a result of an osmotic imbalance in the gut, when sorbitol is consumed in doses exceeding 50 g per day or 10 g per single serving (Jamieson, 2012).

### Production

Although it is found in plants, i.e. stone and berries from trees of the genus *Sorbus*, it is produced on an industrial scale by catalytic hydrogenation. This process requires glucose or sucrose substrates which are hydrogenated at elevated temperatures using nickel catalyst (Barbieri et al., 2014; Evrendilek, 2012; Grembecka, 2015; Kusserow et al., 2003; Ortiz et al., 2013). Sorbitol can be obtained both in liquid and crystalline form (Deis and Kearsley, 2012; Lawson, 2007c), while the latter is produced through evaporation of the solution and crystallization. There are also other routes of sorbitol production such as electrochemical reduction of dextrose in alkaline conditions (Barbieri et al., 2014; Evrendilek, 2012; Grembecka, 2015) or biotechnological using *Zymomonas mobilis* and *Candida boidini* that are able to produce this polyol (Akinterinwa et al., 2008; Jonas and Silveira, 2004; Ladero et al., 2007; Ortiz et al., 2013; Silveira and Jonas, 2002; Silveira et al., 1999).

### Properties and Applications

Although sorbitol is less sweet than sucrose (Table 1), it characterizes with a pleasant taste, which can mask the unwanted one of other substances. Moreover, its sweetness can be increased by blending with other sweeteners. Its solubility is slightly higher than sucrose and high negative heat of solution results in marked cooling effect, which is important for certain applications (Table 2) (Basu and Shivhare, 2013; Deis and Kearsley, 2012; Le and Mulderrig, 2001). Due to high hygroscopicity, easy compression and other physicochemical properties such as thermal stability and chemical inertness, it can be used as a humectant, softener, texturizing and anti-crystallizing agent (Basu and Shivhare, 2013; Deis and Kearsley, 2012; Gombás et al., 2003; Grembecka, 2015; Jamieson, 2012; Jonas and Silveira, 2004; Le and Mulderrig, 2001; Ortiz et al., 2013). It is also an important precursor of the vitamin C production as well as sorbose and surfactants (ADA Reports 2004; Ladero et al., 2007; Silveira and Jonas, 2002). Sorbitol is not digested by mouth bacteria, thus, preventing from cavities and erosion of tooth enamel (EFSA, 2011). Therefore, it can be used as a tooth-friendly substance in foods and pharmaceuticals. This sugar alcohol is also suitable for use in products for diabetics

**Figure 6** Chemical structure of sorbitol.

as well as in sugar-free candies, chewing gums, and sugar free foods such as frozen desserts and baked goods as well as cosmetics (Grembecka, 2015).

### Xylitol

Five-carbon monosaccharide polyhydric alcohol, d-erythro-pentitol (Fig. 7), is usually called birch sugar, as initially birch wood was used for its production. It can be found in nature in fruits (yellow plums - 935 mg/100 g d s.; strawberries - 362 mg/100 g d s.), and vegetables (cauliflower - 300 mg/100 g d s.; endives - 258 mg/100 g d s.), berries, oats and mushrooms and is produced in small quantities in human organism (5 to 15 g/day in carbohydrate metabolism) (Barbieri et al., 2014; Bond, 2007; Evrendilek, 2012; Granström et al., 2007; Ly et al., 2006; Lee and Park, 2014; Nigam and Singh, 1995; Zacharis, 2012b). It has been used as a sweetener since the 1960s (Zacharis and Stowell, 2012).

### Metabolism

Absorption of xylitol amounts up to 50% and takes place in the small intestine. There are two routes of xylitol metabolism, i.e. direct in the liver via the glucuronic acid–pentose phosphate shunt of the pentose phosphate pathway or indirect by fermentation conducted by intestinal flora (Sheet et al., 2014). The unabsorbed part undergoes fermentation in the large bowel, where minor amounts of gas ( $H_2$ ,  $CH_4$ ,  $CO_2$ ) as well as short-chain volatile fatty acids are produced. Xylitol can be consumed even up to 100 g per day (Lee and Park, 2014).

### Production

Commercially, xylitol is produced by a catalytic hydrogenation of xylose, which sources are birch trees, hardwood or lignocellulosic biomass (Chattopadhyay et al., 2014; Granström et al., 2007; Ly et al., 2006; Nigam and Singh, 1995; Park et al., 2016; Zakaria, 2001; Zhang et al., 2012). The whole process consists of xylan hydrolysis, chromatographic purification, and hydrogenation with nickel catalyst (Evrendilek, 2012). Due to the cost of this approach, there are researched other ways of this polyol production including biotechnological ones with the use of such microorganisms as *Candida tropicalis* and *Candida guillermundii* (Akinterinwa et al., 2008; Ortiz et al., 2013; Park et al., 2016). However, these species are not suitable for food industry as these are pathogenic species (Grembecka, 2015, 74, Ortiz et al., 2013). There are also data indicating that recombinant microalgae or fungi might produce xylitol (Hirabayashi et al., 2015; Park et al., 2016; Pourmir et al., 2013).

### Properties and Applications

Xylitol resembles sugar in view of sweetness (Table 1) and pleasant taste. Moreover, it characterizes with the greatest cooling sensation (Table 2) in the mouth and is readily soluble in aqueous solutions (Granström et al., 2007; Mäkinen, 2011). Therefore, it can be used to enhance and complement mint flavor or providing products with refreshing cooling sensation. Moreover, it has non-insulin stimulant properties, thus, is safe for diabetic people (Chattopadhyay et al., 2014; Grembecka, 2015; Nigam and Singh, 1995; Zacharis, 2012b). It is also known for anti-cariogenic effects and is responsible for a decrease in plaque formation as it inhibits the growth and metabolism of *Streptococcus mutans* and *Streptococcus sobrinus*, species responsible for caries and dental plaque acid production (ElSalhy et al., 2012; Lee and Park, 2014; Lee et al., 2012; Misra et al., 2012; Salli and Forssten, 2016; Söderling et al., 2008). What is more, it increases oral pH and forms complexes with  $Ca(II)$  which allows on teeth remineralization (Bahador et al., 2012; Cardoso et al., 2016; Mäkinen, 2011; Tanzer, 1995). Both frequency and amounts of consumption are important and it was found that xylitol works most efficiently when is applied 3 to 5 times a day and the total daily dose ranges from 6 to 10 g (Ly et al., 2006). Due to its properties, xylitol fights unpleasant mouth odor and stimulates saliva production, which is of great importance for people with xerostomia (Grembecka, 2015; Mäkinen, 2011; Ship et al., 2007). Due to its fermentation in the colon, it can be used as prebiotic that increase the growth of *Bifidobacterium*, thus resulting in short-chain fatty acids production and lowering of intestinal pH (Bond, 2007). Xylitol also exhibits antifungal and antibacterial effects and can reduce ear infections incidence and pneumococcal nasal colonization (Lee and Park, 2014; Mäkinen, 2011; Nyssölä et al., 2005; Ortiz et al., 2013; Vernacchio et al., 2007; Uhari et al., 2000). It was also noted that xylitol solution inhibits the growth of *Streptococcus pneumoniae*, *Haemophilus influenza*, *Candida albicans* and *Helicobacter pylori* (Grembecka, 2015; Lee and Park, 2014). There is also data that xylitol is helpful in bone mineralization, through stimulation of calcium absorption, and increases minerals bioavailability (Kaivosoja et al., 2008; Xiao et al., 2015).

**Figure 7** Chemical structure of xylitol.

## Summary

Today we encounter a great variety of readily available sugary foods, which are often of very low nutritional value, but with high energy value, thus, their preference over others can cause many health problems. Sugar alcohols are natural sugar alternatives but are also referred to as semi-synthetic sweeteners. This is due to the fact that they are present in small amounts in plants, fruits, vegetables and mushrooms, but are produced synthetically for technological purposes. They characterize not only with lower caloric content and glycemic index, but with beneficial anti-caries, prebiotic, antioxidant and antibacterial effects. Therefore, polyols are bulk sweeteners that constitute excellent substitutes to sugar in food and pharmaceutical industry. As these substances do not influence insulin level in blood, they can be recommended for people with diabetes but also for everyone who want to lead a healthy lifestyle.

### Glossary

**Coalescence** Is the formation of one droplet from two or more droplets.

**Emulsifier** Are surface-active agents that are amphiphilic compounds containing both polar and non-polar residues allowing them to reside at the oil-water interface and reduce the interfacial tension.

**Flocculation** Is the process by which particulates are caused to clump together into a floc while the individual droplets retain their original interface.

**HLB Value** It is calculated from the weight percentage of the hydrophilic groups to the hydrophobic groups in a molecule, with values ranging from 1–20.

**Ostwald's Ripening** Is the process where droplets (i.e., the discontinuous phase) diffuse from smaller to larger droplets through the continuous phase.

### Introduction to Food Emulsions

An emulsion consists of two liquid immiscible phases: oil and water. Either of these two phases can be the continuous or the dispersed phase and as such there are two primary types of emulsions: oil-in-water (o/w) or water-in-oil (w/o). An oil-in-water emulsion consists of an oil phase dispersed into a continuous water (aqueous) phase. Common food examples include: mayonnaise, salad dressing, whipped toppings, and ice cream. In contrast, a water-in-oil emulsion consists of an aqueous phase dispersed in a continuous oil phase, such as butter and margarine (Kralova and Sjöblom, 2009). In addition to an oil phase and an aqueous phase, the formation of an emulsion requires energy input and addition of surfactants. The resulting emulsion that is formed (o/w or w/o) is greatly influenced by the chemistry of surfactant (Walstra, 1993). Surfactants are used to reduce the work required to overcome surface free energy and disperse one phase into the other and to stabilize the final emulsion. Properties of o/w emulsions rely more heavily on the type of surfactant used and the composition of the aqueous phase; while, properties of w/o emulsions are more dependent on the type of fat (Kralova and Sjöblom, 2009).

Food emulsions exist in a pseudo-equilibrium or 'frozen' kinetic state making them "shelf-stable" only for a limited time. The stability of the emulsion is dependent on the crystallinity of oil/fat droplets, the interfacial material, and the chemistry of the aqueous phase. The degree of crystallinity of the oil phase influences its melting properties, which is important for partial coalescence in ice cream and whipped products. The quality of the interfacial layer depends on the mixture of macromolecules and small molecule weight surfactants. The quantity and structure of the adsorbed surface-active compounds affects interfacial properties. Small molecular weight surfactants often displace adsorbed proteins or bind/interact with proteins (ie. lecithin), which modifies emulsion droplet stability. Therefore, even small changes in interfacial composition can significantly influence overall stability. The interactions between emulsion droplets and the aqueous phase also impacts emulsion stability (Dalgleish, 2006).

The terms emulsifier, surface-active agents and surfactant are often used interchangeably to describe amphiphilic compounds that contain both polar and non-polar residues (Lauridsen, 1976; Weiss, 1971). This characteristic allows them to reside at the oil-water interface and reduce the interfacial tension (Lauridsen, 1976). This general review will focus on the mechanisms of emulsification, prevention of emulsion destabilization, common surfactants, and their applications in food.

### Mechanisms of Emulsification

Emulsions are *thermodynamically unstable* because they have a positive free energy of formation ( $\Delta G_f$ ) and are considered non-equilibrium systems as emulsified droplet sizes increase with time (Taylor, 1998; Bibette et al., 1992). This instability is due to the large interfacial area of droplets, represented by surface area ( $A$ ) & interfacial tension ( $\gamma$ ):

$$\Delta G_f = \gamma A - T\Delta S_f$$

The entropy of formation ( $\Delta S_f$ ) is relatively small because only a small number of droplets are being formed in entropic terms. Hence, the larger interfacial area variable results in an overall  $\Delta G_f \geq 0$ . Nonetheless, emulsions are *kinetically stable* due to the presence of an adsorbed interfacial layer which may include ionic surfactants (electrostatic forces) or non-ionic surfactants (steric forces) (Taylor, 1998).

To reduce the emulsion droplet size, energy is required to overcome its *Laplace pressure* which is the pressure differential between the convex and concave side of the interface:

$$\text{Laplace pressure}(p_L) = \gamma \left( \frac{1}{R_1} + \frac{1}{R_2} \right)$$

where  $p_L$  is the Laplace pressure,  $R_1$  and  $R_2$  are the radii. Accordingly, a smaller droplet radius corresponds to a greater pressure needed to be overcome to achieve further particle size reduction; however, by lowering the surface tension, via the addition of surfactants, the Laplace pressure also decreases. The process of emulsification involves: droplet deformation and breakdown, transportation and adsorption of surfactants to the newly formed droplet interface, and droplets possibly colliding and coalescing. As these processes occur simultaneously a steady-state is not necessarily achieved. Ultimately, the main functions of surfactants are to (1) lower interfacial tension to facilitate a droplet size reduction, and (2) prevent recoalescence of droplets (Walstra, 1993).

### Prevention of Emulsion Destabilization

Without appropriate controls or after a prolonged duration, an emulsion will eventually separate into its two distinct phases. There are four primary mechanisms which destabilize an emulsion: creaming (gravitational separation), aggregation, coalescence, and Ostwald ripening. Typically, these mechanisms occur in combination (Fig. 1) (Fredrick et al., 2010).

Perhaps the most straightforward destabilization mechanism, creaming of an o/w emulsion involves the gravitational separation of the dispersed oil and continuous aqueous phases due to differences in density (Rousseau, 2000). For example, after some time, milk fat droplets in unprocessed raw milk will rise and gather together, forming a cream layer at the top (Fredrick et al., 2010). An effective method of stabilizing against creaming is to simply reduce average droplet size and increase the uniformity of the droplets via homogenization (Rousseau, 2000).

Aggregation occurs when droplets come into contact, but whether they remain in contact depends on internal (attraction/repulsion) and external forces (ie. stirring/agitation) (Fredrick et al., 2010). Flocculation is the aggregation of particles due to weak attractive forces, in which droplets retain their structural integrity. It is also described by the DLVO (Derjaguin-Landau, Verwey-Overbeek) theory as a function of interparticle distance and the balance between attraction (London-van der Waals forces) and repulsion (electrostatic) (Rousseau, 2000). Emulsions stabilized by globular proteins are stable against flocculation if no salt is present – due to electrostatic screening, but this is not usually the case in foods (Zhai et al., 2013). As flocculation involves weaker associations, it is easier to disrupt the aggregates and may be reversible. However, when stronger forces are required to disrupt aggregates, this form of aggregation is referred to as coagulation (Fredrick et al., 2010).

If two droplets remain in close contact for long enough, the film separating them may rupture (Fredrick et al., 2010). Creaming and flocculation are both precursors to coalescence as they bring droplets close together (Taylor, 1998). The likelihood of film

**Figure 1** The relationships between different o/w emulsion destabilization mechanisms. Reprinted with permission from Meinders, M.B.J., Kloek, W., Van Vliet, T., 2001. Effect of surface elasticity on Ostwald ripening in emulsions. *Langmuir*, 17, 3923–3929. Copyright 2001 American Chemical Society.

rupture increases with larger droplet size, thinner film (greater attraction between droplets), and lower interfacial tension (which depends on the surfactant used). Coalescence results in the formation of one larger droplet from two smaller droplets, which assumes a spherical shape as this has the lowest Laplace pressure (Fredrick et al., 2010). To prevent coalescence, surfactants must form a viscous and rigid film at interface that acts as a physical barrier. While complete coalescence occurs between liquid droplets; the presence of crystalline matter within droplets results in *partial* coalescence (Rousseau, 2000). A partly-crystalline oil phase allows for the formation of a crystal network within oil droplets, with some crystal protrusion into the aqueous phase (Fredrick et al., 2010).

Ostwald ripening and coalescence are both examples of “coarsening phenomena”. Coalescence can be prevented by using certain surfactants, Ostwald ripening may occur whenever curved interfaces are present (Meinders et al., 2001). Ostwald ripening does not require droplets to be in close proximity, as it is based on diffusion (Taylor, 1998). It involves the preferential diffusion of small droplets into larger droplets, due to their greater Laplace pressure (Bibette et al., 1992). The solubility of dispersed droplets increases with decreasing radius of curvature, smaller droplets tend to dissolve into the bulk phase and preferentially diffuse to larger droplets. This is because by growing larger to minimize interfacial area, emulsions droplets can reduce their free energy (Taylor, 1998). A critical radius ( $C_r$ ) determines which droplets shrink (radius <  $C_r$ ) and which droplets grow (radius >  $C_r$ ) (Meinders et al., 2001).

### Hydrophilic-Lipophilic Balance of Surfactants

The hydrophilic-lipophilic balance (HLB), often used to describe surfactants, is calculated from the weight percentage of the hydrophilic groups to the hydrophobic groups in a molecule, with values ranging from 1–20 (Kralova and Sjöblom, 2009). The HLB value of a surfactant should match the HLB value of the oil phase based on the notion of “like dissolves like”. It is not a simple linear relationship in which functionality increases with higher hydrophobicity (Nakai, 1983).

As mentioned previously, the type of emulsion formed (o/w or w/o) is mainly determined by the surfactant present (Walstra, 1993). Surfactants with an HLB value between 3–6 (i.e., glycerol esters, propylene glycol fatty acid esters, polyglycerol esters, and sorbitol fatty acid esters) promote formation of w/o emulsions. Surfactants with HLB values between 8–16 tend to form o/w emulsions. Surfactants between 8–16 include: proteins, phospholipids, potassium and sodium salts, and alginates (Kralova and Sjöblom, 2009).

Nevertheless, there are limitations to the HLB concept. Depending on temperature, a single emulsifier can produce either an o/w or w/o emulsion. At high oil concentrations, a single emulsifier can produce an o/w at low emulsifier concentration, or a w/o emulsion at high emulsifier concentration. Furthermore, o/w emulsions can be prepared with emulsifiers across the entire HLB range. The stability of an emulsion prepared with a blend of opposite emulsifiers (ie. Spans and Tweens) will depend on how the emulsifiers are positioned at the interface. Lastly, the theoretical calculation of HLB values does not apply to blends of emulsifiers that associate at the oil-water interface (Boyd et al., 1972).

### Gibbs-Marangoni Effect

The Gibbs-Marangoni effect describes the mechanism that prevents recoalescence of newly formed emulsion droplets (Fig. 2). When two droplets that are insufficiently coated with surfactant move towards each other, they will accumulate additional surfactants as they approach each other (Fig. 2(1)). But, the amount of surfactant available for adsorption will be lowest at the point where the droplets are closest (Fig. 2(2)). This creates an interfacial tension ( $\gamma$ ) gradient, where  $\gamma$  is highest at this point. Due to this gradient, surfactants will move in the direction of highest  $\gamma$ , where there is the least amount surfactant coverage (Fig. 2(3)). This streaming of liquid along the surface is known as the Marangoni effect, a self-stabilizing mechanism in which droplets are driven away from each other. However, this only occurs if the surfactant is present in the continuous phase and before the system reaches equilibrium. According to Bancroft’s Rule, when forming an emulsion, the phase in which the surfactant is most soluble becomes the continuous phase. The efficacy of the Gibbs-Marangoni mechanism depends on Gibbs elasticity ( $\epsilon$ ) of film, where ( $A$ ) represents area of the interface.

$$\epsilon = \frac{2d\gamma}{d\ln A}$$

If  $\epsilon$  is high, there is a strong interfacial gradient and stabilization occurs (Walstra, 1993). Interfacial layers formed by non-protein surfactants are stabilized by the Gibbs-Marangoni effect. This mechanism relies on rapid diffusion of surfactants to the interface to prevent surface concentration gradients (Wilde et al., 2004).

### Critical Micelle Concentration

As surfactants are amphiphilic structures with a non-polar hydrocarbon tail and polar (usually ionic) head group, they arrange themselves into micelles in polar solvents, such as water. This is due to the hydrophobic effect, in which surfactants arrange themselves into a micellar structure with a hydrophobic core and hydrophilic head groups at the interface. The critical micelle concentration (CMC) refers to the concentration of surfactant above which micelles will form. There are three common methods of CMC determination: (1) measure the change in UV-vis spectrum of benzoylacetone, (2) measure the fluorescence emission spectrum of pyrene monomers, or (3) measure the electrical conductivity of an ionic surfactant solution as concentration increases. To

**Figure 2** Portrayal of the Gibbs-Marangoni effect on two approaching emulsion droplets, with surfactants represented by Y. One represents the two emulsion droplet approaching one and other, 2 illustrates the movement of surfactant molecules along the interface and 3 signifies the water flowing between droplets to dilute the high surfactant concentration. Reprinted with permission from Walstra, P., 1993. Principles of emulsion formation. Chem. Eng. Sci. 48 (2), 333–349. Copyright 1993 Elsevier.

determine CMC, simply plot the physical property as a function of surfactant concentration and the CMC will be the point in which the slope changes. CMC decreases with increasing hydrocarbon chain length of non-polar groups, or addition of electrolytes for ionic surfactants (Domínguez et al., 1997).

## Major Food Surfactants

### Low MW Surfactants

Low MW surfactants are very mobile at the interface making them efficient at lowering interfacial tension (Kralova and Sjöblom, 2009). Low MW emulsifiers do not form a viscoelastic interfacial layer, but rather form a compact interfacial layer. Competitive destabilization may occur when both proteins and surfactants are present at the interface. Surfactants weaken protein interactions, while proteins hinder surfactant mobility (Gibbs-Marangoni effect) (Wilde et al., 2004). As low MW surfactants are smaller than proteins, they tend to displace proteins from the interface (Rousseau, 2000). At low surfactant concentration, protein-surfactant complexes form. While, high surfactant concentration results in protein displacement from the interface. Therefore, low MW surfactants are commonly used to intentionally destabilize food emulsions, such as ice cream allowing for partial coalescence (Dickinson et al., 1989).

Lecithin used in foods are a mixture of phospholipids and can be modified to obtain various HLB values (Van Nieuwenhuyzen and Szuhaj, 1998). Methods of modification include: fractionation in alcohol, hydrolysis (enzymatic, acid or alkali), acetylation or hydroxylation. Lecithin can be derived from egg yolk or various oilseeds (soybean, flax, cottonseed, corn, rapeseed, sunflower). However, soybean is the most common source due to its availability, emulsifying properties, color and taste. There are many food applications of soy lecithin, such as: viscosity lowering in chocolate, protein interaction in baked products, retardation of fat crystallization in chocolate, and dispersing effect in instant drinks. Furthermore, its stability increases when used together with other surfactants, such as monoglycerides or proteins (Van Nieuwenhuyzen, 1976).

Mono- and di-glycerides are glycerol esters of fatty acids. They are most commonly used in the food industry for bakery products (bread, cake, cake mixes) and frozen desserts (Weiss, 1971). Monoglycerides have two isomeric forms (1-form and 2-form) based on a temperature-dependent equilibrium (Lauridsen, 1976). Sorbitan esters, also known as “Spans”, are products of a reaction between sorbitol and fatty acids. Polysorbates, also known as “Tweens” are polyoxyethylene derivatives of sorbitan esters. Spans and Tweens are often used together in cakes, cake mixes, whipped toppings, icings, and coffee whiteners (Weiss, 1971). According to Boyd et al. (1972), optimum stability in o/w emulsions is achieved when using a 1:1 ratio of Spans and Tweens.

## Proteins

The main emulsion stabilization mechanism of proteins is through the formation of a viscoelastic adsorbed layer. However, the extent of adsorption depends on protein surface hydrophobicity and charge (Wilde et al., 2004). As non-polar amino acids reside within protein molecules to avoid contact with aqueous surroundings, only some of them partake in the emulsification process. Thus, the term protein hydrophobicity typically refers to *surface* hydrophobicity. As emulsifiers, proteins adsorb to the interface due to their amphiphilic nature and form a thick coating around oil droplets. The emulsifying ability of proteins depends on a balance between hydrophilic and lipophilic portions (Nakai, 1983). As shown in Fig. 3, when protein hydrophobicity increases, interfacial tension decreases and emulsifying activity increases. Thus, greater exposure of hydrophobic residues on proteins improves emulsifying and foaming ability. Additionally, the effectiveness of a protein as an emulsifier is also attributed to its molecular flexibility. For example, casein molecules are better emulsifiers than whey proteins as they have a looser conformation (Nakai, 1983).

## Applications in Food Systems

Cream liqueurs are o/w emulsions that contain ethanol in its aqueous continuous phase. The presence of ethanol (up to 20% wt.) improves emulsification and produces finer droplets, as it lowers interfacial tension. However, increasing alcohol content may eventually lead to protein aggregation, with precipitation observed at > 30% wt. ethanol (Dickinson et al., 1989). Sodium caseinate is the primary stabilizer in cream liqueurs (Kralova and Sjöblom, 2009). Sodium caseinate forms an interfacial layer of caseinate submicelles around fat droplets to stabilize emulsions (Rousseau, 2000). If low MW surfactants are added to cream liqueurs, they reside in the primary interfacial layer with ethanol; while, the secondary interfacial layers contain adsorbed caseinates. But due to the intrinsic emulsifying ability of cream liqueurs, the addition of low MW surfactants does not significantly influence droplet size distribution. Ethanol content also lowers the surface viscosity of adsorbed caseinate film at the interface. This is beneficial for the consumer acceptance of cream liqueurs which should not be too viscous or viscoelastic (Dickinson et al., 1989).

Ice cream and whipped toppings are both examples of partially-coalesced emulsions that undergo shear and incorporation of small air bubbles. Whipped products use surfactants to displace proteins and weaken the interfacial layer, allowing oil from emulsion droplets to spread into the air–water interface (Dalglish, 2006). Compared to whipped products, ice cream has a lower fat volume, presence of ice crystals, and also utilizes a different whipping process (Petrut et al., 2016). For these products, it is important that the fat phase is semi-liquid during whipping, but crystallizes afterward (Dalglish, 2006). The purpose of fat network formation is to entrap air bubbles and stabilize the foam structure (Petrut et al., 2016).

**Figure 3** Relationship between interfacial tension, surface hydrophobicity and emulsifying activity of various proteins. Reprinted with permission from Nakai, S., 1983. Structure-function relationships of food proteins with an emphasis on the importance of protein hydrophobicity. J. Agric. Food Chem. 31 (4), 676–683. Copyright 1983 American Chemical Society.

In ice cream, the destabilization of fat emulsions during whipping and subsequent freezing is necessary to impart dryness during extrusion, smooth mouthfeel/texture, and resistance to meltdown. Ice cream has an aqueous phase composed of sugar, salt, and a colloidal casein suspension. Its discrete globular phase is partially-crystalline and contains triglycerides, diglycerides and monoglycerides. The interface contains milk proteins, phospholipids, lipoprotein particles and any added surfactants (Goff and Jordan, 1989).

Low HLB surfactants are not effective destabilizers as they adsorb to the fat globules, which helps retain their structural integrity. High HLB emulsifiers do not associate with fat globules as strongly and are easily displaced during agitation. This exposes the fat globules and promotes coalescence. For example, Tweens (HLB = 15) are very effective destabilizers, while Spans (HLB = 4.3–8.6) are not (Goff and Jordan, 1989). Casein stabilized emulsions are more stable against partial coalescence than whey proteins; however, caseins are more easily displaced by low MW surfactants. This protein displacement mechanism is important in lowering emulsion stability to reduce viscoelasticity and thickness of interface (Fredrick et al., 2010). Typically, monoglycerides and diglycerides are used to induce partial coalescence, while polysaccharides (such as carrageenan and gums) are used as stabilizers in ice cream (Kralova and Sjöblom, 2009).

Mayonnaise contains up to 70%–80% fat, and is considered an acidic o/w emulsion. The low pH and high fat content of mayonnaise makes it highly resistant to microbial spoilage (Depree and Savage, 2001). To maintain emulsion stability, there must not be fat crystals within the dispersed oil phase. The aqueous continuous phase typically consists of eggs, sugar, vinegar, salt and spices. Egg yolk contains lecithin that function as the emulsifier and stabilizer (Van Nieuwenhuyzen and Szuhaj, 1998). Salt is also an important ingredient as it helps disperse egg yolk granules and neutralizes the charges proteins. This allows proteins to strongly adsorb to the interface and better interact with adjacent droplets, as shown below in Fig. 4 (Depree and Savage, 2001).

To make mayonnaise, the first step is to mix together the components with the aqueous phase. Next, oil must be *gradually* added while continuously blending. This is an important step as the mixing of both phases together all at once will result in the formation of a w/o emulsion. Oil droplets within mayonnaise are distorted from their normal spherical shape as they are tightly associated with each other. This flocculation is important for mayonnaise viscosity and texture. Consequently, the pH of mayonnaise should be near the isoelectric point of the egg yolk proteins ( $\sim 3.9$ ) to allow for maximum viscoelasticity and stability (Depree and Savage, 2001). This partial-phase inversion results in a heat stable emulsion that can be pasteurized. Heating up mayonnaise to 60 °C denatures the egg proteins, followed by hydrolysis to produce phosphatidylcholine which is an effective o/w surfactant. Alternatively, hydrolyzed soy lecithin is also commonly used in mayonnaise (Van Nieuwenhuyzen and Szuhaj, 1998).

## Conclusion

Overall, surfactants have a multitude of applications within the food processing industry. As emulsions are thermodynamically unstable, these surface-active agents are employed to improve kinetic stability and increase product shelf-life. Emulsions may be

**Figure 4** The interfacial components and affect of salts on mayonnaise o/w emulsion. Reprinted with permission from Depree, J.A., Savage, G.P., 2001. Physical and flavour stability of mayonnaise. Trends Food Sci. Technol., 12 (5–6), 157–163. Copyright 2001 Elsevier Science Ltd.

destabilized via creaming (gravitational separation), aggregation, coalescence, and/or Ostwald ripening. However, surfactants may combat these processes through several means. Electrostatic interactions involve the surface charge of emulsions droplets which is influenced by the presence of ionic surfactants, proteins and other charged compounds. Low MW surfactants have the ability to displace proteins to induce partial coalescence which is desired in promoting foam stability of ice cream and whipped toppings. Lastly, dispersed emulsion droplets may also be stabilized by the steric repulsive forces of mono- and di-glycerides or proteins.

NOAEL No-observed-adverse-effect level

PG Propyl gallate

TBHQ *tert*-Butylhydroquinone

THBP 2,4,5-Trihydroxybutyrophenone

## Introduction

It is common sense that the shelf-life of food is a key factor to ensure its perfect state and integral nutritional value. Among major food components, fats are particularly sensitive to different deterioration processes, mainly based in oxidation reactions. These reactions, along with the subsequent decomposition of oxidation products, cause the major losses in the nutritional value and sensory qualities of food products. Therefore, preventing or delaying these oxidation processes is essential for food producers and all intervenient involved in the food chain. Actually, there are different methods employed to inhibit oxidation, such as preventing oxygen access or reducing its pressure, using low temperatures, inactivating specific enzymes, or using suitable packaging. Obviously, another strategy employed against oxidation is the use of specific additives, which inhibit or delay the associated reactions (Yehye et al., 2015). These antioxidant compounds are usually classified as having natural, synthetic or artificial origin.

Since communication in science is highly dependent on precise language, it is mandatory to clarify the differences among those three concepts. Artificial refers to any compound that cannot be found in nature, while synthetic would generally describe any man-made compound. Accordingly, and just to establish an example, chemically synthesized  $\alpha$ -tocopherol should not be considered artificial, since it is chemically, analytically and functionally indistinguishable from  $\alpha$ -tocopherol isolated from natural sources. Likewise, chemically synthesized  $\alpha$ -tocopherol is not a natural compound, as it was not directly purified from natural sources, resulting instead from a synthesis procedure conducted by man (Nielsen, 2010).

Considering the previous concepts, it is easy to conclude that most antioxidants used in Food Industry are either synthetic or artificial, except for some particular cases such as tocopherol-rich or rosemary extracts, identified in the European Union as E306 and E392, respectively (Official Journal of the European Union, 2011a,b).

In addition to their origin-based classification, and owing to their structural diversity and different mechanisms of action, other classification systems were established. In general, antioxidants may be compounds or systems with the ability to inhibit the autoxidation by preventing the formation of free radicals or interrupting their propagation according to different mechanism. One of the most well-accepted defines five types of antioxidant compounds: primary antioxidants, chelators, O<sub>2</sub><sup>-•</sup> quenchers, oxygen scavengers and antioxidant regenerators (Carocho et al., 2015).

In addition to the previous introductory explanations, it should be clarified that the present article will be fully dedicated to aspects related to the application of antioxidants in food products, without detailing their multiple physiological effects or specific laboratorial assays employed in their detection. It is specifically intended to revise antioxidant compounds with top use in food products, their potential interaction with other food components, absorption dynamics, potential toxicological issues and, of course, recent legal aspects.

## Antioxidants in Food Industry

The main reason supporting the incorporation of antioxidants in food products is preventing the oxidation of fats, an undesired process associated with the production of pungent off-flavors (Shahidi et al., 2010). In fact, lipid oxidation causes detrimental changes in taste, odor, texture, flavor and appearance of foods, likewise reducing the levels of fat-soluble vitamins (McClements and Decker, 2000; Zeb and Murkovic, 2013).

In recent decades, different antioxidants such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), *tert*-butylhydroquinone (TBHQ), propyl gallate (PG), 2,4,5-trihydroxybutyrophenone (THBP) and di-*tert* butyl-4-hydroxymethylphenol (IONOX-100) have been widely employed at industrial level with the main purpose of delaying the oxidative degradation of lipids, taking advantage of their high oxidative stability, low cost and good performance (Guo et al., 2006). Besides the indicated compounds, several others are legally recognized as being safe food additives (please check Regulation No 1333/2008 of the European Parliament and of the Council and its further amendments represented by Commission Regulation No 1129/2011 and Commission Regulation No 1130/2011, as indicated in the References section), such as exemplified in Table 1.

Other important antioxidants, despite primarily classified as colorizing agents, are represented by the E160a-f and E161a-j series (which includes mainly carotenoids), as also by E163 (which is composed by different anthocyanins).

Pertaining their use in food products, there is an intense discussion about the pros and cons of artificial antioxidants, particularly regarding BHA (E320), BHT (E321), TBHQ (E319) and propyl gallate (E310), which are the most commonly used (Makahleh et al., 2015; Xiu-Qin et al., 2009). Many studies have been carried out regarding these compounds, but no unequivocal results were obtained on their potentially hazardous effects over human health or lack of acute toxicity. In fact, while some reports point out hazardous effects, such as different toxicity levels or carcinogenicity, others describe opposite effects, classifying them as tumor suppressant (Bauer et al., 2001; Botterweck et al., 2000; Moon and Park, 2011; Saito et al., 2003; Vandeghanooni et al., 2013). Regarding these particular topics, and owing to their immense use, BHA and BHT will be analyzed in detail in further sections.

In either case, antioxidants should be tested for safety and must be approved for use in food, despite the allowable limits for their use vary greatly from country to country (Reische et al., 2008). Their usage in food industry, either as direct or indirect additives, should be made taking into account that all antioxidants have points of strength and weakness. Furthermore, factors, such as, effective concentration, thermal stability and synergism, should be taken into consideration when selecting antioxidants (Saso and Firuzi, 2014).

## Mechanism of Action

Regarding their functional properties, antioxidants might be generally divided into two major groups: primary and secondary antioxidants. The first group includes radical terminators, oxygen scavengers and chelating agents. The majority of antioxidants used as food preservatives, which include BHA, BHT, TBHQ, PG and other gallic acid esters, are all examples of radical terminators, specifically preventing lipid oxidation by terminating the free radical chains (Carocho and Ferreira, 2013).

Still regarding their mode of action, five different types of antioxidants (previously indicated in Introduction) might be considered:

- i) primary antioxidants: also known as radical scavengers or chain-breaking antioxidants, which scavenge species that initiate peroxidation (Muralikrishna Adibhatla and Hatcher, 2006);
- ii) chelators: bind to metallic elements,  $\text{Fe}^{2+}$  in particular, preventing the initiation of radical formation (Brewer, 2011);
- iii)  $\text{O}_2^{\cdot-}$  quenchers: have the ability to deactivate high-energy oxidant species, preventing formation of peroxides (Brewer, 2011);
- iv) oxygen scavengers: act by removing oxygen from the system, avoiding their destabilization;
- v) antioxidant regenerators: regenerate other antioxidants when these are converted into radical species (Carocho et al., 2015).

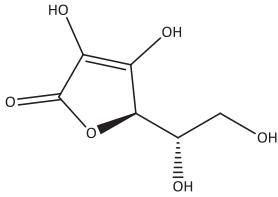

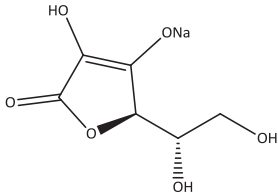

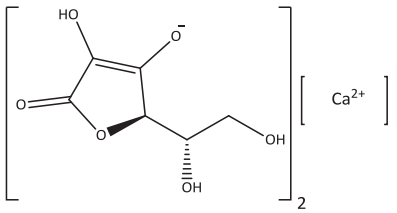

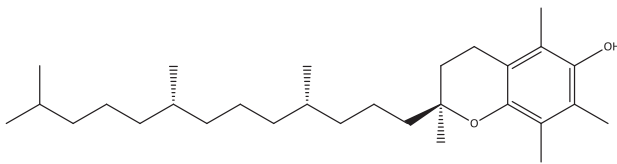

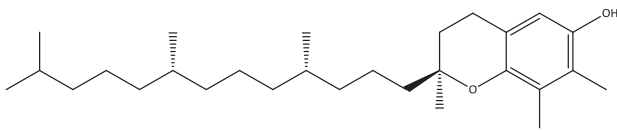

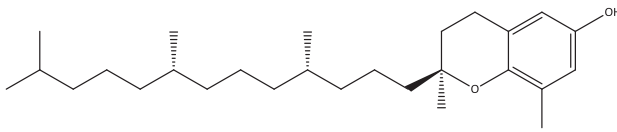

Some specific antioxidants, such as sulphites, glucose oxidase or ascorbyl palmitate, act as oxygen scavengers, operating essentially as reducing agents. In addition, chelating agents might also prevent lipid oxidation by binding specific catalysts (e.g., iron or copper). Their action may occur by either precipitating metal elements or by occupying all their coordination sites. The most well-known examples of these agents include polyphosphatases and ethylene diaminetetraacetic acid (EDTA, which is classified as E385) (Makahleh et al., 2015; Thorat et al., 2013).

On the other hand, secondary antioxidants act by breaking down hydroperoxides formed during lipid oxidation, ending up by forming stable products. Thiodipropionic acid (E388) and dilauryl thiodipropionate (E389) are among the most used secondary antioxidants (Berdahl et al., 2010).

The antioxidant activity is also dependent on structural variations within each compound; for instance, among the two isomers of BHA (3-*tert*-butyl-4-methoxy phenol and 2-*tert*-butyl-4-methoxy phenol), 2-*tert*-butyl-4-methoxy phenol is generally considered to be a better antioxidant.

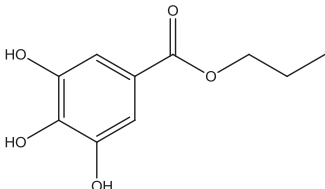

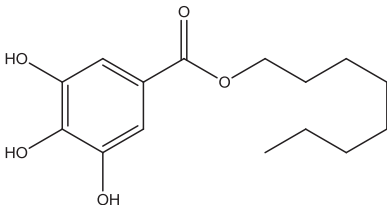

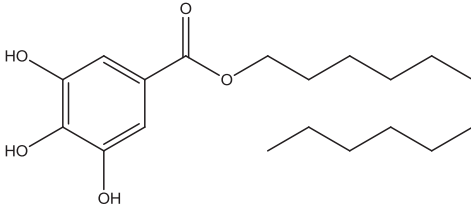

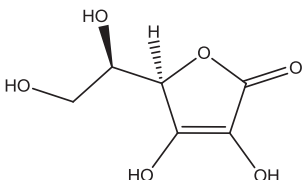

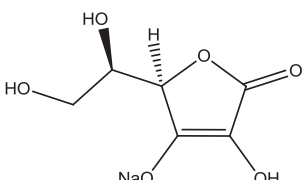

**Table 1** Main antioxidant compounds employed in food industry

Compound name	Molecular structure	Molecular formula	E number	CAS number
Ascorbic acid		$C_6H_8O_6$	E300	50-81-7

## Butylated Hydroxyanisole

BHA (like BHT) is a hindered phenol with di-*tert*-butyl groups in the phenolic ring, representing an extremely effective primary antioxidant (Reische et al., 2008). Owing to its high fat-solubility, BHA is extensively used in bulk oils as well as oil-in-water emulsions. Some of its main applications include the preservation of soybean and palm oil in cereal and confectionery products (nevertheless, TBHQ is more effective in vegetable oils than BHA). Likewise, it is widely employed in baking products, owing to its thermal stability and mild alkaline conditions. However, it is not equally suitable to be applied in frying due to its volatility (Yehye et al., 2015). Furthermore, BHA might act as a co-antioxidant (CoAH) by regenerating other antioxidants such as BHT or  $\alpha$ -tocopherol (De Guzman et al., 2009).

From a metabolic point of view, BHA is rapidly absorbed from the gastrointestinal tract, metabolized and excreted mainly in urine and/or feces. The major metabolites of BHA are glucuronides, sulphates and free phenols (including TBHQ) in proportions that vary from species to species. BHA and its metabolite TBHQ were reported as inducing chromosomal aberrations *in vitro*, but this clastogenic activity was recognized as being an indirect effect resulting from the formation of reactive oxygen species via pro-oxidant chemistry (EFSA, 2011).

In terms of toxicity, BHA present low acute toxicity (with LD<sub>50</sub> in mouse and rat higher than 2000 mg/kg bw/day), having also been reported as having no potential to induce point mutations or to interact with or damage DNA, as reported by different genotoxicity studies. However, after a large number of long-term toxicity and carcinogenicity studies, BHA was demonstrated to induce proliferative changes in the forestomach, including epithelial hyperplasia, papilloma and carcinomas. Nevertheless, and since humans don't have a forestomach, the forestomach hyperplasia in rodents is hardly considered relevant for human risk assessment (EFSA, 2011).

From a legal standpoint, an European Food Safety Authority (EFSA) Panel on Food Additives and Nutrient Sources added to Food (ANS) re-evaluated recently the safety of BHA (E320). Based on a no-observed-adverse-effect level (NOAEL) of 100 mg/kg bw/day for growth retardation, increased mortality and behavioral effects in rat pups at higher dose levels, and using an uncertainty factor of 100, the Panel established an acceptable daily intake (ADI) of 1.0 mg/kg bw/day. This NOAEL also covers the lower confidence limit of the benchmark dose resulting in a 10% extra cancer incidence (BMDL<sub>10</sub>) values for forestomach hyperplasia observed in rat, which was established as 0.5 mg/kg bw/day, based on proliferative changes in the rat forestomach. The Panel also concluded that, at the current levels of use, refined intake estimates are generally below the ADI of 1.0 mg/kg bw/day and that BHA does not represent a major threat with respect to genotoxicity, as indicated by a large number of long-term toxicity and carcinogenicity studies, demonstrating proliferative changes in the rat forestomach with values of 115 mg/kg bw/day (EFSA, 2011).

In related studies, a NOAEL of 0.125% BHA in the diet (equivalent to a dose of at least 100 mg/kg bw/day) was reported for reproductive and developmental toxicity in rats, while a NOAEL of 400 mg/kg bw/day was calculated for reproductive and teratogenic parameters in rabbits (EFSA, 2011).

## Butylated Hydroxytoluene

This compound is one of the antioxidants with higher use in food industry, especially in low-fat foods, fish products, packaging materials, paraffin, and mineral oils (in all food products in which BHT, BHA or TBHQ are not appropriate, the usual alternative is PG). BHT is a white crystalline solid with properties similar to BHA. Despite being resistant to thermal treatment, it is not as stable as BHA. BHT has been documented in thousands of scientific journals, patents, general reviews and conferences, and has been approved for use in foods and food packaging in low concentrations by FDA since 1954, being also recognized as safe for use in foods (Yehye et al., 2015).

In view of its widespread use as a food preservative, its biochemical properties have been studied extensively, mainly to obtain unequivocal information about its possible toxicity. Among other relevant data, it has been reported that large doses of BHT produce centrilobular necrosis, increased serum transaminase activities, hemorrhage in the liver, increased mitotic activity of hepatocytes in rats and cats, potentially promoting hepatocarcinogenesis (Yehye et al., 2015).

However, and despite having been described as a potential liver carcinogen in rat, there are no significant evidences indicating hepatocarcinogenic potential for BHT in either rats or mice. In addition, BHT showed capacity to inhibit chemical carcinogenesis in various organs when fed before or concurrently with specific carcinogens, being also a potent inhibitor of lipid enveloped viruses (Yehye et al., 2015).

Similarly to BHA, BHT was recently re-evaluated by an EFSA ANS Panel. Based on previously established ADI values of 0–0.05 mg/kg bw/day, and considering a NOAEL of 25 mg/kg bw/day and a 100-fold safety margin, the Panel derived an ADI of 0.25 mg/kg bw/day for BHT based on thyroid, reproduction and hematological effects in the rat (EFSA, 2012).

In addition, the established NOAEL (25 mg/kg bw/day) is much lower than 247 mg/kg bw/day, the BMDL<sub>10</sub> derived from data for the incidence of hepatocellular carcinomas in male rats (also observed in long term studies with BHT). Likewise, the exposure of adults to BHT is unlikely to exceed the recently established derived ADI, either at the mean or the 95th percentile. Even using a worst-case scenario of combined exposure to BHT, the estimated dose for adults would be 0.01–0.03 mg/kg bw/day, on average, and 0.03–0.17 mg/kg bw/day at the 95th percentile. However, regarding the exposure of children to BHT (mainly as a food additive), and despite it is also unlikely that the ADI is exceeded at the mean (considering an estimated potential average exposure in the

range of 0.01–0.09 mg/kg bw/day), it surpasses the 95th percentile in some European countries, like Finland or The Netherlands, as an exposure in the range of 0.05–0.30 mg/kg bw/day was estimated at the 95th percentile (EFSA, 2012).

Regarding the acute toxicity, BHT presents relatively low levels, with oral LD<sub>50</sub> values of 1700–1970 mg BHT/kg bw in rats, 2100–3200 mg BHT/kg bw in rabbits, 10700 mg BHT/kg bw in guinea pigs, 940–2100 mg BHT/kg bw in cats, and 2000 mg BHT/kg bw in mice. In general, BHT is not of concern with respect to genotoxicity and any carcinogenicity should be thresholded. In fact, the genotoxicity studies on BHT indicate no potential to induce point mutations, chromosomal aberrations, nor damage or interact with DNA (EFSA, 2012).

Considering the high dissemination of BHT as a food additive, different studies pertaining its absorption, distribution, metabolism and excretion have been performed in mice, rats, rabbits, chickens, monkeys and humans. Overall, the obtained results showed that BHT is rapidly absorbed from the gastrointestinal tract and further metabolized in a complex way, which might be different among species. It is not known, for example, if human organism forms the quinone methides that were found in rats and mice as BHT metabolites (EFSA, 2012).

These conclusions are certainly relevant to maintain BHT as one of the most popular antioxidants, being also used in combination with other antioxidants such as BHA, propyl gallate, and citric acid for the stabilization of oils and high-fat foods (Yehye et al., 2015).

## Conclusions and Future Tendencies

The advantages of using antioxidant compounds in food products are obvious, and their employment seems to be indispensable, but the total absence of potential toxic effect is yet to be validated, thereby requiring careful studies on their direct and side-effects.

Despite the necessity to adequate each antioxidant to its specific use, it might be generally stated that the antioxidants to be used in foods should be economic (or at least representing a minor impact on the product's cost), non-toxic, efficient at low concentrations, easy to incorporate, able to maintain their integrity throughout food processing, stable at least as long as the product shelf-life and capable of exert their action without causing undesirable changes in the organoleptic properties of food. However, there is no antioxidant compound that fulfil all the previous criteria. Even BHA and BHT, which are the most used antioxidants and recognized as being highly effective, present some limitations. For instance, both compounds have a slightly unpleasant odor, especially under high processing temperatures.

Therefore, there is an intensive search for completely effective compounds, aiming to combine multiple functions in a synergistic way. Considering all presented data, it seems quite reasonable to expect that the field of antioxidant research will remain rather active in next years.

# Synthetic Food Colors

Maria G Corradini, University of Massachusetts Amherst, Amherst, MA, USA

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Color plays an essential factor in a food's acceptability and palatability. Color additives are routinely added to foods to enhance their appearance, compensate for natural variations in raw materials or color loss during processing, and assign color/flavor identity to otherwise colorless food products. Since the discovery of the first synthetic color, a purple aniline derivative dubbed "mauveine" or "mauve", by William Henry Perkin in 1856, the food industry has historically favored synthetic food colors over natural colorants. This preference is based on synthetic colors' low production cost, vibrancy, no or limited contribution to flavor and/or aroma in the finished product, high efficacy at low concentrations, and superior chemical stability to processing, distribution, and storage conditions such as heat, low pH, light or oxygen. Despite the technical advantages that synthetic colors provide, concerns about adverse health effects, consumer growing demands for natural alternatives, and misuse and adulteration have driven the strict regulation of their use in foods and their on-going replacement or elimination from the food supply.

## Main Synthetic Food Colors in Foods

The term "synthetic" or "artificial color" is applied to coloring agents that are not nature-identical and have been obtained by chemical synthesis. Chemical modified natural colors, e.g., copper chlorophyllin, or natural colors homologues obtained using chemical synthesis, e.g., nature-identical beta carotenes, are not typically included within the synthetic colors category. The most commonly used synthetic food colorants are mono- and di-azo dyes. More than half of the synthetic dyes approved for food use in the United States (US) and the European Union (EU) belong to this category. Azo food dyes are obtained from the diazotization of an aromatic primary amine and the subsequent coupling of the diazonium salt with a phenol or an aromatic amine. They contain at least one functional azo group with the structure  $R-N=N-R'$  where the pendant R groups are bulky aromatic rings functionalized with large charged groups, which contribute to their coloration and solubility (See Fig. 1). Triarylmethane derivatives, xanthene dyes, quinophthalones and indigoid compounds constitute the rest of the synthetic food colorants approved for foods. Erythrosine, the only xanthene dye accepted for use in food in the US and the EU, and triarylmethane dyes are prepared by condensing a substituted phenol, e.g., resorcinol in the case of erythrosine, and phthalic anhydride. To obtain erythrosine, a halogenation reaction follows. Similarly, Quinoline Yellow, the principal quinophthalone dye used in food products, is synthesized from phthalic anhydride and quinaldine. In the case of the indigoid compounds, the Heumann-Pfleger process is the most important synthetic pathway to obtain indigotine from N-phenylglycine and sodium amide. The extensive  $\pi$ -conjugated structures that are obtained from these procedures confers all these compounds with a vivid coloration as well as photophysical properties that allow for their detection. Currently, 9 and 15 artificial colors belonging to these groups are approved for use in the US and the EU, respectively. Table 1 summarizes their chemical characteristics, common designations, stability, and applications.

The selection of these colors for specific food applications relies on their compatibility and solubility within the target food product. Approved azo dyes are typically commercialized as their sodium salts and are hydrosoluble, except for Citrus Red 2 that is liposoluble and Litholrubine, which disperses in oils. The permitted triarylmethane, xanthene, and indigoid derived compounds are also water soluble. The complexation of these hydrosoluble dyes with an inorganic substrate, e.g., a metal cation such as aluminum, produces lakes with enhanced light and chemical stability, as well as dispersibility in oils. Quinoline Yellow is soluble in water and slightly soluble in organic solvents.

## Uses and Functionality

Among the azo food dyes, Allura red AC, Azorubine, Brilliant Blue FCF, Sunset Yellow FCF and Tartrazine are the most commonly found in edible goods. Due to restricted functionality and/or regulatory requirements, the use of other azo dyes such as Amaranth, Citrus Red 2, Litholrubine BK, Ponceau 4R, and Orange B have been limited to specific applications (see Table 1). For example, Citrus Red 2 is only applied to enhance the external appearance of fresh oranges. Among the triarylmethane dyes, Fast Green FCF is the least used, since similar hues can be obtained using a combination of other colors. The extensive use of the only xanthene compound approved in the US and the EU, erythrosine, has progressively decreased in recent years due to its lower stability in comparison to other available red synthetic food dyes and health concerns associated with its use.

While several natural color additives, such as riboflavin and anthocyanins, contribute the food with desirable functional properties, e.g., antioxidant and bacteriostatic activity, or potential health benefits, synthetic colors do not exhibit any nutritional value or health attribute. Most of them are poorly absorbed in the intestine, and their consumption has been potentially associated with adverse health effects, such as allergenicity and behavioral disorders in children. Additionally, azo and triarylmethane color compounds can electrostatically interact with proteins, which might reduce protein functionality in foods and in the body.

**Figure 1** Molecular Structures of Selected Synthetic Dyes.

Despite their lack of nutritional value, these colors are gaining popularity as stains, markers or intrinsic sensors. Their comparative innocuity makes them adequate replacements of toxic dyes in diagnostic and analytical tools, such as Fast Green FCF as a safe stain for tumor detection, azo dyes as low-cost tracing dyes for the analysis of nucleic acids and proteins, and Allura Red AC as an effective scatterer in luminescence spectroscopy. Additionally, the environmental sensitivity of the photophysical properties, i.e., luminescence intensity, quantum yield and lifetime, of approved food azo dyes and triarylmethane compounds have been recently reported, and their potential application as intrinsic sensors of food quality attributes, e.g., micro and bulk viscosity of liquid and semi-solid foods has been described. Similarly, the use of xanthene dyes as sensors of molecular mobility, dynamic heterogeneity, and air permeability has been extensively explored and used in food model systems to evaluate and characterize them.

### Analysis of Synthetic Colors in Foods

Several analytical methods have been developed to determine the purity of synthetic colors and detect their presence in food matrices. The extraction of the dyes from the food matrices is crucial to their appropriate assessment, which can be accomplished using liquid-liquid, solid-phase, ultrasound-assisted and cloud-point extraction methods, for example. Spectrophotometry has been traditionally used to determine the dye content and the authenticity of food additives based in their characteristic absorbance and extinction coefficients, for example, absorbances at 526, 540, and 625 nm are used for erythrosine, Allura Red AC, and Fast

**Table 1** Commons designations, color provided, stability, and main uses of synthetic food colors

Type of compound	Common designations & Molecular formula	Color provided	Stability	Main applications
Azo dyes	Allura Red AC FD&C Red # 40, E129 $C_{18}H_{14}N_2Na_2O_8S_2$	Orange/Red	Highly stable to light, heat, acid. Degraded by reducing and oxidizing agents	Baked goods, beverages, candies, desserts, extruded foods, salad dressings
	Amaranth FD&C Red # 2, E123 $C_{20}H_{11}N_2Na_3O_{10}S$	Bluish Red	Highly stable to light, heat, and acid. Ascorbic acid, $SO_2$ , and alkali reduce its stability	Beverages, confectionary products, preserves
	Azorubine Carmoisine, E 122 $C_{20}H_{12}N_2Na_2O_7S_2$	Magenta Red	Highly stable to light, heat, and acid. Degraded by reducing agents	Chocolates, confectionary products, salad dressings, beverages
	Brilliant Black BN Food Black 1, E151 $C_{28}H_{17}N_5Na_4O_{14}S_4$	Purple/Deep Blue	Medium stability to light. Low stability to heat. Ascorbic acid and $SO_2$ reduce its stability	Desserts, dairy and confectionary products, fish roe
	Brown HT Food Brown 3, E155 $C_{27}H_{20}N_4O_9S_2$	Reddish Brown	Highly stable to light and heat. Stability reduced by oxygen and $SO_2$	Confectionery and baked goods
	Citrus Red 2 E121 $C_{18}H_{16}N_2O_3$	Orange/Red	Highly stable to heat.	In the US, limited to fresh orange surfaces (<2 ppm)
	Litholrubine BK D&C Red # 6, E180 $C_{18}H_{12}N_2Na_2O_6S$	Orange/Red	Highly stable to light and heat.	In the EU, limited to rind of hard cheeses
	Orange B C.I. Acid Red 137 $C_{22}H_{16}N_4Na_2O_9S_2$	Orange/Red	–	In the US, limited to hot dogs and sausages casings (<150 ppm)
	Ponceau 4R C.I. Acid Red 18, E124 $C_{20}H_{11}N_2Na_3O_{10}S_3$	Bright Red	Medium stability to light and acid. Ascorbic acid and $SO_2$ reduce its stability	Confectionery products, beverages, canned fruits, jellies, soups
	Sunset Yellow FCF FD&C Yellow #6, E110 $C_{16}H_{10}N_2Na_2O_7S_2$	Yellow/Orange	Highly stable to light, heat, and acid. Ascorbic acid and $SO_2$ reduce its stability	Baked goods, beverages, desserts, extruded foods, confectionary products
	Tartrazine FD&C Yellow # 5, E102 $C_{16}H_9N_4Na_3O_9S_2$	Greenish Yellow	Highly stable to light, heat, and acid. Ascorbic acid and $SO_2$ reduce its stability	Baked goods, candy, desserts, jellies, pickles, sauces, ice creams
Xanthene dye	Erythrosine, FD&C Red # 3, E127 $C_{20}H_{6}I_4Na_2O_5H_2O$	Bright Pink/Red	Medium stability to heat. Susceptible to photodegradation. Precipitates at pH < 4.5	Canned foods, cocktail cherries, dairy products, desserts
Triaryl methane derivatives	Brilliant Blue FCF FD&C Blue # 1, E133 $C_{37}H_{34}N_2Na_2O_9S_3$	Blue Greenish blue (pH < 3)	Medium stability to heat, light, and acid. Sensitive to oxygen	Beverages, candies, dairy products, jellies, condiments, syrups
	Fast Green FCF FD&C Green # 3, E143 $C_{37}H_{34}N_2Na_2O_{10}S_3$	Teal to Blue (low to high pH)	Medium stability to light and acid. Sensitive to oxygen	Beverages, candy, dairy products, puddings
	Green S FD&C Green # 4, E142 $C_{27}H_{25}N_2NaO_7S_2$	Green/Blue	Highly stable to heat and acid. Medium stability to light	Canned vegetables, desserts, sauces
	Patent Blue V Food Blue 5, E131 $C_{27}H_{31}N_2O_7S_2Ca_{1/2}$	Turquoise Blue	Highly stable to light and heat. Acids, ascorbic acid, and $SO_2$ reduce its stability	Beverages, canned products, baked goods, jellies
	Indigotine FD&C Blue # 2, E132 $C_{16}H_8N_2Na_2O_8S_2$	Blue (pH < 11), Yellow (pH > 11)	Low stability to heat and acid. Oxygen, $SO_2$ and ascorbic acid reduce its stability	Baked goods, desserts, candies, confectionary products
Quinophthalone	Quinoline Yellow D&C Yellow # 11, E104 $C_{18}H_9N Na_2O_8S_2$	Greenish Yellow	Medium stability to heat, light, and acid.	Beverages, juices, ice cream

Green FCF, respectively. Currently, the use of chemometric tools has expanded the use of spectrophotometric methods permitting the simultaneous determination of numerous artificial dyes. Due to their sensitivity and reliability, chromatographic techniques, particularly, thin-layer chromatography (TLC), high performance liquid chromatography (HPLC), ion-pair liquid chromatography, and reversed-phase high performance liquid chromatography (RP-HPLC), equipped with adequate detection systems, e.g. diode-

array (DAD), are routinely used to quantify the levels of permitted food colors, verify their authenticity and potential adulteration, and identify the presence of banned food dyes. The utilization of liquid chromatography-tandem mass spectrometry (LC-MS/MS) allows for multiple identification of food dyes with increasing accuracy. Adsorptive voltammetry, differential pulse polarography, and capillary electrophoresis techniques have also been reported as adequate tools to monitor food dyes content and quality. Enzyme-linked immunosorbent assays (ELISA) provide convenience for this kind of tests. ELISA kits are available to detect approved synthetic dyes such as Sunset Yellow FCF and Tartrazine and banned artificial colors such as Sudan I, a frequent adulterant in chili powders, and rhodamine B. Electrochemical methods, for example, detection of Tartrazine with a boron-doped diamond electrode, provide reasonable sensitivity at a low cost. The development of fluorescence-based sensors and surface enhanced Raman spectroscopy (SERS) techniques have received attention due to their high sensitivity, convenience, rapid response, and low cost. It should be noted that the development of in-situ, fast, and economic multi-colorant screening and confirmatory techniques has been identified as a priority by regulatory organisms around the world to ensure compliance with current specifications regarding the application of synthetic food dyes in approved foods, quantity used, purity, and potential adulteration.

## Regulatory Status and Labeling

Although the use of synthetic colors is highly regulated, and their permitted uses and doses are continually being re-evaluated, their status, acceptable daily intake (ADI), applications, and labeling requirements differ significantly among countries. Despite these discrepancies, most regulations list the color additives that are approved and to which extent and form they can be incorporated into foods. The specifications of the Codex Alimentarius or the Joint FAO (Food and Agricultural Organization)/WHO (World Health Organization) Expert Committee on Food Additives (JECFA) are used by most countries to guide their use and set allowable doses in foods.

In the United States, the Food and Drug Administration (FDA) determines their regulatory status. The FDA regulations allow for the classification of food colors into two categories, namely certified and exempt from certification. All permitted synthetic food colors fall within the former categorization, and as such, when produced, they should be assessed for identity and purity prior to their commercialization. All certified food colors, i.e., synthetic colors, should also be listed on the label of the food product and in the case of Tartrazine, since it is considered a potential allergen, it should be declared as such on the label. The safety evaluation of these dyes is based on toxicological data, chemical structure and potential exposure.

In the EU, the European Food Safety Authority (EFSA) is responsible for the evaluation of the safety of synthetic colors and establishes their ADI. It also requires that the synthetic color name or its corresponding additive identification number, i.e., E number, is stated in the label within the ingredient list. Additionally, if any of the six synthetic colors identified as potential causative agents of behavioral problems in children, i.e., Allura Red AC, Azorubine, Ponceau 4R, Quinoline Yellow, Sunset Yellow FCF, and Tartrazine, is present in the food product, its label should include a warning that indicates that adverse effects on activity and attention may arise. Within the EU, the Rapid Alert System for Food and Feed (RASFF) facilitates the exchange of information on risks associated to foods. Regarding food colors, this system issues notifications about the detection of illegal colors, banned or unauthorized use of these components, and failure to declare a food dye in the label in inspected food products. This system also keeps records of the frequency of each infraction and provides an additional level of safety to the consumer. Recently, in the United Kingdom, a voluntary action of the food industry has been instrumental in the removal of these colors from foods and their replacement with natural colors by most major food manufacturers.

The acceptable daily intakes (ADI) for synthetic colors currently authorized in United States (US) and the European Union (EU) are summarized in [Table 2](#).

## Health Concerns

Allergenicity, behavioral problems such as hyperactivity syndrome in children, neurotoxicity, genotoxicity, and carcinogenicity are some of the potential adverse health effects that have been linked to synthetic food colors. Concerns about the safety of these additives from the general public, food additive regulatory organisms, and the food industry currently drive the continuous re-evaluation of the potential risks and the exposure to colorants for specific populations such as children.

Genotoxic and carcinogenic effects have not been consistently reported for approved food synthetic dyes, however the similarity of their metabolic products to potentially carcinogenic or genotoxic compounds has fueled extensive, although for some dyes inconclusive, evaluations. The *in vivo* reduction of azo-dyes by the intestinal flora results in the formation of sulfonated aromatic amines such as 1-amino-2-naphthol-6- sulfonic acid and sulfanilic acid. The genotoxicity and carcinogenicity of the unsulfonated analogues of these compounds have been demonstrated and consequently has caused severe scrutiny of the potential effects of the ingestion of food dyes that can be metabolized into aromatic amines. A recent study on the genotoxicity of Allura Red AC and their metabolic products, i.e., sulfonated naphthylamines, was required in 2016 by the Joint FAO/WHO Expert Committee on Food Additives (JECFA). The lack of genotoxicity of the sulfonates metabolites of Allura Red AC was corroborated, and it was proposed that due to the molecular structural resemblance of Allura Red AC to other permitted azo dyes, this conclusion could be extended to the whole category. Similarly, no genotoxic activity was found for Sunset Yellow in *in vivo* and *in vitro* studies. However, in the case of Tartrazine, its metabolic products, i.e., sulfanilic acid and aminopyrazolone, have been linked to the formation of reactive oxygen species (ROS) which can affect renal and hepatic tissues.

**Table 2** Acceptable daily intake (ADI)<sup>a</sup> and regulatory status of commonly used synthetic food colors in the United States (US) and The European Union (EU)

Synthetic Color	Acceptable daily intake (mg kg bw <sup>-1</sup> per day) <sup>a</sup>	Regulatory status	
		US	EU
Allura Red AC	0–7	Approved	Approved
Amaranth	0–0.5	Not Approved	Approved
Azorubine	0–4	Not Approved	Approved
Brilliant Black BN	0–1	Not Approved	Approved
Brilliant Blue FCF	0–6	Approved	Approved
Brown HT	0–1.5	Not Approved	Approved
Citrus Red	Not to be used	Approved- Limited applications	Not Approved
Erythrosine	0–0.1, 0–2.5 (US)	Approved	Approved
Fast Green FCF	0–25, 0–2.5 (US)	Approved	Not Approved
Green S	No ADI allocated, 0–5 (EU)	Not Approved	Approved
Indigotine	0–5, 0–2.5 (US)	Approved	Approved
Litholrubine BK	No ADI allocated, 0–1.5 (EU)	Not Approved	Approved - Limited Applications
Orange B	–	Approved - Limited Applications	Not Approved
Patent Blue V	No ADI allocated, 0–15 (EU)	Not Approved	Approved
Ponceau 4R	0–4	Not Approved	Approved
Quinoline Yellow	0–3	Not Approved	Approved
Sunset Yellow FCF	0–4, 0–3.75 (US)	Approved	Approved
Tartrazine	0–10, 0–5 (US), 0–7.5 (EU)	Approved	Approved

<sup>a</sup>Values reported as established by the Joint FAO (Food and Agricultural Organization)/WHO (World Health Organization) Expert Committee on Food Additives (JEFCA, <http://apps.who.int/food-additives-contaminants-jecfa-database/search.aspx?fc=31>). Alternative values used by US or EU are specified between brackets when needed.

Compiled from Letho et al. (2017), Feketea and Tsabouri (2017), US FDA ([www.fda.gov](http://www.fda.gov)) and EFSA ([www.efsa.europa.eu](http://www.efsa.europa.eu))

Allergic and pseudo-allergic adverse reactions to synthetic dyes are non-immunoglobulin E (non-IgE) mediated. These reactions are rare in the general population; however, they are a frequent cause of mild and moderate clinical manifestations, e.g., urticaria, facial flushing, itching, and angioedema, in hypersensitive individuals. Tartrazine has been consistently correlated with intolerance and allergic reactions in atopic populations and Patent Blue has been documented as a causative agent of allergies in adults.

Since the 1970s, the potential adverse effects of synthetic food dyes and behavioral disorders in children, i.e., hyperactivity, sleep disorders, irritability, and learning disabilities, have been studied. In 2007, the Southampton study conducted by McCann and others revived the attention to this topic. Links between a significant reduction in attention deficit and hyperactivity disorder (ADHD) symptoms due to the withdrawal of synthetic dyes from the diet have been reported and required further investigation. Both the EFSA and the FDA consider that the present evidence does not conclusively sustain the relation between consumption of food dyes and behavioral disorders. However, the EFSA has modified its labeling requirements to include a warning on potential effects of synthetic dye consumption on children behavior (see section **Regulatory Status and Labeling**). The FDA did not revise its labeling requirements but requested an exposure assessment of the population to the seven permitted synthetic dyes in the US. Estimations of additive intakes suggest that the average intake for all permitted synthetic food colors are below their corresponding ADI, however, for high consumers of artificially colored products, the estimations indicate that the intake for Tartrazine, Sunset Yellow, and Erythrosine might exceed their corresponding acceptable limits.

## Concluding Remarks

The replacement of synthetic colors in food products by natural alternatives, guided by consumer demands for cleaner labels and the public perception that natural compounds are safer than artificial ones, will continue. Attaining the same attributes conferred by synthetic colors to foods using natural colors is challenging and slows down this inevitable process. This trend will shift the use of synthetic colors from being the most prevalent in foods to the least desirable in the future.

## Glossary

**Bound Water** Bound or vicinal water interacts very closely with ions, solutes, proteins and carbohydrates and does not significantly contribute to the water activity.

**Capillary Water** Capillary water is more mobile than bound water and aids in deleterious reactions in foods supporting microbial growth and aiding in oxidative and enzymatic pathways.

**Bulk Water** Free or bulk water has no hindrance of molecular mobility and is readily available to partake in deleterious microbial and enzymatic reactions.

**Chaotropes** Chaotropes are solutes that interfere with the tetrahedral hydrogen bonding networks of water.

**Kosmotropes** Kosmotropes are solutes that increase the tetrahedral hydrogen bonding networks of Water–Water interactions.

**Glass transitions** A glass is a non-equilibrium, metastable, amorphous solid with an apparent viscosity greater than  $10^{12}$  Pas.

## Introduction to Water

The bent configuration and dipole moment causes water molecules to attract each other due to the presence of the partial charges on the oxygen and hydrogen atoms leading to intermolecular hydrogen bonding (average bond energies between 5 and 40 kJ/mol). The interaction between a positively charged hydrogen atom on one molecule of water with a negatively charged atom on a different water molecule neutralizes the charges and is the basis of hydrogen bond between two molecules of water (Pauling, 1945).

Water exists in numerous states, if water is present as an isotope it can vary the interactions between water molecules. For example, if an isotope of oxygen (i.e.,  $^{17}\text{O}$  or  $^{18}\text{O}$ ) is present than the molecule becomes more electronegative and the hydrogen bonding is stronger. If deuterated water ( $^2\text{H}$ ) is present the hydrogen bonding is weaker because more positive protons are present in the hydrogen atom to attract the electrons, reducing the dipole moment. When two water molecules hydrogen bond, one of the water molecules partially donates a hydrogen atom to the other. For the molecule which donates its hydrogen, the lone pair of electrons, on the oxygen atom, becomes increasingly electronegative. This increased electronegativity amplifies the strength of the dipole of the water molecule which is donating its hydrogen, causing a cooperative interaction between the next water molecule which hydrogen bonds (i.e., a stronger hydrogen bond) with the next incoming water molecule (Bartha et al., 2003). The other water molecule which accepts the hydrogen atom attains a greater positive charge, which results in the lone pair of electron being less electronegative causing the next water molecule to interact less strongly with this water molecule. This type of hydrogen bond is termed anti-cooperative hydrogen bonding (Bartha et al., 2003). Hence, in bulk water, there is a distribution in hydrogen bond distance, strength and angle due to the complex interactions between molecules.

## Ionization of Water

Typically, water exists with a molecular formula,  $\text{H}_2\text{O}$ , however it is capable of endothermically ionizing to form  $\text{OH}^-$  and  $\text{H}_3\text{O}^+$ . The generation of ions is due to an excited O–H stretching overtone vibration (Bakker and Nienhuys, 2002). Once these ions are generated, typically they are unstable and recombine to form  $\text{H}_2\text{O}$  in a few femtoseconds. Hence, water reaches equilibrium with an autoionization constant  $K_w$ :

$$K_w = [\text{OH}^-][\text{H}_3\text{O}^+]$$

$K_w$  represents an equilibrium constant between the formation of water and hydroxyl ions ( $\text{OH}^-$ ) and hydronium ions ( $\text{H}_3\text{O}^+$  which is often simplified to  $\text{H}^+$ ). Any changes to the system, including addition of acid products and changes in temperature, adjusts the balance between water and the hydroxyl and hydronium ions according to Le Chatelier's principle. It is possible that the  $\text{OH}^-$  and  $\text{H}^+$  interact independently with other water molecules and form stable hydrates. This has effects on the native structure of water because they are capable of forming hydrogen-ionic bonds which are stronger than typical hydrogen–hydrogen bonds which increase the order of liquid water. The ability of water to dissociate is a function of the temperature (Table 1).

Although we often assume that the pH of pure water is always 7, this is not true because the autoionization constant is a function of temperature. This does not mean that the solution is basic at low temperatures and acidic at elevated temperatures. For a system

**Table 1** Autoionization constants for water at different temperatures

Temperature (K)	$K_w$	pH
273	$0.11 \times 10^{-14}$	7.47
283	$0.68 \times 10^{-14}$	7.27
288	$1.00 \times 10^{-14}$	7.00
313	$2.92 \times 10^{-14}$	6.77
373	$51.3 \times 10^{-14}$	6.14

to be acidic, there has to be an excess of hydronium ions compared to hydroxyl ions. In pure water, these are always equal. Commonly, we refer to basic systems as having  $\text{pH} > 7$  and acidic systems having  $\text{pH} < 7$ . This is only true at 25 °C. Hence, if the system is at 100 °C, an acidic solution would have  $\text{pH} < 6.14$ . If pure water is at 100 °C with a  $\text{pH} = 7$ , it would be considered slightly basic. Using  $\text{pH} = 7$  as the distinction between acidic and basic properties for pure water only applies when water is at 25 °C.

## Physical Properties of Water

It is the bent configuration and dipole moment of water that gives rise to the numerous very interesting and unique properties of water. For example, water takes up a smaller volume and is lighter than other atmospheric molecules including  $\text{O}_2$ ,  $\text{N}_2$ , Ar,  $\text{CO}_2$ . If molecules are symmetrical (i.e., group IV hydrides  $\text{CH}_4$ ,  $\text{SiH}_4$ ,  $\text{GeH}_4$ ,  $\text{SnH}_4$ ), they are nonpolar and rely on van der Waals forces for adhesion forces. This results in significantly lower melting and boiling points. The group VI hydrides (i.e.,  $\text{H}_2\text{O}$ ,  $\text{H}_2\text{S}$ ,  $\text{H}_2\text{Se}$ , and  $\text{H}_2\text{Te}$ ) lack symmetry due to the two lone electron pairs in their valence shells and each should be capable of hydrogen bonding. Group VI hydrides demonstrate some interesting properties, if the boiling point was a function of only London dispersion forces,  $\text{H}_2\text{Te}$  would have the highest boiling point when in fact it has the lowest boiling point.  $\text{H}_2\text{Te}$  boils at  $-2^\circ\text{C}$ ,  $\text{H}_2\text{Se}$  at  $-42^\circ\text{C}$ ,  $\text{H}_2\text{S}$  at  $-60^\circ\text{C}$  and  $\text{H}_2\text{O}$  would be predicted to boil below  $-60^\circ\text{C}$ . However, the unusual ability of  $\text{H}_2\text{O}$  to hydrogen bond causes water to boil at 100 °C.

Changing the temperature modifies the dipole moment of the molecule which results in changes to the length of the hydrogen bond which is directly correlated with the strength of the hydrogen bond (Dougherty, 1998). An increase in hydrogen bonding leads to increased cohesion, dielectric constant, specific heat, and viscosity; while a decrease in hydrogen bonding leads to a decrease in adhesion forces, density, diffusion coefficient, and thermal conductivity (Table 2). As the temperature is reduced to approximately 4 °C there is a maximum in hydrogen bonding strength resulting in the highest possible density for water. As a food product is frozen, water turns to ice at the surface and then continues to freeze inwards. As the layer of ice builds at the surface of the material it begins to freeze quicker, this is due to an increase in the thermal diffusivity and thermal conductivity. However, as a food product is thawed, the ice turns to water at the surface which then acts as an insulator resulting in significantly longer thawing than freezing times.

## Types of Water

Water is typically subdivided into three categories which include bound, capillary and bulk water. Each of these types of water behaves and influences the product very differently. Typically bound or vicinal water interacts very closely with ions, solutes, proteins and carbohydrates. This water is required for proteins to fold correctly and is tightly bound to the macromolecule or solute. When drying foods or when measuring water content, this water is not removed or accounted for because it is bound so tightly via hydrogen bonding or dipole–dipole interactions with ions that it does not behave as free water. Bound water is unable to partake in chemical reactions and no added molecular mobility is attained from the presences of this water.

Capillary water is far more mobile than bound water and aids in deleterious reactions in foods supporting microbial growth and aiding in oxidative and enzymatic pathways. Although this water does have limited molecular mobility due to the confinement induced by the capillary walls, there is sufficient mobility to support diffusion of waste and nutrients, respiratory gases and enzymes.

**Table 2** Physical properties of water

Temperature (°C)	Density ( $\text{kg/m}^3$ )	Thermal conductivity ( $\text{W/m}^2\text{C}$ )	Thermal diffusivity ( $\times 10^{-6} \text{ m}^2/\text{s}$ )	Absolute viscosity ( $\times 10^{-6} \text{ Pas}$ )
20	998.2	0.597	0.143	993.414
5	1000	0.568	0.135	1534.74
0 (water)	999.9	0.558	0.131	1793.63
0 (ice)	916.2	2.22	11.82	N/A
−7	917.8	2.27	12.23	N/A
−18	919.4	2.32	12.91	N/A

Adapted from Dickerson (1969) and Raznjevic (1976).

During drying, capillary water may be removed via vigorous processing and occurs during the falling rate period which is controlled by the rate of removal of moisture from the interior and is often referred to as being “mass-transfer limited” (Onwude et al., 2016).

Finally, free or bulk water has no hindrance of molecular mobility and is readily available to partake in deleterious microbial and enzymatic reactions. This water is very volatile and is rapidly removed during processing and is removed during the constant rate period.

## Water – Ion Interactions

Addition of small amount of ions (i.e., salts) to water affects the interactions between water molecules. Since the strength of hydrogen – ionic bonds is stronger than hydrogen – hydrogen bonds, water will associate with ions before they interact with another water molecule. The native tetrahedral structure of water is disrupted by the addition of salt. When NaCl is hydrated water molecules interact such that the slight positive charge on hydrogen atom in water non-covalently interacts with the negatively charged chlorine and the negatively charged oxygen atom in water interacts with the sodium. Regardless of the ion added the native structure of water is always altered.

There are two possible outcomes when different salts with different polarizing powers are added to water. The polarizing potential is a function of the charge versus the molecular radius. Small and/or highly charged ions (i.e.,  $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{H}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , etc.) have a high charge density (strong electric field for a small atomic volume) and are therefore “structure formers” or kosmotropes. The high charge density of these ions causes water molecules to become highly structured upon solvation of the ion, creating multi-layers of up to six mono-layers of water. Structure formers modify the structure of water such that the viscosity of the ion solution is greater than pure water. On the other hand, if low charge density ions (i.e., an ion with a low charge and large atomic volume (i.e.,  $\text{K}^+$ ,  $\text{NH}_4^+$ ,  $\text{Cl}^-$ ,  $\text{I}^-$ , etc.) are added to pure water they tend to break, or disrupt the structure of water, and are thus called “structure breakers” or chaotropes. The disruption the water–water interactions is not compensated by the new interactions with the ion in solution such that a solution has a lower resulting compared to pure water.

## Water – Solute Interactions

Addition of non-ionic kosmotropes solutes can structure water (i.e., trehalose, maltose, sucrose, glucose, galactose, glycine, proline and numerous zwitterions) in a similar manner as observed with the addition of ions while other, non-ionic chaotropes solutes (i.e., urea), can disrupt the structure of pure water. Generally, non-ionic kosmotropes are very soluble and are well hydrated by water. The hydration of these compounds depends on the ability of water to interact with the hydrogen bonding groups of the solute. These molecules efficiently hydrogen bond to water and have very little tendency to aggregate or hydrogen bond internally. Compounds such as sugars can replace an all-*gauche* chair-form hexamer from an icosahedral water cluster. The counter clockwise equatorial arrangement of hydroxyl groups is likely due to the lone oxygen pair repulsion rather than the very weak hydrogen bonds. Such weak interactions are easily overcome by hydration forces (Ramadugu et al., 2009). Hence the complimentary structure of the chair configuration of sugars does not disrupt the native structure of water.

The ability for sugars to hydrate in water is dependent on the equatorial/axial configuration of the hydroxyl groups on the sugar which promotes intramolecular interactions. When sugars form intramolecular bonds, it increases the hydrophobic nature of the carbohydrate and decreases the ability to be hydrated (Dashnau et al., 2005). Trehalose, has a larger hydrated volume than other sugars and is often excluded from the hydration shell of macromolecules decreasing the solvation of proteins and hence stabilizing their ternary structure (Sola-Penna and Meyer-Fernandes, 1998). This is crucial in enzymatic reactions in aqueous medium to preserve the native structure of a protein.

Chaotropes interfere with the tetrahedral hydrogen bonding networks of water. Therefore, water is more likely to interact with proteins and other macromolecules which often induces denaturation of the ternary structure. These solutes reduce the order of water, leading to weaker hydrogen bonds, as well as reductions in viscosity and surface tension. Urea, at high concentrations, disrupt the structure of water because it has a tendency to hydrogen bond with other urea molecules forming long linear chains, up to 60 molecules long. The urea–urea interactions limit the amount of water capable of interacting with water and it is observed that only one molecule of water can hydrogen bond two times to one urea molecule (Stumpe and Grubmüller, 2007). The urea–urea interaction limits the amount of water–urea interactions leading to a disrupted structure of water.

## Water – Hydrophobic Structure Interactions

Hydrophobic compounds (i.e., hydrocarbons, fats and oils) are molecule which “hate water” and interact via van der Waals interactions. When hydrophobic compounds mix with water generally they aggregate to minimize their surface contact with the water. When apolar compounds are added water, water restructures itself forming clathrates to minimize its interactions with the apolar compounds. Clathrates may be thought of as an ice-like inclusion of highly ordered water entrapping the apolar compounds.

## Water Activity

It is often believed that the water content of foods is directly related to food perishability. Foods with the exact same amounts of water may perish very different. Hence, it is the free water which determines the shelf-life of foods. The term water activity ( $a_w$ ) refers to the amount of water, in equilibrium, available to hydrate material, or the water which is not bound by solutes or macromolecules such as proteins and carbohydrates.  $a_w$  is a measure of the energy status of water in the system. The addition of solutes and macromolecules to water results in a decrease in the entropy of the solution relative to pure water, resulting in a decrease in the vapour pressure. Materials have an  $a_w$  between 1 and 0 (100% and 0% relative humidity) indicating pure water and no water; respectively.  $a_w$  effects microbial growth, deleterious reactions, oxidations, and vitamin and color degradation. The addition of solutes and macromolecules effect  $a_w$  via colligative effects. When salts, sugars, and other soluble components are added to water they interact via non covalent interactions (i.e., dipole–dipole, ionic and hydrogen bonds). In complex systems, such as bread, water exists in capillaries which affects the vapour pressure differently than the addition of solutes because in bread water is affected by surface confinement within the capillaries. As well, macromolecules, even though they are not soluble, are able to interact via non-covalent interactions. The addition of solutes, macromolecules and interfaces all interact with water thereby reducing the entropy of the water and lowering the  $a_w$ .

The concept of water activity is derived from laws of thermodynamics. In the equilibrium state, the chemical potential,  $\mu$ , is the same everywhere in the entire system, the temperature must be defined and pure water must have a water activity equal to 1:

$$\mu = \mu_o + RT \ln \frac{f}{f_o}$$

where  $\mu$  (J/mol) is the chemical potential of the system,  $\mu_o$  is the chemical potential of the pure material at temperature,  $T$  (K),  $R$  is the ideal gas coefficient (J/mol K),  $f$  is the fugacity and  $f_o$  is the fugacity of the pure material (Berg and Bruin, 1981). Fugacity is a measure of the tendency of the substance to escape from the system. When dealing with water,  $f/f_o = a_w$  which represents the escaping tendency of water in the system. For water the fugacity is closely related to the vapour pressure and hence water activity may be rewritten as:

$$a_w = \frac{f}{f_o} \sim \frac{p}{p_o}$$

where  $p$  is the vapour pressure of water in the material and  $p_o$  is the vapour pressure of pure water at the same temperature. The equilibrium relative humidity is the water activity multiplied by 100.

Water activity affects many aspects of food stability including microbial growth, enzymatic and non-enzymatic spoilage. The  $a_w$  of a food may be reduced by adding humectants or by the removal of water during drying. Processed foods with water contents below 15%, with lower  $a_w$ , have their water associated in monolayers and multilayers and are not capable of participating in hydration of microbes or partaking in mobility of enzymes. Therefore, foods with low  $a_w$  are stable and the shelf-life is not affected by microbial degradation. Intermediate moisture foods, between 20% and 40% moisture, contain monolayer and multilayer water and also capillary water. These foods are highly susceptible to enzymatic reactions and to a lesser extent microbial spoilage. And high moisture foods above 40% moisture will undergo rapid spoilage if there are no alternative processes which limit deleterious reactions from occurring.  $a_w$  can be used to predict the occurrence of different types of food spoilage. For example, when the  $a_w$  is reduced below 0.65 very little to no spoilage occurs via microbial populations. Lipid oxidation shows interesting behaviour where a minimum in oxidation is observed at  $a_w$  of 0.2. This is attributed to small amounts of water binding hydroperoxides and when more water is added to the system it aids in the solubility of oxygen into the food matrix thereby increasing the rate of oxidation (Karel and Yong, 1981). Vitamin degradation, Maillard reactions and microbial growth each exhibit a rate maximum at a specific  $a_w$  (Fig. 1). Rate maxima may be due to feedback inhibition when water is an end product or enhanced solubilization of substrates.

## Hysteresis

Hysteresis has important applications and challenges in food science when it pertains to food chemistry, processing and microbiology. Hysteresis occurs when the addition of water to a sample, also known as resorption, does not superimpose onto the isotherm generated by removal of water or desorption. The deviation of the two isotherms is referred to as hysteresis. Typically, the resorption isotherm is lower than the desorption isotherm. A physical description for hysteresis is based on principals of capillary condensation for water. The Kelvin equation was developed for capillary condensation (Kapsalis, 1981).

$$\ln \frac{P_v}{P_{sat}} = \frac{-2H\gamma V_l}{RT}$$

where  $P_v$  is the equilibrium vapour pressure above the curved meniscus,  $P_{sat}$  is the saturation vapour pressure of water,  $\gamma$  is the liquid/vapor surface tension,  $V_l$  is the molar volume of water,  $H$  is the mean radius of curvature for the meniscus,  $T$  is the absolute temperature and  $R$  is the ideal gas constant. The ink bottle theory is used to describe water being added and removed from capillaries. The ink bottle is comprised of a thin neck ( $r_1$ ) and a large well ( $r_2$ ). Upon addition of water the entry into the capillary is restricted until it has first condensed in the well ( $r_2$ ) at:

**Figure 1** Reaction rates related to the moisture content of the food.

$$\frac{P}{P_o} = e^{\left(\frac{-2\sigma V}{r_2 RT}\right)}$$

Now we can substitute  $r_2$  for the Kelvin equation. This suggests that water desorption (i.e., during drying) is governed by the small capillary radius and undergoes evaporation immediately only when the desorption pressure ( $P_d$ ) is equal to:

$$P_d = e^{\left(\frac{-2V}{r_1 RT}\right)}$$

## States of Water

The physical state of water may influence aspects of food quality including microbial growth, physical disruptions of cellular components, rates of chemical reactions and sensory properties. Typically in literature when discussing state diagrams, as they pertain to foods, they are referred as phase diagrams. However, a phase is under equilibrium conditions and since foods contains complex interfaces and meta-stable forms the term state diagram is more suitable. There are many important aspects which will be discussed regarding a simplified water state diagrams.

Water can exist in three states, solid, liquid and/or vapour. Within the ice and liquid phases there are sub-phases which relate to how the molecules interact and how water molecules pack into crystal lattices. We typically think of water boiling at 100 °C; however this is only true at 101 kPa or atmospheric pressure whereas water would boil at 71 °C on the top of Mt. Everest. If we increase the pressure, water boils at higher temperatures; conversely, if we pull a vacuum (i.e., decreased the pressure) water will boil at lower temperatures. The ability to modify the boiling point of water is often overlooked when discussing water chemistry but it has tremendous consequences as it pertains to food processing. Water is only capable of boiling when the vapour pressure of the liquid is equal to the pressure of the atmosphere or the headspace of the package. This is often used during thermal processing and drying of heat sensitive foods. For example, when sterilizing a can of soup, the cans are placed into a pressurized retort and steam is injected into the headspace of the retort to increase the pressure while the product is being sterilized in the can. If the cans were not heated in a pressurized environment, the water would boil in the can. Since, water vapour is far less dense than liquid water, the can would expand and in some cases explode. On the other hand, when drying heat sensitive foods a vacuum is applied reducing the headspace pressure causing water to boil at lower temperatures. Rising film evaporators, used to produce orange juice concentrate from fresh orange juice, allow water to boil at ambient temperature by reducing the pressure from 101 kPa to 2.9 kPa. This allows water to be removed without developing cooked flavours in the final product.

The second important phase boundary is the ice-liquid boundary. The slope of this boundary is far less sensitive to pressure compared to the vapour-liquid or solid-vapour boundaries because the density of liquid and ice are very similar compared to the density of the vapour. Hence, there are no food processing techniques which use pressure to modify the ice liquid boundary. The triple point is where all three phase boundaries meet. Here the three states (i.e. ice, water, vapour) all exist in equilibrium. Hence, a water molecule in the vapour phase can condense into a liquid or a solid. Similarly, a water molecule in the ice phase may either melt into a liquid or sublime into the vapour phase. Below the triple point, ice may directly sublime into the vapour phase and vapour may condense directly to the ice phase. Freeze drying is an important application to food scientists where a food is frozen placed into a chamber and the pressure is reduced allowing the ice to sublime into a vapour. This has tremendous benefits when drying because it prevents cooked flavours and prevents case hardening.

## Crystalline Nature of Water

The formation of ice is a complex event which involves nucleation followed by crystal growth. Depending on the nature of nucleation and crystal growth the number, size and shape of crystal depend on the cooling regime, storage temperature and fluctuations in storage temperature. In aqueous system, water and solute may crystallize. Lactose is prone to crystallization during scraped surface freezing of ice creams which produces long thin crystals inducing a grainy texture. Nucleation results in a new phase developing such that the chemical potential of the new phase is smaller than the existing phase. This results in small clusters of water associating and orientating together in a manner similar to ice. This small cluster of molecules is referred to as an unstable crystal embryo. During the early stages of nucleation, they are unstable because the embryo has excess free energy which is associated with the creation of the new surface. Embryos and nuclei form in a spherical geometry to reduce the surface area to volume ratio. Hence, the free energy of the embryo with radius  $r$  is a combination of surface (positive) and volume changes (negative):

$$\Delta G_n = A_n \delta - V_n \frac{\Delta \mu}{V_m^s}$$

where  $A_n$  is the surface area of the nuclei,  $\delta$  is the surface free energy per unit area,  $V_n$  is the volume of a nuclei,  $\Delta \mu$  is the chemical potential difference between the solid and liquid and  $V_m^s$  is the molar volume of the solid.

For nucleation to occur, the free energy associated with the phase change must be negative. This does not indicate the rate of the reaction; just that in time the reaction will occur. Examining the free energy associated with a new phase, when a small embryo forms there is a critical size in which it becomes stable. Unstable nuclei result in the area and interfacial term dominating over the volume and chemical potential thus  $\Delta G_n$  is positive indicating that the system is not thermodynamically stable. At early stages of nucleation, the nuclei form and break down because there is a large free energy association with their surface. Upon further cooling, the nuclei grow and the embryo reaches a critical radius and becomes stable. This occurs when the volume term becomes larger than the surface area term and the change in the free energy is negative. Since there is a critical size, pure water with no impurities may not freeze until  $-40^\circ\text{C}$ . Impurities include dissolved gasses, solutes, ions or surfaces.

Following nucleation, crystal growth occurs where liquid molecules diffuse to the surface of the nuclei and adsorb onto the growing surface. Crystals have highly ordered structures which are ordered into Bravais lattices. The unit cell of hexagonal ice contains 4 molecules held together via hydrogen bonding. This results in an open structure which is less dense than water. Irregular crystal growth often forms as thin dendrites which is very undesirable in food systems because it results in a graining texture (Raza et al., 2011).

Follow nucleation and crystal growth, the shape of the crystal may change in time due to recrystallization. Recrystallization changes the number, shape and size of the ice crystals. During storage small crystals disappear and result in larger crystals growing to even larger crystals. This type of recrystallization is referred to as Ostwald ripening where large crystals grow and small crystals disappear at a constant temperature and pressure. This occurs because of differences in the surface free energy between different size crystals. Temperature fluctuations accelerate recrystallization resulting in all the depletion of small crystal and the increase in the size of larger crystals. The outcome results in grainy texture and consumer rejection of products. Typically, crystals that are not spherical do not have an optimal surface area to volume ratio and attempt to minimize this surface area to volume ratio via iso-mass recrystallization which results in crystals becoming spherical.

## Rubbery and Glass States of Water

A glass is a non-equilibrium, metastable, amorphous solid with an apparent viscosity greater than  $10^{12}$  Pas. Although both glasses and crystalline materials appear solid, a glass demonstrates no regular periodicity and the molecules do not orient onto Bravais lattices. X-ray diffraction is the simplest method to determine if a glass or a crystalline solid is present. Crystalline solids have sharp peaks which correspond to reflections from crystalline planes while a glass demonstrates no peaks. When a food becomes a glass the molecular mobility decreases. Molecular mobility of molecules is related to the diffusion coefficient ( $D$ ):

$$D = \frac{k_B T}{6\pi\eta r}$$

where  $k_B$  is boltzman constant,  $T$  is the absolute temperature,  $\eta$  is the viscosity, and  $r$  is the molecular radius. The diffusion coefficient is  $D \sim 10^{-24} \text{ m}^2 \text{ s}^{-1}$  if we assume a viscosity of  $10^{12}$  Pas. The advantage of using glasses to preserve foods is that any deleterious reaction relying on diffusion cannot occur. Typically, enzymatic reactions cannot occur because the enzyme and substrate cannot diffuse preventing contact with each other. Another major advantage occurs due to the lack of ice crystals. Therefore, there is no cellular disruption due to crystals rupturing plant and animal cells.

Theoretically, it is possible to reach a glass transition of pure water (Fig. 2) by rapidly cooling to  $-134^\circ\text{C}$  to avoid the formation of ice. From a food processing perspective, this does not occur because the material will crystallize before the glass transition is reached. Typically, during the freezing of foods, water undergoes a phase change from liquid to ice via nucleation and crystal growth. When water is removed from the unfrozen phase via the conversion to ice the unfrozen phase becomes more concentrated with solutes. At every temperature, a thermodynamic equilibrium is reached between the unfrozen phase and ice. This ideal cooling regime follows the equilibrium freezing line to the eutectic point. From a thermodynamic standpoint, at the eutectic point the solute

**Figure 2** Solid/liquid coexistence boundaries and glass transition profile for a binary sucrose/water system. Below and to the right of the glass transition line, the solution is in the amorphous glass state, with or without ice present depending on temperature and freezing path followed, while above and to the left of the glass transition line, the solution is in the liquid state, with or without ice depending on temperature.

should begin to crystallize out of solution. However, in the time frame of food processing conditions this often does not occur due to the kinetic conditions including low temperatures and a very high viscosity of the unfrozen phase. Hence beyond the eutectic point freeze concentration continues to occur until the glass transition is reached with further reduces the molecular motion.

Although we have focused on glasses produced with small solutes, there is also the possibility to form a glass with polymers. When a polymer chain, such as starch or gelatine, undergoes a glass transition they are completely immobile causing the final product to become very brittle. Near the glass transition is the rubbery transition which still has a high viscosity however the product becomes malleable. Increasing water content in these products, at a constant temperature, will significantly reduce the viscosity. Hence it is said that water acts as a plasticizer to polymer glasses. From a food perspective, generally they contain several components which may pass through the glass transition, such as starches and sugars, in the same material allowing the food to attain the physical properties of a glass much more readily.

## Edible Glass Structure

Many food products get their desirable final physical properties, microbial stability and sensory characteristics from removing water from the systems and creating a new state. When complex food systems are baked often their stability and structure is obtained by removing sufficient water to reach the glass transition. Crackers, cookies, milk powders and hard candies all obtain their structure by creating an edible glass. The simplest system is hard candies. Typically, a sucrose solution containing small amounts of colours and flavours is boiled to remove water. By doing so, we continually concentrate the sugar until it is approximately 82% of the final weight. This is sufficient to produce a sucrose glass. The end result is the same as the unfrozen phase glasses we discussed earlier. Hard candies seem like a crystalline solid however they have no crystal lattices. One major problem hard candies encounter is a limited shelf-life. Once the package is opened the sugar attracts water to absorb since it is very hygroscopic. Upon absorbing atmospheric water, the concentration of sucrose decreases and eventually a state transition occurs from the glassy state to the rubbery state which causes the product to become sticky. This is why when candies are placed into a dish they stick together.

Crackers and milk powders are also glasses however in this case, they rely on creating a glass due to the presence of polymers including proteins and long chain carbohydrates, such as starches. Water is removed from these foods either through baking or spray drying, and a glass of the macromolecule is produced. This is why crackers are crispy. However, if crackers absorb water they become soft and malleable which makes them far less desirable and more susceptible to microbial growth. When milk powders absorb water they also become very soft and sticky as well the dramatic decrease in the viscosity allows for the porous structure to collapse making them much harder to re-solubilize.

## Conclusions

Water plays an essential role not only in food structure but also in limiting the spoilage microorganisms. It dictates stability of foods, textural properties, microbial stability and consumer acceptance. By controlling the amount and state of water in foods we can control the structure of food which gives rise to the desirable organoleptic properties of the food as well as its safety.

# Water-Soluble Vitamins

Hannah Pinchen and Paul Finglas, Quadram Institute Bioscience (QIB), Norwich, United Kingdom

© 2019 Elsevier Inc. All rights reserved.

## Overview

A vitamin is an organic compound that is required in small quantities for normal functions of the body including growth and metabolism (Table 1). It cannot be synthesised in humans to meet the required needs of the individual and deficiency symptoms will occur if a single vitamin is omitted from the diet of a species which requires it. Many vitamins act as coenzymes, whereas others have no single role but to perform certain essential functions. Vitamins are grouped by function rather than their chemical characteristics. Certain substances that are considered vitamins can be synthesized in small amounts by gastrointestinal tract bacteria (e.g. B-groups). Vitamins are generally grouped into two groups: water- and fat-soluble, based on their solubility characteristics. Water-soluble vitamins are found in all living tissues, whereas fat-soluble vitamins are completely absent from some tissues. Water-soluble vitamins generally contain one or more polar or ionizable groups (carboxyl, keto, hydroxyl, amino, phosphate) (Combs and Mcclung, 2017).

## Classification and Properties

Identifying and classifying vitamins can be difficult due to a number of reasons: (1) a vitamin can exist in a number of different structures with similar, or different, biological activities; (2) most vitamins are only active when converted to another form or when attached to a specific protein; (3) the biological activity is organism-dependent; (4) vitamins can be biologically active in different forms (forms that are active in humans may not be the form that is found in food e.g. B vitamins are active in coenzyme forms); (5) vitamins can change into different forms during extraction (e.g. pyridoxine, pyridoxamine, pyridoxal, and their phosphorylated derivatives); and (6) the man made version of a vitamin can be more stable than the natural form.

Multiple biosynthetic pathways are involved in the synthesis of the water-soluble vitamins. Some compounds are classified as 'vitamin-like' compounds and are related to a vitamin in activity. In general, they can be synthesised by the body in required amounts. These include vitamins F (essential fatty acids), L (*o*-aminobenzoic acid), P (bioflavonoids), U (S-methylmethionine sulfonium chloride), and B<sub>13</sub> (orotic acid); choline;  $\alpha$ -lipoic acid; myoinositol; plastoquinone; pyrroloquinoline quinone; and ubiquinones.

During the early years of vitamin discovery, their chemical composition was largely unknown and vitamins were each assigned a letter of the alphabet for convenience. This was further complicated when it was found that the activity attributed to a single vitamin was, in some instances, the result of a combination of several vitamins, for example, vitamin B complex. To simplify the system, letters were sometimes replaced with names, for example, thiamin (vitamin B1) and biotin (vitamin H), based on the chemical structure of a specific function or source. 'Thiamin' contains the prefix 'thi', which is derived from the Greek word for sulfur and refers to its sulfur content.

Vitamins work in metabolism by the following ways: as coenzymes, as substances that can be oxidised or reduced in metabolism, as antioxidants, as hormones, and as gene transcription effectors (Combs and Mcclung, 2017).

## Occurrence in Food and Methods of Analysis

Water-soluble vitamins are found in all living tissues. The major vitamin forms found in foods and some examples of rich food sources are given in Table 2.

The UK Composition of Foods Dataset contains 3291 foods each of which contain up to 185 nutrient values. Around 90% of the data are analytical values; the methods that have been used for the analysis of foods can be found in McCance and Widdowson's, The Composition of Foods book (Finglas et al., 2015). The nutrient values quoted in the tables have been determined by a variety of methods and in many cases laboratories would have used modified versions of the methods referenced in the book. It should be noted that although most give results of the same order of accuracy, with new methods merely improving the efficiency of analysis, some methods may give different results because they only measure certain forms of the vitamin. It is important that all biologically active vitamins of a certain nutrient are included in the nutrient analysis, otherwise the results may not reflect the nutritional value of the food.

Recent reviews into analytical methods have suggested there may be some advances in vitamin analysis (Wang et al., 2018). Microbiological assays are still used to quantify certain vitamins, such as biotin and niacin, however HPLC is most commonly used in vitamin analysis as it is highly selective and sensitive. A large volume of sample is required when analysing samples by HPLC. Capillary electrophoresis is a newer alternative to HPLC and produces results faster from smaller amounts of sample at a lower cost, however it uses a short light path so its sensitivity may be a problem for some vitamins. Capillary electrophoresis can be coupled with other techniques such as UV absorbance, laser-induced fluorescence, electrochemical and MS detection to allow for different needs. Chemiluminescence is a very sensitive method that doesn't require a bulk light source but it is expensive. It can be coupled with electrochemical detection to produce a very effective method for electroactive analytes such as vitamin C.

**Table 1** Water-soluble vitamins: forms, functions, deficiency symptoms and potential health benefits

<i>Vitamin</i>	<i>Vitamins<sup>a</sup> and related forms</i>	<i>Functions</i>	<i>Deficiency symptoms</i>	<i>Potential health benefits</i>
B <sub>1</sub> /Thiamin	Thiamin, thiamin monophosphate (TMP), thiamin pyrophosphate (cocarboxylase, TTP) complexed to proteins	Helps convert carbohydrates into energy metabolism; required by the brain, nervous system and heart	Beriberi	Important role in energy metabolism
B <sub>2</sub> /Riboflavin	Flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD)	Involved in carbohydrate, protein and fat metabolism; helps release energy into cells; part of the blue-sensitive pigments in the eye	Legions on mouth, magenta tongue, seborrheic dermatitis	Important role in energy metabolism; healthy skin
Niacin	Nicotinic acid, niacinamide (nicotinamide), nicotinamide adenine dinucleotide (NAD), and nicotinamide adenine dinucleotide diphosphate (NADP)	Involved in carbohydrate, protein and fat metabolism	Pellagra, nervous manifestations	Reduces risk of atherosclerosis
B <sub>6</sub>	Pyridoxine, pyridoxal, pyridoxamine, and related phosphorylated forms	Essential for proper protein utilisation; involved in homocysteine metabolism	Retarded growth, acrodynia, alopecia, skeletal changes, anaemia, seizures	Reduces risk of cardiovascular disease (with folate and B <sub>12</sub> ) and osteoporosis
B <sub>12</sub>	Cyanocobalamin, methyl- and hydroxocobalamins, adenosylcobalamin	Needed for red blood cell formation and DNA and RNA synthesis; involved in homocysteine metabolism	Macrocytic megaloblastic anaemia, paraesthesia, leg weakness, memory loss	Prevents certain anaemias and reduces risk of cardiovascular disease
Folic acid (folacin); folate	Pteroylmonoglutamic acid, 5-methyl-tetrahydrofolic acid as both mono- and polyglutamates, tetrahydrofolic acid, 5-formyltetrahydrofolic acid	Involved in amino acid interconversions and methylation reactions, needed for red blood cell formation and DNA and RNA syntheses, involved in homocysteine metabolism and protection against neural tube defects	Megaloblastic anaemia, increased homocysteine level, depression, irritability, neural tube defects in foetuses	Prevents certain anaemias and birth defects, reduces risk of cardiovascular disease (with B <sub>6</sub> and B <sub>12</sub> ) and certain cancers
Pantothenic acid	Coenzyme A, pantotheine, and acyl carrier protein (ACP)	Active in protein, carbohydrate and fat metabolism	Burning feet syndrome, headache, fatigue, insomnia, paresthesia, increased insulin sensitivity	General health and well-being
Biotin	Biotin, desthiobiotin	Active in protein, carbohydrate and fat metabolism	Alopecia, depression, muscular pain, paresthesia	Helps develop healthy nails
C	Ascorbic and dehydroascorbic acids, isoascorbic acid	Helps form/maintain collagen; important for healthy tissues and wound healing; enhances iron absorption; protects against free-radical damage and infection	Scurvy, fatigue, weakness, anaemia, aching joints and muscles, bleeding gums, delayed wound healing	Protects against cancer and cardiovascular and eye diseases; reduces symptoms of colds and flu and risks of osteoporosis

<sup>a</sup>The term 'vitamins' relates to the nutritionally active chemical species.

**Table 2** Water-soluble vitamins – main food forms and rich dietary sources

<i>Vitamin</i>	<i>Main food forms</i>	<i>Rich dietary sources</i>
B <sub>1</sub>	Thiamin, thiamin monophosphate, thiamin pyrophosphate complexed to proteins	Yeast and beef extract, wheat germ, pork, peanuts
B <sub>2</sub>	Riboflavin, riboflavin mononucleotide, flavin adenine dinucleotide complexed to proteins	Yeast extract, liver, kidney, brown crab meat
Niacin	Nicotinic acid, nicotinamide adenine dinucleotide (NAD) and its phosphate form (NADPH) complexed to proteins	Yeast and beef extract, wheat bran, tuna, liver, chicken
B <sub>6</sub>	Pyridoxine, pyridoxal, and pyridoxamine and their phosphorylated forms bound to proteins	Wheat germ, yeast extract, turbot, plantain
B <sub>12</sub>	Methyl-, adenosyl-, hydroxy-, and sulfitecobalamins	Liver, kidney, cockles, brown crab meat, mussels, oysters, yeast extract
Folic acid (only in fortified foods), folates	Folic acid, 5-methyltetrahydrofolate, 5-formyltetrahydrofolate, 10-formylfolate, tetrahydrofolate as mono- and polyglutamates	Yeast and beef extract, liver, wheat germ, blackeye beans, broccoli, asparagus, spinach, fortified foods (bread, breakfast cereals)
Pantothenic acid	Pantothenic acid, coenzyme A and acyl carrier protein (ACP)	Liver, kidney, broad beans, heart, egg yolk, mushrooms, peanuts
Biotin	Biotin and biotin bound to lysine and proteins	Widely distributed, especially liver, kidney, nuts, egg yolk, pangasius, plaice
C	Ascorbic acid, dehydroascorbic acid, isoascorbic acid	Guava, blackcurrants, spring greens, capsicum peppers, watercress, papaya, citrus fruits

LC-MS/MS is a fast method that is used to profile and quantify folate vitamers. LC-MS/MS differs to GC-MS as GC-MS cannot distinguish all folate forms within a sample (Vishnumohan et al., 2011).

## Nutritional Aspects

Nutritional requirement values represent the daily amount of a nutrient that a person would need to ensure that deficiencies are prevented and all their requirements are met. They are determined by each country based on statistical distributions of individual nutrient requirements which are determined from primary research including nutrient balance studies, measures of tissue saturation, normal vitamin intakes in the general population, and extrapolation from animal studies. Therefore, recommended nutrient values vary between countries. With new research and policies, there is a need to review the values, for example, the UK dietary reference values are monitored by the Scientific Advisory Committee on Nutrition (SACN) and are reviewed periodically. In a 2017 report by EFSA, the 1993 DRVs for the European population was updated. The report contains population reference intakes, which relate to the level of nutrient intake that is adequate for virtually all people in a population group; these values are given in Table 3 for adult males and females.

Some vitamins have been shown to have additional health benefits when given via diet or by supplementation, at levels above those required for eliminating classical deficiency states. Although, for most vitamins the optimal levels are not yet established, for some vitamins such as folic acid, the health benefits have been clearly demonstrated for taking higher intakes to protect against spina bifida or other neural tube defects. A higher intake of vitamin B<sub>6</sub> has been linked with a lower risk of impaired mobility in older adults (Struijk et al., 2017). In general, water-soluble vitamins have a safety level of 100 times or more the RDA for which there is no clear indication of any adverse effect; this is mainly because water-soluble vitamins are

**Table 3** Population reference intakes (PRIs) for water-soluble vitamins in adult males and females

<i>Category</i>	<i>Age (years)</i>	<i>B<sub>1</sub> (mg/MJ)</i>	<i>B<sub>2</sub> (mg/day)</i>	<i>Niacin (mg NE/MJ)<sup>a</sup></i>	<i>B<sub>6</sub> (mg/day)</i>	<i>B<sub>12</sub> (μg/day)</i>	<i>Folate (μg DFE/day)<sup>b</sup></i>	<i>C (mg/day)</i>
<b>PRI</b>								
Males	≥18	0.1	1.6	1.6	1.7	4.0	330	110
Females	≥18	0.1	1.6	1.6	1.6	4.0	330	95

<sup>a</sup>NE: niacin equivalent (1 mg niacin = 1 niacin equivalent = 60 mg dietary tryptophan).

<sup>b</sup>DFE: dietary folate equivalents. For combined intakes of food folate and folic acid, DFEs can be computed as follows: μg DFE = μg food folate + (1.7 × μg folic acid).

Reproduced from EFSA, 2017. Technical Report: Dietary Reference Values for Nutrients, Summary Report. EFSA Supporting publication 2017, e15121.

excreted readily in the urine and are generally not stored within the body (the exception being vitamin B<sub>12</sub> which can accumulate in the liver) (Combs and Mcclung, 2017). Deficiencies can occur from inadequate intake, malabsorption or from an intake of drugs or food that interact with factors or compounds related to absorption. Water-soluble vitamin deficiencies in Western countries has been relatively uncommon, however with a rising consumption of nutrient lacking food, low micro-nutrient levels has been seen in overweight and obese adults (Kimmons et al., 2006). Deficiencies can also result from certain conditions, for example the thiamin deficiency disease, beriberi, was recently seen in a dialysis patient (Jankowska et al., 2017).

Nutrient reference values provide a good estimate of adequate intake for the majority of the population; however, some factors will influence the uptake in vivo.

### Availability and Bioavailability

The term bioavailability (biological availability) is used to describe the proportion of a nutrient in food that is utilised for normal body functions. The way in which vitamins are absorbed and utilised in the body can be affected by several factors that can be broadly divided into dietary-related factors and physiological factors related to the host, for example thiamin requirements are higher when the diet contains large amounts of carbohydrate or alcohol. In addition, the vitamin may not be in a form that can be readily absorbed by the body. For example, nicotinic acid occurs in cereals in a form that is not absorbed from the gut. Some synthetic vitamins have different absorbance rates compared to naturally occurring vitamins in foods due to matrix effects and inhibitors in some foods, for example, synthetic B<sub>12</sub> in fortified foods is readily available compared to natural, food-bound B<sub>12</sub> (Institute of Medicine, 1998). Other components in the diet may also interact with the vitamin, causing an enhancement, or depression, of absorption. Thus, the nutritive value of a diet for a given vitamin may be somewhat different from the amount analysed chemically. Absorption of water-soluble vitamins can be directly through the gut via passive diffusion, or via specific carriers. In some cases, the vitamin is absorbed via specific carriers when present in low doses and by passive diffusion when present in high doses (Combs and Mcclung, 2017). Not all the vitamins needed by a human are only acquired via the intake of food; vitamin B<sub>12</sub>, thiamin, riboflavin, vitamin B<sub>6</sub>, biotin and folate can be synthesized in small amounts by gut bacteria. In addition, biosynthesis of niacin from tryptophan and vitamin C from glucose does occur, however these amounts are not substantial for the requirements of a human being (Combs and Mcclung, 2017). Most vitamins need to be bound to a protein, enzyme or modified in some way to be biologically active; one of the exceptions to this rule is vitamin C.

### Adverse Effects

Along with the increasing evidence of health benefits from consumption of diets containing vitamins at levels much higher than the RDAs, there is concern over potential adverse effects and even toxicity. The European Food Safety Authority (EFSA) has produced guidelines on the upper levels of micronutrient intakes which are likely to result in adverse effects in the general population (European Food Safety Authority, 2006). For example, EFSA advise that the upper intake of vitamin B<sub>6</sub> should not exceed 25 mg/day for adults; intakes as low as 50–100 mg/day have even been associated with symptoms of nerve damage (Bender, 1997). Similarly, high doses of nicotinic acid have been linked to a decrease of LDL cholesterol and increase of HDL cholesterol (Carlson, 2005), however effects like this should be considered alongside the possible toxic effects, particularly for the liver. One of the main concerns of folic acid fortification is its potential to mask the diagnosis of pernicious anaemia, which is caused by vitamin B<sub>12</sub> malabsorption causing progressive and irreversible nerve damage.

### Effects of Processing on Vitamin Stability

Vitamin stability varies greatly and depends on several factors such as temperature, oxygen and acid or alkali strength. Table 4 provides general information on the stability of water-soluble vitamins under several conditions. Several processes have been developed to produce stabilised forms of the vitamins, including spray drying in a suitable matrix (e.g. gelatin) and encapsulation.

Conserving nutrients in processed products has been of growing interest to consumers. A major benefit of processing, for example canning and freezing, is that it generally preserves vitamin concentrations by inactivating food enzymes.

The amount of a vitamin in a processed product will be determined by the concentration in the unprocessed, raw product, of which there can be great variability. For example, carrots may vary in their vitamin C levels by as much as 35-fold. This can be due to several factors, including variety differences, climate and growing conditions, maturity at harvest, and postharvest storage conditions. Thus, the vitamin content of raw materials for processing can vary enormously, in many cases exceeding that found in normal processed food. Boiling rice can result in thiamin, riboflavin and niacin losses of around 45%, even washing milled rice can cause a dramatic loss of some B vitamins (Kyritsi et al., 2011).

The different chemical and physical properties of the vitamins mean that they vary widely in their degree of stability. In the pure crystalline form, they retain their activity for long periods of time. However, when foods are processed, vitamins are subjected to a range of conditions that can be detrimental to their stability such as light, moisture, oxygen, heat and pH, these being typical environmental factors to which the food will be subjected in the food chain (see Table 4). Vitamins that are unstable to oxidation are

**Table 4** Water-soluble vitamin stability under certain conditions

Vitamin	Vitamin	Stable (S)/Unstable (U) to						To enhance stability
		UV	Heat <sup>a</sup>	O <sub>2</sub>	Acid	Alkali	Metals <sup>b</sup>	
Thiamin	Disulfide form	S	U	U	U	U	U	Keep at neutral pH <sup>c</sup>
	Hydrochloride <sup>d</sup>	S	U	U	U	U	U	Exclude O <sub>2</sub> , at neutral pH <sup>c</sup>
Riboflavin	Riboflavin	U <sup>e</sup>	U	S	S	U	U	Keep in the dark, at pH 1.5–4 <sup>c</sup>
Niacin	Nicotinic acid	S	S	S	S	S	S	Good stability
	Nicotinamide	S	S	S	S	S	S	Good stability
Vitamin B <sub>6</sub>	Pyridoxal	U	U	S	S	S	S	Keep cool, work in subdued light
	Pyridoxol HCl	S	S	U	S	U	S	Good stability

therefore degraded by heat, oxygen, metal ions, polyunsaturated lipids undergoing peroxidation and ultraviolet light (Combs and McClung, 2017). The rest of the water-soluble vitamins tend to be stable under most normal conditions. The most liable water-soluble vitamins are vitamin C, folate and riboflavin.

### Domestic Cooking

Typical percentage losses of vitamins on cooking for selected food groups are given in Table 5. Vitamin C is one of the most labile of all the vitamins and is readily leached into water on boiling, particularly when the surface of the food has been cut or damaged. Vegetables are an important source of vitamins in the diet and typical losses on boiling vegetables are quite variable. Steaming, microwaving and pressure cooking can reduce water-soluble vitamin losses for cooked vegetables (Bureau et al., 2015), however microwaving conditions, e.g. cooking time and water volume used can affect the vitamin retention.

Meat is the main source of B12 in the diet and is also a good source of other B vitamins. Dry cooking meat has been shown to result in a loss of B vitamins; the most pronounced being thiamin (Lombardi-Boccia et al., 2005). Losses are less when pot roasting

**Table 5** Typical percentage losses of vitamins on cooking for selected food groups

and braising are used. Some vitamins that leach into the meat juices during cooking will not be lost if the sauce or the gravy is eaten as part of the actual dish. This means that average losses in meat dishes are not higher than for grilled or fried meat, even though the cooking times are longer. Similarly, when using classic breadmaking techniques, 48% of the thiamin can be lost when making white bread. However, it was also shown that keeping the fermentation of yeast or sourdough separate during whole wheat bread making kept the thiamin levels close to the original level of the flour (Batifoulie et al., 2005).

### Other Processing Methods

Extrusion cooking is a common method of producing crisp, shaped cereal products such as breakfast cereals, snack foods and other textured foods. Various factors influence the retention of vitamins during extrusion, such as cereal type, sensitivity of the vitamin to heat, type of extruder. Heat sensitive vitamins are particularly susceptible to degradation during extrusion. Thiamin, riboflavin, niacin and vitamin B6 have been shown to have varying retention rates in different cereal types. For example, vitamin B6 was shown to be stable in maize but less so in oats (Athar et al., 2006). Moisture content, energy input, mass temperature, screw geometry, and rate of throughput are thought to influence retention. For example, short barrel (90 mm) extruders had a higher retention rate of B vitamins (44%–62%) compared to 20% for long barrel extruders (Brennan et al., 2011). It appears that retention can be improved by increasing both the rate of throughput and moisture content. Losses of vitamin C during extrusion of 25%–40% have been found.

Irradiation is an application that ensures the safety and quality of food by destroying microbes. Irradiation-induced changes in vitamin concentrations in foods during irradiation have been reviewed extensively in the literature. In practice, irradiation doses are usually lower than 10 kGy although even low doses can produce an effect on the level of vitamin in a product; losses of thiamin can be as much as 20% at an irradiation dose of 1 kGy. However, other vitamins can be relatively unaffected, for example a study showed that low irradiation of citrus fruits resulted in no loss of vitamin C. In others, an increase can occur due to potential that irradiation changes a precursor to the vitamin; this was seen in a study that showed a 25% increase of riboflavin in pork chops and chicken breasts when irradiated by up to 6.6 kGy. In addition, losses can vary depending on the structure of the food, for example whole grain products show small losses but these increase after milling (Kilcast, 1994).

It is well known that fermentation can increase the B-vitamin content (e.g. folates) of some foods, such as cheese, milks, yogurts and other dairy foods, and this is a potential area for production of foods with enhanced health benefits. *Streptococcus thermophilus* and *Propionibacteria* naturally produce folate and vitamin B<sub>12</sub> respectively, however microorganisms generally require vitamins for growth. This rule does not apply to *Lactobacilli* which grows without vitamins and produces vitamin B<sub>12</sub>. Gene mutation, incubation conditions and medium will also have an input on the amount of vitamin released by the microorganisms (Walther and Schmid, 2017).

Fortification of common foods can be an acceptable way of supplementing the population's diet with lacking nutrients. Recent studies have shown that even soaking rice in water-soluble vitamins can improve the nutrient composition, with up to 70% retention of the applied vitamin (Kyritsi et al., 2011). In addition, it has been shown that it is possible to encapsulate vitamins using different biopolymers via a spray-drying process (Estevinho et al., 2016).

### Conclusion

Water-soluble vitamins are an essential part of a human diet. As they cannot be stored in the body, a daily intake must be met to prevent any associated deficiencies from forming. Daily needs will vary from person to person due to different factors such as the form of the vitamin that is ingested and the way in which it is utilised in the body. They can be greatly affected by storage, cooking and processing techniques and it is therefore evident that the vitamin levels present will vary from food to food.

## Waxes

Yaqi Lan, South China Agricultural University, Guangzhou, PR China

© 2019 Elsevier Inc. All rights reserved.

### Introduction

A broad definition of “waxes” was dated back from 1975 when H. Bennett defined it as “an unctuous solid with varying degrees of gloss, slipperiness and plasticity, which melts readily” (Bennett, 1975). There are various definition of waxes. Waxes can be referred to fatty components obtained from plants, insects, animal skins, or mineral origin. They can also be described as hydrophobic organic substances of medium or long chain length (Post-Beittmiller, 1996). Generally, waxes contain very long chain ( $>C_{18}$ ) fatty acids, hydrocarbons, alcohols, aldehydes, ketones, esters, sterols, triterpenes, and flavonoids (Post-Beittmiller, 1996). Waxes are insoluble in water and soluble in specific organic solvents. Since waxes are complex mixtures, their physical properties vary dramatically depending on their sources, and are often used to describe specific products. Regardless if its broad definition and complex composition, there is no dispute that wax is broadly used in various industries. So far, there is not any review focused from the aspect of food science. Therefore, in this chapter, classic waxes from various sources as well as their food-related applications are discussed.

### Classification of Wax

Waxes can be classified into synthetic and natural waxes. The synthetic waxes are generally low molecular weight polymers derived through polymerization of feed stocks, such as methylene, ethylene and  $\alpha$ -olefins. Natural waxes are from various origins, i.e., waxes from animals and plants, mineral waxes from petroleum, coal and peat. The composition of waxes largely depends on their sources. Most natural waxes from animals and plants consist of hydrocarbons, long-chain alcohols, long-chain carboxylic acids and long-chain esters (Fig. 1). While waxes of mineral origin contain almost exclusively long-chain hydrocarbons. The nature and classification of waxes, sometimes, may be misunderstood with fats and gums. For example, wool wax derived from lanolin is often considered as a fat because of its properties, although it is a wax in nature (Tinto et al., 2017). In this part, examples of some typical waxes from different sources are briefly introduced.

#### Animal Wax

Animal waxes are generally obtained from insects (bees, *Apis mellifera*), whale (shellac, *Physeter macrocephalus*), and sheep (*Ovis aries*), etc.

Beeswax is a naturally occurring wax secreted mainly by honeybees *A. mellifera*, for constructing honey combs (Tulloch, 1970a). Unhydrolyzed beeswax consists of approximately 71% esters, 15% hydrocarbons, 8% free fatty acids, and 6% other components (Tulloch, 1970b). Natural beeswax is brittle when cold, with melting temperature ranging from 62 to 65 °C. Beeswax is inert with high plasticity. It protects against corrosion, abrasion as well as moisture loss. Beeswax is one of the most useful commercially available waxes (Ogutcu et al., 2015; Martins et al., 2017). Commercial beeswax is used for metal castings, candle making, as well as in cosmetics, textiles, varnishes and food processings. Related food applications will be discussed in later part.

Other animal waxes include spermaceti (from whale) and wool wax (from sheep). Spermaceti is acquired from the frontal organ in the head of the sperm whale *P. microcephalus*, which is used as a sonar by the animal (Morri, 1973). Back in 15th century, it was used in medicine in England. However, it is no longer produced and is replaced by synthetic spermaceti that consists of pure acetal

**Figure 1** General structure of major constituents in waxes including (A) hydrocarbons (n-alkanes where  $n = 22-36$ ); (B) long chain fatty alcohols (ROH, where R is 12–34 carbon atoms in length); (C) long-chain carboxylic acids (where R is 12–34 carbon atoms in length); and (D) long-chain esters (where  $R_1$  and  $R_2$  are 10–20 carbon atoms in length).

palmitate or mixtures based on jojoba, because of the prohibition of whale capture (Crisp et al., 1984). Wool wax is secreted by the sebaceous glands in sheep skin, protecting sheep skin and fleece against exposure (Horn, 1958). Wool wax finds its intensive application in personal care products, such as facial cosmetics and lip products (Jover et al., 2006).

### Plant Wax

Plant waxes are generally the waterproofing components found in an amorphous layer on the outer surface of the plants. They are essential for plants as barrier protection against environmental stress. Many of them have gained GRAS (Generally Regarded as Safe) status approved by FDA (Marangoni, 2012), allowing for extensive food applications. Typical plant waxes include candelilla wax, carnauba wax, rice bran wax as well as sunflower wax, etc.

**Candelilla wax** is mainly obtained from the leaves of plant *E. antisiphilitica* Zuccarini native to northern Mexican and south-west Texax (Arato et al., 2014). Unpurified candelilla wax contains approximately 42% hydrocarbons, 39% wax, resin and sitosteroyl esters, 8% free wax and resin acids, 6% lactones, and 5% free wax and resin alcohols (Fraps and Rather, 1910). It is interesting to mention that majority of hydrocarbons are odd number in candelilla wax, and only trace quantities are found in even number. Candelilla wax is an FDA-approved food additive used for glazing in certain foods. Microemulsions of candelilla wax are also used as coatings for fruits (Hagenmaier and Baker, 1996).

The main source of **carnauba wax** is the Brazilian palm *Coernicia cerifera* Martius, also known as carnauba wax palm. It is found on the upper and lower surface of the palm leaves. One of the unique characteristic of carnauba wax is that it contains a high proportion of “unusual” chemical constituents such as un-esterified alcohols (12%), x-hydroxy esters (14%) and esters of hydroxylated cinnamic acid (30%), with the remainder being unidentified impurities (Vandeburg and Wilder, 1970). Carnauba wax is one the hardest plant waxes, with melting temperature ranging from 82.5 to 83 °C. Therefore, it is often used as a hardener to elevate the melting temperature of wax mixtures. Carnauba wax is the most commercially important plant wax. It has extensive applications and uses in foods, confectionery coatings, cosmetics, automobile and furniture wax, etc. (Tinto et al., 2017) Food related use of carnauba wax is outlined in the FDA regulation 21 CFR 184.1978.

**Rice bran wax** is another high melting vegetable wax found in husks of rice *O. sativa* (Feuge and Cousins, 1957). It is obtained as a by-product from the de-waxing of rice bran oil. The composition of rice bran wax is relatively homogeneous, with the major components being even-numbered aliphatic acids (wax acids) and higher alcohol esters, mainly C<sub>46</sub>–C<sub>62</sub> esters from C<sub>20</sub>–C<sub>36</sub> fatty alcohols and C<sub>20</sub>–C<sub>26</sub> fatty acids. Other constituents include free fatty acids (palmitic acid), phospholipids, phytosterols and squalene (Ishaka et al., 2014). The hydrocarbon content of rice bran wax is typically as low as 2%. Rice bran wax has been approved by FDA as a safe food additive (21 CFR, 172.890). It has extensive applications due to its relatively low cost and abundance in Asia. Food applications include fruit and vegetable coatings, confectionery and chewing gums. Other applications include candles, textiles, lubricants, cosmetics, etc. (Sabale et al., 2009)

**Sunflower wax** is found in the seed and seed hulls of *H. annuus* (sunflower) (Matyushenskii, 1960). It is obtained through the winterization of sunflower oil. Like rice bran wax, sunflower wax is also a hard, high melting wax mainly consisting of long chain saturated fatty esters (C<sub>40</sub>–C<sub>44</sub>). Sunflower wax has not been approved GRAS status by the FDA. Therefore, its applications are primarily in cosmetics, such as lipsticks, mascaras, lip balms, emulsions, etc. It functions as a consistency modifier and regulates the hardness, texture and mold release of cosmetic formulations. It can also be used as replacement of candelilla wax, carnauba wax and rice bran wax (Tinto et al., 2017).

### Applications of Waxes

Uses of waxes vary from consumer products, such as chewing gum, cosmetics, and candles, to industrial applications, such as hot-melt adhesives for carton sealing, flow modifier for plastic resins, and process additive for suspension polymerization. In regard of food applications, waxes are most widely used in coatings for food products to maintain quality and extend shelf life. They were less used in chewing gums nowadays. Novel applications include utilizing wax crystal networks for oleogelation as some waxes exhibit strong oil binding capacity. Other applications include delivery system such as serving as nanostructured lipid carriers, etc.

#### Traditionally Used as Edible Films or Coatings for Food Products

Mass transfer including water, oxygen and flavor, between food and the surrounding environment is a main cause for food quality deterioration. Edible films or coatings are developed to reduce such transfer and maintain the quality of food products. Lipid-based materials, especially waxes, are the most efficient substances to retard moisture loss and dehydration, due to their high hydrophobicity (Morillon et al., 2002). Waxes have been traditionally used as edible films or coatings for a variety of food products including fruits and vegetables, candies, cheese, egg shells, etc.

#### Advantages of Wax-Based Edible Coatings

**Retardation of moisture permeability:** The retardation of moisture loss and desiccation is one of the mostly notable benefits offered by waxes in coatings. Fresh produce such as fruits and vegetables may suffer from weight loss and loss of marketability because of dehydration. Processed food products may undergo undesirable changes due to water loss. Because of the apolar nature,

wax functions as a barrier against moisture migration and maintain the quality of food products. Waxes, wax emulsions as well as wax mixtures have been successfully applied to reduce moisture loss for a variety of products, including but not limited to blueberries (Chu et al., 2018), pineapples (Li et al., 2018), citrus (Hagenmaier and Baker, 1994; Kellerman et al., 2018), eggplants (Singh et al., 2016), walnut kernels (Kowalczyk et al., 2017) etc.,

**Regulation on internal atmosphere:** Waxing also creates modified internal atmospheres for fruits, which influences fruit metabolism, especially respiration, leading to change in fruit interior quality. Sometimes gentle atmosphere modification is used for fruits that are harvested un-mature and thus extend their shelf life (Baldwin et al., 1997). The efficacy of atmosphere modification depends on the type of waxes used, as waxes with different chemical composition exhibit different gas permeability. Reports showed that both grapefruits and oranges coated with polyethylene wax and carnauba wax had lower CO<sub>2</sub> and higher O<sub>2</sub> content than fruits coated with shellac (Hagenmaier and Baker, 1995). Wax treatment has also been reported to reduce internal browning of pineapple under chilling stress, but the mechanisms is not clear (Hu et al., 2012). In addition, waxing reduces spoilage and decay of fruits and vegetables. It has been reported that fresh cucumbers coated with carnauba wax microemulsion reduced decay by 17% compared to uncoated ones under simulated commercial conditions, with no reduction in weight loss (Baldwin et al., 1997).

**Improvement of appearance:** Waxing treatment improves the overall appearance of food products thus improves the marketability. Some waxes provide a glossy appearance when coated on fresh fruits, vegetables and confectionery products. Use of wax coatings also maintains the strength of peel tissue, avoids surface abrasion during handling of fresh produce, thus reducing spoilage from infection at injury sites. It has been reported that avocado coated with candelilla-based films alleviated the sharp change in color by browning (Saucedo-Pompa et al., 2009). Another study reported that cherry tomatoes coated with rice bran wax delayed the decrease in firmness during 10 days of cold storage (Zhang et al., 2017).

## Novel Application in Oleogelation

### Gelation of Oil by Waxes

In recent years, waxes have been used as effective structuring agents to immobilize a high amount of liquid oil (>95%wt) within a three-dimensional network and creates a semisolid, thermo-reversible soft materials, called oleogels. Compared to traditional hardstock fats, where higher melting, solid TAGs (>0.2) form a three-dimensional crystal networks, oleogelation can be employed as an alternative strategy to formulate lipid-based food products with zero trans fats and significantly reduced saturated fats. In order to form a wax-based oleogel, specific amount of wax is first dispersed in a selected liquid oil, normally at elevated temperature, until the wax crystals completely dissolve. Upon cooling, the high melting wax gelators form crystals of characteristic size and shape. These crystals further assemble into a three-dimensional colloidal network via noncovalent interactions, and entrap the liquid oil within the network through surface tension and capillary force (Co and Marangoni, 2012; Singh et al., 2017).

### Natural Wax Gelators

Among various oleogelators that have so far been explored, natural waxes are of particular interest for their excellent oil-binding properties, capability of gelling oil at low concentration (as low as 0.5%wt), the wide range of properties that can be tailored, economical values (abundance in resources and relatively low in cost), and their natural origin as well as availability of some waxes with GRAS status. So far, most natural waxes that have been found with oleogelation capability are plant origin, such as rice bran wax, carnauba wax, candelilla wax, sunflower wax, sugar cane wax, and berry wax (Mattice et al., 2018). There are also some wax-based gelators from animal sources, the most notable one being beeswax (Ogutcu et al., 2015). The gelation of edible oil by rice bran wax was first reported by the group of Ueno at Hiroshima University, Japan (Dassanayake et al., 2009). It is a highly efficient gelator with a critical gelator concentration (CGC) of 1% (w/w) in canola oil (Dassanayake et al., 2009), and 0.5% wt/wt in soybean oil by controlling cooling rate (Hwang et al., 2012). Sunflower wax is another highly efficient gelator with a CGC of 1% (w/w) in canola oil, and 0.5% (w/w) in soybean oil at specific cooling rate (Hwang et al., 2012). Candelilla wax has a moderate gelation efficiency of 2% (w/w) in canola oil (Blake and Marangoni, 2015). Carnauba wax is considered as one of the least efficient gelators due to the formation of spherical, grain-like crystals with low aspect ratio that are less capable of entrapping oil. Even though, the CGC is 4% (w/w) in canola oil (Blake and Marangoni, 2015). Considering the economical values and the small amount (0.5%–4%, wt/wt) of waxes required to structure liquid oil, these natural wax gelators are very promising in industrial applications on a large-scale basis.

## Physicochemical Properties of Wax Oleogels

Given the complex composition of each wax, it varies greatly in physicochemical properties. No two wax-based oleogels are identical. Therefore, it is of great importance to identify the precise composition of each wax, in order to truly understand how the subsequent gels behave in specific manners. Doan et. al. have conducted a systematic investigation on the chemical profile of some natural waxes and established correlation between their chemical composition and gelling properties. The general chemical composition of some common wax gelators have been shown in Table 1. The order of importance for oil gelation was reported as hydrocarbons > fatty acids > wax esters > fatty alcohols.

The microstructure of wax-based oleogels is also unique to the type of wax used. It has been demonstrated that waxes with more homogeneous composition, such as rice bran wax and sunflower wax, tend to have thinner and needle like fibers or platelets (Lim-pimwong et al., 2017). A more complex system, such as candelilla wax and carnauba wax, allows for co-crystallization of multiple

**Table 1** General chemical composition of some natural waxes investigated through HPLC-ELSD on the Alliance system<sup>a</sup>

components, hindering the tight molecular packing and prevent the ordered crystal structure (Morales-Rueda et al., 2009). Such systems usually result in the structural features of a larger scale. Wax-based oleogels exhibit very interesting and complex rheological characteristics of both flocculated suspensions and semi-dilute polymer solutions. The rheological profile is also affected by the chemical composition of various types of waxes. It was found that waxes consisted of saturated fatty acids and high melting fatty acids produce viscous and hard oleogels (Dassanayake et al., 2012).

### Other Applications

Other food-related applications of waxes include plasticizing in chewing gums and fabricating microencapsulation systems for bakery additives (Al-Widyan and Small, 2004; Lakkis, 2007). Microencapsulation of bakery additives allows for better manipulation of dough characteristics during bread-making process. When it comes to medicine drugs or poisonous baits, some natural waxes have been used to preserve the bioactive compounds and achieve controlled release (Tinto et al., 2017; Soleimanian et al., 2018).

## Introduction to the Volume: Food Adulteration & Contamination

**Richard H Stadler**, Nestlé Research, Nestlé Institute of Food Safety & Analytical Sciences, Lausanne, Switzerland

© 2019 Elsevier Inc. All rights reserved.

Protecting consumers from foodborne contaminants that may lead to a possible health risk is vitally important to avoid harm, but also to retain consumers' trust and confidence in our food supply chains. This requires a thorough understanding of the potential contaminant hazards that may be introduced at any of the many steps along the food chain, i.e. from "farm to fork".

This volume of the Encyclopedia entails more than 50 articles, addressing those foodborne hazards identified as most significant in terms of (i) health impact (acute or chronic), (ii) major recent developments in the scientific knowledge and/or regulations in the past years, and (iii) that have a significant degree of public/media attention. The authors have focused largely on "what is new", providing a concise expert assessment that highlights progress as well as current knowledge gaps.

The readers will notice that the topics are spread rather broadly, encompassing food fraud, food defense, natural toxins, process contaminants (and processing technologies to mitigate risks), packaging migrants, genetically modified organisms (GMO), endocrine disruptors, nanotechnology, allergens, pesticides, veterinary drugs, and biocides. Due to the rapid advancement in detection techniques (including untargeted approaches) and data management, selected chapters deal with next generation sequencing (NGS), chemical profiling, "omics", and big data applications. Although most of the chapters are related to chemical hazards, a few have been included that emphasize microbiological risks and associated detection methods.

To avoid food safety issues, mechanisms need to be in place to conduct reliable risk assessments and identify emerging risks timely, and when necessary act on these appropriately. Thus, separate chapters are dedicated to emerging food safety risks and advanced concepts of risk assessment. The management of chemical hazards through HACCP at operational level, as well as proportionate risk management measures, are essential elements to reliably manage and control foodborne exposure to undesired contaminants, with the end goal to protect consumers and build trust in our food systems and supply chains. The legislative landscape particularly for chemical contaminants has evolved nearly exponentially in the past decades, especially within the EU, with unfortunately little alignment visible at a global level and apparent disconnect to the way food materials are traded. In some cases, manufacturers are faced with major challenges in terms of compliance, exemplified by traces of "dual use" substances. These may enter the food chain inadvertently, leading to serious economic consequences if not managed early in the process with the involvement of all stakeholders.

A key topic covered by several chapters in this volume is food fraud, which encompasses a wide range of malpractices, including adulteration, mislabelling, and counterfeiting. Our food supply chains can be highly complex and global in scope, with the possibility of multiple intermediate steps from "farm to fork". Several incidences in the past years have contributed to eroding the trust of consumers in the quality & safety of our foods, such as the "horsegate" scandal that surfaced in 2013. This scandal involved the fraudulent use of horse meat added to beef and not declared as such across several EU countries. The occurrence of traces of the anti-inflammatory drug phenylbutazone in some horse meat samples exacerbated the issue, due to possible health concerns which after testing luckily revealed a low risk to public health. The authorities reacted quickly, introducing EU-wide measures to better control the European meat supply ([EC Recommendation, 2013](#)). In this context, major advancements were also made related to the development of meat speciation testing such as for example NGS technologies as well as mass spectrometry based methods. These methods achieve detection limits down to 0.1% or lower on a weight basis and surpass the traditional Polymerase Chain Reaction (PCR) and ELISA meat speciation tests, in both performance and scope.

To effectively combat food fraud, processes that reach beyond traditional chemical risk-assessment need to be implemented, i.e. a food fraud prevention management system, ideally incorporated within a food manufacturers food safety management system. In economically motivated food adulteration, a plethora of possible fraudulent acts can be considered, mainly at the food raw material/ingredient preparation step. The inherent vulnerability of a material will depend on factors such as its physical state (e.g. liquid, powder), its level of processing, and its composition. In general, the higher the degree of processing, the greater the vulnerability of the material. For example, the composition of a fish powder is far more difficult to verify (particularly by rapid methods) than the whole fish or a single filet ([Cavin et al., 2016](#)). Other drivers that determine vulnerability are the material cost – which incidentally may fluctuate significantly over time – and the degree of supplier engagement/transparency. The latter includes any verification measures that may be in place at the suppliers end to ensure traceability and detect adulteration (mislabelling, substitution, dilution, concealment, unapproved enhancement etc.).

A segment of the foodborne chemical contaminants dealt with in this volume are dedicated to the mycotoxins, representing six major compounds/classes of relevance (aflatoxins, ochratoxin A, zearalenone, fumonisins, patulin, and the trichothecenes). In the past decade, mycotoxins have accounted for 30%–60% of all food and feed rejections at EU borders, signifying challenges in managing these contaminants at a global level. In fact, one additional concern today are the effects of climate change and its impact on fungal growth at the crop stage and toxin profiles, which may shift fungal occurrence patterns more toward southern and central Europe (example, aflatoxins in maize). Besides a more general overview chapter on mycotoxins in food and feed, specific contributions on aflatoxins and ochratoxin highlight latest information on occurrence and associated risks. Research today on mycotoxins continues to focus on the development of both screening and rapid techniques, but also continues to reveal new risks, such as the

“modified forms” that may contribute to the overall human exposure (EFSA, 2014). These modified forms (e.g. the *Fusarium* toxins zearalenone, nivalenol, T-2 & HT-2 toxins, and fumonisins) - that are poorly understood from a toxicologically perspective - are either bound, conjugated or “hidden” (complexed or physically entrapped by macromolecules). Today, there is a clear lack of analytical standards and reference materials, which hinders routine analysis and the gathering of reliable data for risk assessment purposes.

Another intensive area of research is the occurrence of toxic plant alkaloids in foods and their significance to human health, notably the pyrrolizidine alkaloids (PAs) and tropane alkaloids. More than 600 PAs have been identified in roughly 5% of all flowering plants, mainly of the families Boraginaceae, Asteraceae and Fabaceae. PAs have been associated with food poisoning in humans, with hepatotoxic and carcinogenic effects (1,2-unsaturated PAs). Similar to mycotoxins, PAs produce typical « spot » contamination, thereby they are unequally distributed in the raw material and require tedious sampling procedures. In addition, there is a lack of harmonized analytical methods, and no consensus on exactly which compounds to analyse. Similar to PAs, tropane alkaloids are natural secondary plant metabolites (mainly present in the seeds of *Datura* spp.) that may lead to human poisoning. More than 200 compounds (e.g. atropine/hyoscyamine, scopolamine) have been identified, and limits within the EU set for cereal-based foods for infants and young children, at 1 ng/g for each scopolamine and atropine (Commission Regulation (EU) No 2016/239, 2016). The *Datura* seeds are similar to millet/sorghum/quinoa seeds in terms of weight and color, making separation highly challenging.

Of the foodborne chemical contaminants, probably the most studied over the past decade are those formed during processing, particularly when food is subjected to thermal treatment. Consequently, several chapters are dedicated to these substances, i.e. acrylamide, furan/methyl furans, polyaromatic hydrocarbons, biogenic amines, MCPD esters and glycidyl esters, N-nitrosamines, furfuryl alcohol, heterocyclic aromatic amines, advanced glycation end products. These undesired substances may occur at different amounts in a wide range of processed foodstuffs that we ingest on a daily basis, as well as those foods prepared in a domestic (kitchen) environment. Of the substances listed, acrylamide-encompassing several articles - is the most intensively investigated over the past 15 years and deserves this heightened attention. These contributions on acrylamide help to (i) better understand the human health risks; (ii) describe chemical pathways of formation in food; (iii) find ways to mitigate its formation, also at the agricultural stage; (iv) elaborate on measures that can be introduced to reduce levels in the concerned foodstuffs. Importantly, a USA FDA approach in the form of guidance to the food industry is provided. In this context, the EU recently introduced mandatory risk management measures for acrylamide in foodstuffs (Commission Regulation (EU) 2017/2158 of 20, 2017), which on a positive note will undoubtedly accelerate the usage of the FoodDrinkEurope (FDE) acrylamide “Codes of Practice” across the food industry. Regulations have also been drafted for glycidyl esters, that are formed in all refined vegetable oils during the thermally driven deodorization process. The food industry is encouraged to continue research into mitigation options for those contaminants/foods of concern, ideally sharing this information openly in a non-competitive manner, as exemplified over the past 10 years by the “Acrylamide Toolbox” (FDE, 2013), and more recently the MCPD esters/glycidyl esters Toolbox (BLL, 2016).

Reviews on endocrine disruptors, biocides and nanoparticles summarize the status of research in these areas but also highlight the challenges and constraints. In the case of biocides, the use of cleaning and disinfection agents can be considered a part of the production cycle, avoiding the excessive growth of microorganisms. Recently, issues have arisen related to the use of chlorinated sanitizers such as hypochlorite and the presence of the undesired byproduct chlorate. Produce such as vegetables washed with chlorinated water will retain up to 20% of the chlorate present in the wash water (or potable water in case chlorinated), leading in most cases to amounts above the current EU legislative limit for chlorate in foods (10 ng/g). The risk of use (byproduct formation and exposure) versus benefit (microbial reduction or elimination) requires careful evaluation prior to introducing any maximum levels, as the avoidance of highly effective sanitizers may lead to more serious, acute microbial risks with possibly fatal consequences.

We have chosen to allocate several chapters to allergens, that also warrant careful consideration in economically motivated fraud. For example, a material/ingredient may be partially substituted with an allergenic food, risking serious injury to health or even fatalities. Better food labelling to address inconsistencies among countries, identifying thresholds of elicitation of allergy symptoms, and regulatory gaps in how to deal with unintended allergen contamination of foods are topics discussed in these contributions. A dedicated chapter has been included on rapid and confirmatory testing methods for allergens, including current deficiencies in the analytical methodology and how these could possibly be overcome.

Other “hot topics” in this volume are the pesticides, with emphasis on the evaluation process and impact of MRLs on global trade, a much disputed issue. Excellent regulatory overviews and/or recent analytical developments are presented in chapters related to acrylamide, veterinary drugs, allergens, GMOs, and the dioxins/polychlorinated biphenyls.

Modern analytical techniques continue to evolve in terms of sensitivity, coverage of analytes and speed of analysis. Analytical equipment is becoming more “affordable”, easier to use and the data can be interpreted faster. Researchers will undoubtedly continue to detect undesired chemicals or residues of contaminants in foodstuffs at low to trace levels, but need to understand that not all chemicals or hazards need to be managed, i.e. may not represent a health concern. What is lacking today is a clear prioritization of the risks and agreement on management measures, taking into account the feasibility to reliably measure the contaminants, as well as mitigate and effectively lower the levels of exposure.

The food industry has an important role to play in being transparent with new scientific findings, so that food regulators are better equipped to control undesired contaminants, while not inadvertently placing undue restrictions on their citizens’ food supplies.

### Glossary

**Agroinfiltration** an *Agrobacterium* based method used to induce transient expression of genes in a plant, generally to express a protein

**Cis-genesis** a transgenesis, with DNA sequences transferred between individuals from the same species, the same pangenome

**CRISPR-endonuclease** a technique using initially Double strand DNA endonuclease and RNA guide to modify genome or epigenomes

**Graft** the result of the insertion of a shoot or twig into a slit of a living plant, named the rootstock, from which it receives sap for further growth.

**Epigenome** originally a set of chemical modifications of DNA and chromatin's proteins that modify the genes' expression. Can also be used to also encompass epitranscriptomic modifications.

**Epitranscriptome** a set of biochemical modifications of the RNA (the transcriptome)

**Floral dip** a genetic modification, without plant tissue culture or regeneration, by modified *Agrobacteria* infiltrated through vacuum

**Intragenesis** a transgenesis, with DNA sequences transferred between closely related organisms.

**ODM** Oligonucleotide directed Mutagenesis. A generic terme covering several techniques of chromosomal or episomal genetic modification by introducing chemically synthesized oligonucleotide to modify targeted sequences

**Pangenome** very complex genomic context due to large variations in gene and regulatory elements contents among closely related varieties or ecotypes

**RdDM** RNA-directed DNA methylation. An epigenetic modification of DNA (methylation) due to the action of natural or introduced small interfering homologous RNA

**SDN** Site Directed Mutagenesis. A targeted genetic or epigenetic modification due to endonuclease such as "native" or modified ZFN, TALEN or Crispr-endonuclease

**TALEN** Transcription activator-like effector nucleases. Initially an artificial complex made with a double strand endonuclease domain fused to a DNA binding domain for targeted genetic and epigenetic modifications

**Transgenesis** a set of methods to introduce exogenous nucleic acids, either from distantly or closely related organisms, for genetic and epigenetic modifications by random or targeted insertion

**ZFN** Zinc-Finger Nuclease. Initially an artificial complex made with a double strand endonuclease domain fused to a DNA binding domain for targeted genetic and epigenetic modifications

### Introduction

The world of detection, analytical traceability still faces many challenges, whether to specify the geographical origin of a product, prevent adulteration of food by non-compliant products or pathogens, or the multiplexing of isothermal amplification methods.

In this chapter we focus on another challenge of detection and identification, the one what the Advocate General of the European Court of Justice recently advocated to consider as GMOs, but maybe exempting it of risk assessment and traceability/labeling, if no recombinant DNA was used in the modification processes of the species considered (Goldstein, 2014). These are 'new techniques of breeding' (NBT), i.e. of genome, epigenome and epitranscriptome modifications.

The challenge, beyond the easy and cheap documentary traceability which can easily be set up in the supply chains once big retailers wish it, is to both detect the final product of these NBT techniques and especially, in front of a non-traced element, to identify the NBT technique initially used.

The NBT techniques as grouped by the European Commission in the 2007 first report of the Dutch COGEM include several techniques that may lead to epigenome (RdDM, interfering RNA) modifications of mutations with intentional or not epimutations (epimutation of DNA and chromatin, or of RNA = epitranscriptome), sequences insertions ... ex: ODM, meganucleases, ZFN, TALEN and CRISPR systems for genome modification and epigenome (Claeys and Vialatte, 2016), transient or stable expression systems of transforming nucleic acids (agroinfiltration, floral dip ...) new formats of traditional processes for which the nature of the components varies (such as the graft of a non-GM scion on a GM rootstock), or new denomination of techniques according

to the origin of genetic sequences (cis-, intra- and trans-genesis), and finally a set of techniques grouped under the generic term of synthetic biology which was later on omitted.

Many of the techniques and molecules considered can be combined with each other or modified (e.g.: double-stranded endonuclease transformed into nickase) and involve the expression, penetration with or without the stable or provisional insertion of nucleic acid molecules, in the form of DNA (e.g. plasmids) and/or RNA (e.g. mRNA) and/or ribonucleoproteins complexes. In this later case, most authors did not ensure that RNP were free of contaminating DNA, a defect common to many, even commercial, preparations of purified proteins.

This short document does not allow to detail each of the specific characteristics to identify the implemented technique. We will also not discuss non-intended changes of organelle genomes or extrachromosomal DNAs despite their retrotransposition and persistence capabilities as episomes (Koo et al., 2018; Lanciano et al., 2017).

Finally, this chapter will not focus on the assessment of inherent risks, while several areas such as epigenetics remain largely unknown (EFSA et al., 2016).

## Overview

It is often argued that organisms contain many mutations, making them both 'Natural GMOs' and 'unable' to distinguish NBT induced mutations induced from so-called 'natural' mutations.

## Genomes Stability

Due to the evolution, genomes are essentially stable.

Evolution has indeed implemented a large number of genome protection mechanisms against transposable elements, invasive DNA ... and more generally non-self recognition systems, such as immunity in animals or PAMP in plants (Boller and He, 2009; Boyd et al., 2013; Iriti and Faoro, 2007; Liu et al., 2017b; Muthamilarasan and Prasad, 2013). As for prokaryotes, the Crispr-endonuclease defense system and the NHEJ, MMEJ ... are only some of the numerous elements of genomes' repair and protection against invasive DNA (Doron et al., 2018).

Plants like animals protect themselves from mutations not only by isolating germ cells with low reproductive rates during the early development, but also somatic cells through "stem cells" such as apical and axillary meristems. The mechanisms in place explain the very low rate of mutations transmitted to offspring even by old plants and old parts of plants as it can be observed for several years with old trees (Burian et al., 2016; Grant and Mitton, 2010; Lanner, 2002; Ledford, 2017; Sarkar et al., 2017; Watson et al., 2016). Millennia during which it is intuitively difficult to think that they could accommodate a growing number of genetic mutations ...

The work on the Napoleon's oak on the campus of the University of Lausanne is a very good example of this resistance of plant genomes to mutations and thus of their elimination during cells' cycles (Kuhlemeier, 2017; Schmid-Siegert et al., 2017).

Cellular systems repair DNA damages even the neutral mutations that are generally the most numerous to 'survive'. This corresponds well to the very modest rates of the residual spontaneous mutations found in both prokaryotes and eukaryotes (Badran and Liu, 2015; Lynch, 2010).

Given the very low known values of the spontaneously appeared mutations which are kept (Oksman-Caldentey and Barz, 2002), it is therefore wrong to say that apart from stressful situations (ranging from meiosis to the physical stress of mutagenic radiation, high temperature or drought, to those induced by cell cultures and mutagenic chemical products) many mutations persist in plant tissues. Moreover, it is well known that, in addition to the lack of reproduced experiments, the rates of spontaneous mutations differ according to the study methods used, the species and parts of the genome considered.

Apart from a selection pressure and a better "fitness" granted by some rare mutations or epimutations, conserved naturally born mutations therefore appear empirically very low and mostly neutral before disposal, as it can be seen in plants with vegetative reproduction.

## The Circulation of Informative and Detectable Molecules

A recurrent question in varietal selection, revived by the NBT, concerns the remote influence of a gene or of an epiallele, or of its expression products, thus beyond the cells in direct contact via the plasmodesma?

The outstanding long-distance information between the various parts of the plant, but also of animals via e.g. the placenta, between a parasite plant and its host and finally of the ingested nucleic acids on the animal's genes is now well documented (Avramidou et al., 2015; Citovsky and Zambryski, 2000; Fuentes et al., 2014; Goldschmidt, 2014; Hannapel et al., 2013; Lewsey et al., 2016; Shahid et al., 2018; Springer and Schmitz, 2017; Stegemann and Bock, 2009; Stephenson et al., 2018; Thieme et al., 2015; Zhang and Hu, 2017). Information is conveyed via hormones, proteins, electrical signals, but also nucleic acids (mRNA, miRNA, siRNA, large DNA fragments ...). More than 3000 genes are involved in grapevine in such transmissions at different frequency s according to the environment (Yang et al., 2015).

Finally, on the contrary of pompous titles (Kyndt et al., 2015), horizontal gene transfers that participate in evolution remain rare in eukaryotes. They cannot suggest that “GMO by horizontal transfer” are the norm, especially when the responsible living organisms differ (Chen and Otten, 2017).

It is therefore possible to find inheritable genetic, epigenetic and epitranscriptomic modifications in the distal parts of the rootstocks, and therefore in the detached fruit.

## Detection and Identification Techniques

Detection methods, aimed at ensuring a difference, can be used to identify an organism or techniques at its origin.

### Target Detection Methods

The methods of detection, qualitative and/or quantitative cover a very broad spectrum of techniques allowing

- (i) the observation of phenotypes (seed germination in the presence of a herbicide),
- (ii) the study of gene expressions (immunology, transcriptomics, exome sequencing),
- (iii) the detection of coding or non-coding genetic targets by signal or target amplifications (DNA or RNA), followed or not by hybridization ... (PCR, LCR, LAMP, NASBA, HIP, <sup>1</sup> Q  $\beta$  Replicase, SDA, <sup>2</sup> RCA, <sup>3</sup> RPA, <sup>4</sup> HDA, <sup>5</sup> NEAR, <sup>6</sup> SHERLOCK<sup>7</sup> ...), isotherms or not, <sup>8</sup> with or without a combination of techniques and targets (singleplex to multiplex, SNPLex, DNA chips after amplification ...), from single nucleotide variant (SNV) to large size with edge fragments with high fidelity DNA polymerases, helicase, nickase or recombinase (Barabaschi et al., 2016; Chang et al., 2012; Daher et al., 2016; Thomas et al., 2014; Zhang et al., 2017).
- (iv) the sequencing of modified or not DNA and RNA (Sanger method, high throughput sequencing according to various technologies and platforms [multiparallel, single molecule] thus genomes (whole or reduced to the exome), epigenome, transcriptome and epitranscriptome, per tissue or single cell) (Holst-Jensen et al., 2016; Pauwels et al., 2015).

Finally, chromosome walking, asymmetric PCR, *in silico* or effective genomic subtraction between genomes or transcriptomes are available as needed (Darrasse et al., 1994; Fu et al., 2010; Gong et al., 2018; Pawelkiewicz et al., 2017; Tengs et al., 2009).

Many of the necessary devices are available in miniaturized forms thus allowing amplification or sequencing to be used from the laboratory to the field.

These techniques allow unambiguous detection and identification over a very wide range of sequences, from the point mutation of an SNV to the insertion of sequences of any size (as for GMOs resulting from transgenesis), from chromosomal rearrangements to multiple copies of sequences. It is thus possible to unambiguously detect, on the contrary of what was asserted by the some people, by SNPLex, LCR or OLA, alone, with or without hybridization of the amplicons, any point modification in a specific 20 nt sequence of a genome (Beerli et al., 1998; Gaj et al., 2013).

These tools for studying polymorphism are relatively easy because they are often accompanied by other tools, for example data bases, statistics and decision tools (Schmid and Bennewitz, 2017; Willems et al., 2016).

Various combinations of techniques make it also possible to increase the sensitivity of the detection (enrichment by prior scavenging of target sequences, DNA chips, prior chromatographies, etc.), biosensors (DNA chips, etc.) with for example Raman spectrometry (Arulandhu et al., 2016; Kadam et al., 2017). All the detection techniques mentioned in this article and several other ones not listed here can be used in detection/identification of the products and techniques used, as they are in marker-assisted selection.

Results are generally gathered in genetic maps for varietal improvement, barcoding or meta-barcoding, and genotype/phenotype relationship identification. The choice of techniques (simplex vs. multiplex, junction of large junction fragments or SNV) to implement, targets to combine (genetic, epigenetic, etc.) according to the uses and costs will be largely facilitated by the use of databases, artificial intelligence, statistical tools and decision support systems (Dobnik et al., 2018; Marschall et al., 2018).

### Strategies for Identifying NBT Techniques and Traceability Targets for Derived Products

The majority of the reports and articles dealing with the subject of the detection of NBT products or the identification of the techniques at their origin do not establish, voluntarily or otherwise, a clear distinction between (i) the needs of the operators of the sectors, (ii) those of the owners of patents and producers of NBT products and (iii) those of the competent authorities in charge of the labeling of GMOs or the withdrawal from the market of unauthorized GMOs in the EU. Finally, a constant confusion has been maintained between (i) traceability, in the ISO documentary meaning, an easy and inexpensive procedure to implement when a large retailer requires it, (ii) detection that is limited to ensure the presence/absence of a detectable element, and (iii) the determination of the origin (NBT or “natural”) or the owner (producer of this GMO).

Confusion has thus been rapidly settled between the routine techniques used for enforcement, such as detecting the edge fragment PCR of GMOs derived from transgenesis, and detection and identification strategies prelude to routine analyzes.

It is therefore necessary to precisely distinguish the objectives sought as well as the targets (proteins, nucleic acids of the DNA, exome, epimutations, metabolites, etc.) and the techniques used (detection of phenotypic or genetic modifications, by amplification or sequencing or spectrometry ...) in combination or not.

The deployment of the variety of detection and identification methods used is always part of technical strategies that vary according to the purpose. Depending on the importance (significant proven risk, unauthorized product entering the EU area, high cost of products possibly to be withdrawn from the market, etc.), various methods performed by personnel of different qualification levels can be mobilized. Feedback from laboratories is important, hence the importance of the guidelines and meetings of the European ENGL network<sup>9</sup> with its national network heads.

Considerations of habit, cost, ease of use, available materials and staff training are not absent in the choice of techniques and the willingness to detect and identify targets, especially in the period of budget restriction of these last two decades.

Lastly, the States have favored self-checks in private companies in recent decades, with the enforcement laboratories of the Member States intervening, with ever-decreasing resources, only on a case-by-case basis (crises, doubts, legal procedure, etc.).

## The Matrix Approach

Detection and identification techniques of an organism or technique can rely as much on unambiguous signatures as on convergent clusters of evidence. A strategy more and more considered by risk assessment agencies under the name of "weight of evidence". Such a multi-target approach has been developed under the name of matrix approach in the case of the detection of known GMOs, for reasons of cost and speed of analysis, and unknown, supported when necessary by decision support systems (Dobnik et al., 2018; Holst-Jensen et al., 2009, 2013).

These convergent clusters of evidence can then be developed, combining technical and target, according to the needs and requirements of analysts and ordering party (complete control, routine traceability, legal framework with reinforced evidence, certainty *versus* speed, cost optimization. with documentary traceability ...).

More generally, the matrix approach is analogous in its principle to the anthropometric methods developed by Bertillon (Farebrother and Champkin, 2014). This principle is also the basis of biometric methods for digital fingerprint identification, facial and iris recognition, or DNA fingerprinting as used by the police (Jeffreys, 2013).

The data gathered for the matrix approach of GMOs identification, issued or not from NBT techniques, are nothing more than indices like those collected by the technical and scientific police and whose evidence can be statistically evaluated (Aitken, 2018; Kirk, 1953).

The matrix approach is therefore nothing more than a particular use of polymorphism, similar to that breeders use in markers assisted selection.

## Detection and Identification Targets

### Stresses Impacts and Consecutive Scars

The implementation of NBT techniques involves the use of the same set of old related techniques used for transgenic GMOs. Namely, the preparation of plant protoplasts or tissues, cells cultures, the vectorization of molecules so that they reach their nuclear target, generally a selection of the transformed cells followed by the elimination of the selection factors, new cells cultures for callus and seedling regeneration, all for the few non recalcitrant plant species (Marx, 2016b; Yau and Stewart, 2013). All these stressful techniques, sources of somaclonal variation, leave detectable scars in the genomes and epigenomes (Altpeter et al., 2016; Ledford, 2016; Miguel and Marum, 2011; Neelakandan and Wang, 2012).

These remaining scars have long been valued by seed producers in varietal selection (Karp, 1995). Conversely, these breeders attempt to reduce the effect of these unwanted mutations and epimutations in nuclei and organelles, generators of off-type during *in vitro*-propagation (Miguel and Marum, 2011; Rout et al., 2006).

Again, the identification of these scars results in genetic maps and marker-assisted selection irrespective of the target cell compartment (Bonev and Cavalli, 2016; Ciabrelli and Cavalli, 2015; Dekker, 2016; Dekker et al., 2017; Elsner, 2017).

These characteristic scars of cell lineages are obviously not specific to plants. Any change even a point mutation, like SNV,<sup>10</sup> usually affects the 3D structure of genomes, genes regulation, conformation of proteins, epistasis ... inducing various genomic disorders, factors of diseases as cancer for animals (Bianco et al., 2018; Editorial, 2018; Hehir-Kwa et al., 2016; Li et al., 2015a; Marx, 2017; Mendizabal et al., 2014; Niel et al., 2015).

In animals, these scars, which can be induced even by the immersion oil of the microscopes and may affect the development of the embryo, are known to be caused by various diagnosis and monitoring effects of preimplantation diagnoses and *in vitro* fertilization (Cyranoski, 2017; Dirix et al., 2005; Guil and Esteller, 2009; Hayward et al., 2017; Martinez et al., 2017; Marx, 2016a; Mulero-Navarro and Esteller, 2008; Scarpa et al., 2017; Zhao et al., 2014). More generally, all *in vitro* manipulations, including those used in assisted reproduction induces, by their epigenetic effects, Large Offspring Syndromes (Chen et al., 2017d; Ventura-Juncá et al., 2015).

There is therefore no domain or organism for which stresses, especially *in vitro* ones, do not induce inheritable scars which are identifiable, traceable and can be organized in patterns.

### The Persistence of Scars, Signatures and Unintended Effects During Backcrossing

Most of the changes intentionally or unintentionally induced by the related techniques, or NBT are transmitted to their cells offspring thus allowing the identification of products and techniques to their origin.

Indeed, the number of backcrosses effectively performed with Elite varieties for the marketed modified products is generally below the 6 backcross (Ferreira et al., 2016) necessary for a ca 95% of genomic “purification”. Moreover, far from these theoretical statistical values, the number of backcross needed to ‘clear’ a genome varies enormously with the species and the varieties considered, the number of loci to be separated, the relationships between loci that can be located in large non-Mendelian segregated blocks or co-segregate with unwanted loci, and the genomes’ size which may be allopolyploids (Wang et al., 2017c, 2018a, 2018b). These cleaning issues of genome cleaning are particularly true for the Elite varieties originating from selection process which may have led to fitness decreases (Bertheau, 2016; Kremling et al., 2018).

In the genomes can thus persist millions of ‘uncleanable’ base pairs (over 500 million in the case of *Triticum aestivum*), all detectable in subsequent generations (Batista et al., 2017; Holland, 2007; Hollick, 2017).

Finally, vegetatively propagated plants or those resulting from micropropagation, due to either phytosanitary or mass production reasons cannot ‘benefit’ of such ‘cleaning’, even partial, of their generally polyploid genomes and epigenomes (Bado et al., 2017).

As a result, much, if not the majority, in several instances, of unintentional mutations and epimutations, caused in a variety modified by any of the related techniques or NBT have a very good probability of ending up in its offspring.

### Limitations of the Identification Techniques of Unintended Changes

Numerous authors using NBT are claiming that they either drastically reduced the number of unintended changes (up to a 15000 FACTOR), i.e. generally off-targets, or they were unable to detect one.

In view of these claims it should be reminded that the majority of them are restricting their searches for cost reasons to partial sequencing of areas predicted by still imperfect off-target software (Cyranoski and Reardon, 2015; Haeussler et al., 2016; Kodama and Komamine, 2011; Tycko et al., 2016). Because of the currently important associated costs, most authors do not perform whole genome sequencing, especially in the case of species without a reference genome. Finally they do not search for epigenetic and epitranscriptomic modifications.

With the unexhaustive searches the authors are thus missing numerous mutations, including structural ones such as chromosome inversions, and exon skipping (Anderson et al., 2017; Kapahnke et al., 2016; Xiao et al., 2013; Zhao and Wolt, 2017).

The search for genetic, epigenetic and epitranscriptomic modifications due to related techniques and NBT therefore requires complete and reliable sequencing of genomes and epigenomes. Which is currently far from being the case.

### Sequencing

Genome sequencing is not just a simple alignment of nucleotides for which many errors already exist due to systematic biases of platforms for example (Alic et al., 2016; Goodwin et al., 2016). The multiple readings needed from deep-sequencing and now from ultra-deep-sequencing, not to mention ‘coverages’ generate large amounts of data whose analysis requires trained personnel, time, high-performance computers and thus important funding (Dahlö et al., 2018).

The work continues with the annotation step, again to be drastically improved, in order to detect point mutations and indels, variations in the number of copies and structural variants, not to mention the relation with functional changes (Hwang et al., 2015; Poplin et al., 2018; Xu, 2018). The proliferation of sequencing programs of thousands of plant varieties or animals shows how far we are from having reliable reference genomes, even for humans or important food species (Hehir-Kwa et al., 2016; Kehr et al., 2017; Wang et al., 2018c; Weller et al., 2017).

The same goes for epigenomics and transcriptomic variations related to alternative splicing and epitranscriptomic variations. If a number of sequencing errors could be overcome by avoiding tissue, i.e. multicellular, sequencing in favor of isolated cells (Ranasinghe et al., 2018), there is also much progress to be made (Yang et al., 2012).

Apart from the still costly whole genome sequencing, chromosome walking, asymmetric PCR, *in silico* or effective genomic subtraction between genomes or transcriptomes can be mobilized to discern more quickly and at a lower cost the differences between modified and conventional genomes (Darrasse et al., 1994; Fu et al., 2010; Gong et al., 2018; Pawelkowicz et al., 2017; Tengs et al., 2009).

The detection of unintentional changes therefore requires more sequencing than the one presented in the majority of published articles (Hardwick et al., 2017; Lam et al., 2012; O’Rawe et al., 2013).

### Sequence Analysis

Assembly, alignment and sequence comparison give rise to many errors in the absence of good reference genomes, errors also enhanced by the presence of repeated sequences.

Only a few rare species better studied, for which large funding has been spent have already been committed, and allow fairly reliable analysis (Shendure et al., 2017; Sims et al., 2014). Guidelines have yet to be enacted as to what to know and do (Domínguez Del Angel et al., 2018) and not only in the field of medical diagnostics (Santani et al., 2017). This need is found even for the

easiest sequencing such as exomes with 'gold standard' because of the current software flaws (Chowdhury and Garai, 2017; Diroma et al., 2017; Eisenstein, 2017; Goldfeder et al., 2016; Hwang et al., 2015).

Computers and analysis software as well as the training of staff are sources of many approximations that cannot ensure the absence of off-targets and other mutations in most, if not all, cases of NBT induced changes.

### Sequence Databases

Finally, the sequences databases still contain numerous errors of both sequences and annotations. Many improvements, including a drastic curation of databases, are still needed, even with 'gold standard' before asserting the absence of unintended effects (Jones et al., 2007; Zischewski et al., 2017).

More generally, the deficiencies detected in the quality of sequencing and the need for quality control and reproducibility enhancement led to the Massive Analysis and Quality Control (MAQC) society (Shi et al., 2017). It is also envisaged to develop aptitude tests and to set up a laboratories' accreditation system as in many other areas of detection (Davies et al., 2016; Hardwick et al., 2017).

While it is therefore necessary to remain skeptical about claims of no unintentional changes following the use of random or targeted mutagenesis techniques, we can expect when taking into account these limitations to discern many of these modifications in order to identify NBT techniques and analytically trace their products.

### Identification of Detection Targets

Historically, random mutagenesis techniques, applied to cell cultures or not, preceded the more or less targeted mutagenesis which evolved for plants from random transgenesis to more targeted NBT techniques.

### Effects of the Old Related Techniques

Apart from the graft, the NBT techniques employ the same intermediate *in vitro* steps, and their variants, as those used in transgenesis, techniques that we will call later *related techniques* (Ghosh et al., 2017; Heidebrecht, 2017; Lowder et al., 2016; Ran et al., 2017; Smith, 2017; Weeks and Yang, 2018).

These steps include protoplast production or tissue isolation for cell cultures, transformation with NBT products (ex: DNA, RNA or RNP system Crispr-endonuclease) generally vectorized (see below) which must pass the plasma and nuclear membranes while damaging the organelles' genomes (Liu et al., 2017a; Marx, 2016b; Mout et al., 2017; Thakore et al., 2018; Wang et al., 2016).

Then the few modified cells have to be selected before the selection system is more or less easily removed, by site-specific recombinase systems like Cre-Lox accompanied with the usual removal scars. Finally, after a new phase of cell culture, the whole process of cell transformation finishes with a callus then seedling regeneration step of the few non-recalcitrant plant species.

This set of *in vitro* techniques leaves sets of genetic and epigenetic scars, whose use, under the name of somaclonal variation of this somatic embryogenesis, has been a source of genetic diversity for plant breeders for decades.

### Scars of Cell Cultures and Seedlings Regeneration

This somaclonal variation stemmed from DNA mutations and epimutations of DNA, chromatin and RNA associated with the mobilization of transposable elements generating thus unstable genomes and epigenomes with hypermutations (Altpeter et al., 2016; Aydin et al., 2016; Kaeppler et al., 2000; Krishna et al., 2016; Marx, 2016b; Miguel and Marum, 2011; Neelakandan and Wang, 2012; Stroud et al., 2013; Yau and Stewart, 2013).

This somaclonal variation, making these plants GMOs according to the European 2001/18 directive, has never been considered in the risk assessments, nor labeling and post-market monitoring obligations even for GMOs issued from transgenesis (EFSA et al., 2016; Schouten et al., 2017).

These old related techniques have very little evolved since the beginnings of transgenesis in the 80–90s. They always require a laboratory specific know-how that can be lost due to lack of specific training, as it was recently noted in a recent conference (Ledford, 2016).

As a stress memory, the epigenomes influence the 'choice' of proliferation or quiescence of the daughter cells (Kedziora and Purvis, 2017; Yang et al., 2017). The estimation of the duration required to erase this 'memory' of stress depends on the techniques used to evaluate it.

The effect of such *in vitro* stress on isolated cells or multicellular clusters on their further development as bodies and reprogramming are well documented for animals (Ventura-Juncá et al., 2015). The intracellular injections are similar, not only by the sizes of the involved molecules, to the delivered "packages" of nucleic acids, proteins and/or ribonucleoprotein complexes of NBT.

It is only recently that the richness and unpredictability of unintentional changes has been better documented.

The *in vitro* resulting genetic and epigenetic modifications differ from the natural ones. For instance inheritable CHH<sup>11</sup> hyper-methylations are observed in *Arabidopsis* and rice (Springer and Schmitz, 2017) in which the mutation frequency (SNP, indels, base substitutions) is multiplied by a factor 248 compared to that, spontaneous, of *Arabidopsis thaliana* (Miyao et al., 2012). *Arabidopsis* cell cultures also induce more cytosine methylation, particularly in the heterochromatin regions, with in addition to class modifications of the small interfering RNAs (Tanurdzic et al., 2008).

Compared to wild rice, cell cultures enrich the epigenome by inheritable hypomethylated CG (Stroud et al., 2013), as observed in several other cases (Berdasco et al., 2008; Kumar and Van Staden, 2017; Tanurdzic et al., 2008). Other unintentional changes such as duplication genome result in tetraploid with methylation patterns differing from diploids (Springer and Schmitz, 2017).

We could multiply the number of examples of inheritable genetic and epigenetic modifications induced by related techniques but not addressed in the current risk assessments procedures (Arpaia et al., 2017; Filipecki and Malepszy, 2006; Neelakandan and Wang, 2012; Wolt, 2017). Yet epigenetics is increasingly seen as providing a significant part of progress in varietal selection, when it is not considered as a cause of heterosis (Gallusci et al., 2016; Jaligot and Rival, 2016; Springer and Schmitz, 2017).

Markers of *in vitro* cultures are therefore numerous, detectable (Bairu et al., 2011) and easily organized as the markers of assisted selection.

### Reagents' Delivery Scars

As for transgenesis issued GMOs most NBT use vectorization systems which damage cells, as for instance the very large molecule Cas9 DNA, RNA or RNP.

We thus find residues of these delivery systems (viruses, *Agrobacterium* ... but also biolistic, PEG, electroporation, lipofection with or without nanoparticles ...) targeting the site of action (nucleus and organelles) as DNA of plasmids, encoding or not RNA, or the recent RNP. These RNP use partially purified protein with contaminating recombinant DNA, which can be inserted in the genomes, as it was previously observed even for the commercial highly purified DNA polymerases used in PCR (Altpeter et al., 2016; Cameron et al., 2017; Chen et al., 2015; Engelke et al., 1990; Gelvin, 2003, 2008; Iulia et al., 2013; Kim et al., 2017; Songstad et al., 2017; Ulker et al., 2008; Witt et al., 2009).

*Agrobacterium* remains still the most effective vector (Pitzschke, 2013) with always many genetic and epigenetic traces. Those traces often small and difficult to detect originate not only from the plasmids, but also from the bacterial genome or from extrachromosomal circular elements never taken into account in the risk assessments of transgenesis issued GMOs (Gelvin, 2008; Ito and Machida, 2015; Schouten et al., 2017; Singer et al., 2012). The mechanism of integration of T-DNA is still unknown even if it seems to integrate preferentially into active genes with additional epigenetic modifications, which can facilitate the discovery of the scars of this reagents' delivery system (Bourras et al., 2015; Gelvin, 2017; Shilo et al., 2017).

Aborted natural infections of *agrobacteria* can be distinguished from those resulting from *in vitro* techniques by the scars' sequences and the bacterial origin (Chen and Otten, 2017).

These reagents' delivery scars are all accountable for determining the use of *in vitro* techniques.

### Scars of the Transformed Cells Selection Systems and Their Removal

Despite an improvement in transformation efficiencies, the selection of modified cells and the subsequent excision systems such as Cre-Lox or R/RS is still relevant (Germini et al., 2018; Manimaran et al., 2011). We thus find the usual scars of these selection systems, possibly with 'episomes' over several generations (Cheng et al., 2014; Scabill et al., 2008; Srivastava and Ow, 2003; Zhang et al., 2016b).

In conclusion, depending on the size, the type and location of inserted fragments, patterns, genetic and epigenetic maps can therefore be established for related techniques in use for NBT (Alkan et al., 2011). Moreover, the improvement of the algorithms, which for instance make it possible to differentiate microorganisms within complex species mixtures in metagenomic studies, should still benefit the establishment of these genomics and epigenomics patterns of scars left by related techniques (Albanese and Donati, 2017).

All these reviewed scars and other ones are constitutive of the identification tool of *in vitro* techniques.

### Random Mutagenesis Markers

Induced mutagenesis results either from the random action of mutagenic physical or chemical agents, or *in vitro* mutagenesis by random insertion, or finally by targeted modifications of the genomes and epigenomes (Oladosu et al., 2016). Among these methods, *in vivo* methods always result in chimeras (Bado et al., 2017). On the contrary the *in vitro* cultures can benefit from the totipotency of plant cells resulting in homogenous modified organism.

The *in vitro* application of chemical agents such as EMS,<sup>12</sup> ENU<sup>13</sup> or physical, be there *in vivo* or *in vitro*, such as UV or neutron flux,<sup>14</sup> induce mutations types depending on the agents used as well as the doses and duration of application. Various signatures, such as the types of mutation and epimutation caused, such as homo- or hetero-zygotes point mutations and transversions, their frequency of occurrence and location, at relatively constant or random intervals, can characterize the constitutive elements of the random mutagenesis, basis of Tilling and its variants (Blumenstiel et al., 2009; Doitsidou et al., 2016; Flibotte et al., 2010; Henry et al., 2014; Lehrbach et al., 2017; Li et al., 2001, 2015b; Roberts and Gordenin, 2014; Smith and Yun, 2017; Songstad et al., 2017; Till et al., 2007).

The induced mutation and epimutations rates exceed by several orders of magnitude those of spontaneous mutations, which can lead to hypermutation situations (Botstein and Shortle, 1985; Roberts and Gordenin, 2014). Again, the types of the provoked mutations and hypermutations can in themselves be signatures of past events (Fleta-Soriano and Munné-Bosch, 2016; Jaligot and Rival, 2016; Probst and Mittelsten Scheid, 2015; Wibowo et al., 2016). They also provide a higher level of knowledge through density differences e.g. in the form of hotspots, by the possible vicinity of changes, their positioning in areas frequently transcribed or not, the participation or not to structural rearrangements ...

This information constitutes a huge information source from the past of organisms, and thus of the mutagenesis techniques and culture conditions previously applied. However, this information is very rarely exploited, in addition to the organelles' scars due to stress are never taken into account (Chen et al., 2017; Sablok et al., 2017).

Genome and epigenome sequencing and omics can now complement or replace the polymorphism patterns (Batista et al., 2017; Endo et al., 2015; Fonseca et al., 2015; Henry et al. 2014, 2015; Li et al., 2016).

As with somaclonal variation, breeders collect the information in genetic and epigenetic maps (Doitsidou et al., 2016; Flibotte et al., 2010; Lehrbach et al., 2017; Li et al., 2001; Revollo et al., 2018). Due to the cost and information management difficulties these polymorphism profiles are often reduced in practice to some SNPs and QTL phenotypes more easily manageable. They are nonetheless identifiers of the technique initially and thus can be used to monitor the product in selection schemes and then in production (Daher et al., 2016; Godbout et al., 2017).

The increasing use of isogenic and single cells and of their sequencing will uncover more and more genomic and epigenomic scars issued from *in vitro* manipulation. The inheritable scars could help establishing cell lineages, histotypes, cell lines stratifications, and other tissue subtyping usable for identifying all kind of cell manipulations (Alexandrov et al., 2016; Chen et al., 2017b; Hayward et al., 2017; Kuipers et al., 2017; Lal et al., 2017; Letouzé et al., 2017; Nawy, 2017; Pennisi, 2018; Pfeifer, 2016; Villani et al., 2017; Wang et al., 2017a, 2017b; Zou et al., 2018).

There are thus clearly no technical barriers to differentiating between organisms with spontaneous natural mutations from random *in vivo* and *in vitro* induced mutations.

### Signatures of the NBT Techniques Used

In this short document we will only consider a few general aspects of these many NBT techniques, with multiple combinations and numerous modifications resulting in very numerous variants (eg: double-stranded cleavage activity of a nuclease transformed into a nickase or a methylase activity added to he nuclease activity).

Many NBT techniques initially focused on DNA modification before targeting the epigenome. However, all nucleic acid sequence change, whether of endogenous or exogenous origin, seeks to be accompanied by epigenetic signature (Sullivan et al., 2015). Epigenetics seems again to perform a cellular memory of all stress, including genetic manipulation, usable even after cisgenesis and intragenesis (Henikoff and Greally, 2016).

NBT techniques using mainly (except Floral dip and graft and some applications of RNAi resulting in chimeras (Shim and Kwon, 2010)) *in vitro* techniques unless producing chimaeras, their products are discernible *ab initio* from those resulting from spontaneously arising mutations. The challenge to differentiate NBT techniques themselves from derived products appears attainable...

It is therefore only a question of bringing together in some relevant subsets some of the scars and signatures left by the different techniques used to produce the NBT derived produce. Thus, essentially to perform the very classic work of any scientist involved in genetic diversity analyses, such as a breeder.

The detection/identification targets will in part vary with the type of NBT involved. The scientific and technological watch as conducted for ca. 2 decades by the ENGL laboratories will therefore remain relevant.

For example, in the case of grafting a non-GM scion onto a GM rootstock, it will be wise to first look for the DNA, mRNA and small RNA circulating from the GM part to the non-GM part or in both directions (Avramidou et al., 2015; Citovsky and Zambryski, 2000; Cuerda-Gil and Slotkin, 2016; Gallusci et al., 2016; Hannapel et al., 2013; Hovel et al., 2015; Koepke and Dhingra, 2013; Lewsey et al., 2016; Panda et al., 2016; Sharma, 2013; Zhang and Hu, 2017). But any other circulating signal influencing the distal parts of plants and animals can also be used in the initial phase of identifying the technical origin of the product (Savadi, 2017; Servick, 2017; Springer and Schmitz, 2017; Thieme et al., 2015). These epigenetic changes induced in the scions by the circulating RNAs allow the induction of canonical or not RdDM mechanism in addition to the activation of transposable elements.

Some quantification is foreseeable in a near future (Eisenstein, 2017; Li et al., 2017). Of course, for traceability purposes the signals originating from the GM parts will be more actively sought in the detached non-GM parts, such as fruit.

Generally speaking, NBT such as interfering RNA and oligonucleotides cause numerous false positives and false negatives (Heigwer et al., 2018; Jackson and Linsley, 2004; Kodama and Komamine, 2011; Mockenhaupt et al., 2015; Smith et al., 2017; Xu et al., 2006). All these unintended mutations and epimutations, as well as off-target effects are difficult both to predict and detect (Casacuberta et al., 2015; Riba et al., 2017).

We also frequently find vectorization residues (Sarita et al., 2017). It is likely that the tender<sup>15</sup> for a systematic review launched in 2016 by EFSA will provide a better understanding of the scars, signatures and other unintended effects left by non-coding RNAs and by extension on all types of interfering RNA and OdM. In the case of these interfering RNA the uncover of the 'seed regions' of the off-targets will facilitate the identification of the use of interfering RNA (Buehler et al., 2012; Das et al., 2013; Marine et al., 2012; Sigoillot and King, 2011).

Generally speaking, distal off-target effects (mutations and epimutations) therefore contribute to the set of signatures in addition to the targeted changes (Khan et al., 2016. Ramesh, 2013; Sullivan et al., 2015; Thakore et al., 2016).

On another issue, the use of nucleases, such as CRISPR-Case9 generates traceable indels inherited by the daughter cells, with even some specific 'patterns' such as the occurrence frequency and rather specific sizes (Junker et al., 2016. Songstad et al., 2017). These results are similar to those highlighting cells genealogies bearing genomic signature of the origin and history of the cells as imprinted alleles (Callaway, 2017; Frumkin et al., 2005; Junker et al., 2016; Kalhor et al., 2017; Rodrigues and Zilberman, 2015;

Sulston et al., 1983; Waters et al., 2013; Woodworth et al., 2017). Unintentional changes that can lead to a single barcode (Nawy, 2018; Williams, 2016).

If the transcriptome sequencing of isolated cells is still problematic for establishing cell lineages, the current technical improvements offer hope that tracking all the cells and their offspring will become accessible (Smaglik, 2017).

For SDN techniques based on Crispr-endonuclease targeting either DNA or RNA the signature of the technique can be constituted by the proximity (approximately 3–4 nucleotides) of a nuclease specific PAM sequence and of the desired mutation (within a target sequence of about 20 nucleotides). Recurrent detection of differences (on target and off-targets) and close PAM<sup>16,17</sup> sequence [s] would form a strong predictor, not to say an unambiguous signature of the employed technique. As PAM sequence vary among Cas nuclease, the analyst could even predict the kind(s) of the used nuclease (s). The suspicion of the artificial origin of the on-target mutation(s) will be reinforced by the type and frequency of off-targets still present, detection of exon skipping and structural mutations, the indel profiles already mentioned, and finally a large set of scars due to the *in vitro* related techniques. Some variants, such as modifications to change the double strand nuclease into a nickase, which require the proximity of 2 PAM, will increase the univocal side of the modifications signatures (Kleinstiver et al., 2015; Zhang et al., 2016a). The proxy-Crispr tool developed by Merck requires a succession of PAM sequences also providing an unambiguous signature of the NBT used (Chen et al., 2017a).

These SDN changes limited to the proximity of PAM sequences explains the race for discovering new endonucleases to expand the accessible part of genomes as well as the sequences' size to be integrated. Without going into details, such recognition sites also are discernible for the meganucleases, and TALEN as well as ZFN systems, be they canonical or modified.<sup>18</sup> The efficiency and specificity of ZFN and TALEN are indeed dependent on the sequence context as for the other SDN technologies, sequences usable as signature (Gaj et al., 2013; Gao et al., 2018; Luo et al., 2016; Sander and Joung, 2014).

Finally, as part of a matrix approach, we shall remember that stable modifications, particularly knocking and gene stacking, do not occur anywhere in the genome. Breeders are therefore looking for these 'safe harbor' that we can use in our matrix approach (Cantos et al., 2014; Rudgers and Sastry-Dent, 2015; Songstad et al., 2017).

If we remember that the bacterial adaptive immunity system introduce foreign sequences in genomes (ca 85% for archaea and ca 50% for eubacteria genomes), we cannot be surprised that genome changes induced by CRISPR-Cas9 be also 'saved' in the genomes.<sup>19</sup> These stress recordings would lead to a kind of barcode through a succession of mutations induced in Crispr sequences (Duarte, 2016; Kupferschmidt, 2016; McKenna et al., 2016; Nawy, 2016). The induced changes, and probably any biological event including environmental signals (Borkowski et al., 2016; Roquet et al., 2016), could therefore be tracked as it seems to be the case for humans (Perli et al., 2016) and bacteria (Barrangou and Doudna, 2016; Shipman et al., 2016; Wang and Qi, 2016).

Spontaneously occurring and induced univocal signatures therefore seem to be available for identifying NT and tracing their products. These biological recording systems of modifications might be imposed on laboratories and companies. To protect their patented products, there is nothing to prevent seed companies from developing an official registration system for SDN changes and other technical stresses (Ledford, 2018; Sheth et al., 2017; Tang and Liu, 2018). But the polymorphism patterns we presented above for related techniques and NBT could be sufficient in a more cost-effective way.

A large set of signatures and scars specific to the use of NBT techniques are therefore accessible by conventional polymorphism studies for the identification of NBT at the origin of a product. Signatures and scars which can complete with the previously considered ones.

### The 'Matrix Approach' for Differentiating *In Vivo* and *In Vitro* Modification Techniques and for the Identification of NBT

We previously saw that several elements, scars and signatures, could be linked to *in vitro* and NBT techniques. The next step is now to rationally organize them into patterns for unequivocally identifying the NBT and their products. It is essentially the day to day job of scientists in charge of studying genetic diversity and breeders in charge of exploiting it.

The availability of prior knowledge of what to target makes detection and identification easier and cost-effective. However, this knowledge does not constitute yet a prerequisite for initial identification. Here we meet strategies developed for identifying unknown objects or persons from clues as done by forensics and biometrics using e.g. facial and iris recognition, or fingerprinting.

Detection and identification can indeed much rest on unequivocal relationships with an element, like the fragments of the edge of the current transgenesis issued GMOs, that result from a body of convergent evidence, indirect presumptions and knowledge as it was done for detecting unknown GMOs by the matrix approach (Bohanec et al., 2013; Holst-Jensen et al., 2013).

Data bases, such as CRAVAT, decision support systems, data mining and artificial intelligence helps the analyst to gather the numerous data of polymorphism, select the relevant combinations of markers and typing, put into place the appropriate detection tools according to the purpose (Bohanec et al., 2016; Dobnik et al., 2018; Golestan Hashemi et al., 2018; Guinney et al., 2015; Holst-Jensen et al., 2016; Mallah et al., 2017; Paape et al., 2018; Roberts and Gordenin, 2014).

Agricultural production already uses such 'big data' approaches, whether for field diagnosis of deficiencies or diseases, or improvement of marker plants. Marker-assisted selection with or without high-throughput phenotyping uses strategies, statistical analysis software and other tools similar to those used to identify NBT techniques and products (Bhat et al., 2016; Crossa et al., 2017; Jahufer and Luo, 2018; Martinelli et al., 2015; Poland and Rutkoski, 2016; Valente et al., 2013; Varshney et al., 2016).

It is therefore surprising that the European Commission has not followed up on the proposal made in 2013 by its ENGL network to develop tools for the identification of NBT and derivatives. The proof of concept would have been available at the time of deciding the status of NBT derived products, while currently markets could be overloaded by consumers not desired products.

Socio-economic and political considerations are probably the cause of this failure to meet the labeling and information needs of consumers.

### Distinction Between Natural and Induced Mutations

It is often argued that targeted mutations due to NBT techniques are 'natural' and therefore indistinguishable from those spontaneously arising. Assumption under which the identification of techniques would be impossible and the traceability of products questionable.

As we have seen before, it is more of a political assertion than a scientific truth.

There are several ways of considering a mutation and thus of determining whether its origin is natural or induced, according to the philosophical definition that one wants to take from nature. Claiming the 'naturalness' of a mutation is of the same line of reasoning that asserting the current climate change is natural and not due to anthropic changes.

More prosaically, such an assertion puts forward only the tree that hides the forest.

The probability of occurrence of mutations and their maintenance in the absence of selection pressures are so low (the estimated probability of a mutation in the order of a substitution at a given moment by sampling natural populations would be from 0.01 to 0.0001 [Wakeley, 2008](#), [Watterson, 1975](#)), that human intervention is necessary to accelerate the occurrence of genetic diversity, as recognized by all plant breeders. In view of such probability values, the simple increase of mutations frequency is a constituent element of the artificial character of the mutations and therefore participates in the convergent body of evidence.

Finally, more generally, considering a mutation *per se*, isolated from its context, cannot constitute by itself a sufficient factor of proof of naturalness. As usual in logic, we must indeed consider all available information such as genomes and epigenomes modifications, their frequencies, their types ... associated to this element. In short, we need to consider a situation analogous to that of biometric identification systems such as fingerprints, iris recognition or facial recognition for which several indices converge toward the identification of an individual, and consequently of his past, as in the matrix approach developed above.

Logically, and according to the very similar approach of forensic medicine, any assertion, and more generally the formulation of a proposition, is admissible only according to the context ([Hicks et al., 2015](#)). Taking into account this context, there is therefore no difficulty in distinguishing a mutation spontaneously appeared, in non-particularly stressful conditions, from an induced mutation such as those that we have been preoccupied with so far.

### Detection in Routine

As usual, routine detection use only a relevant subset if not a single element of the initial identification matrix.

#### Quantification

The quantification required for labeling in the EU can be ensured for the majority of technical methods to modify genomes and epigenomes listed above, such as for Crispr-endonuclease induced mutations ([Harayama and Riezman, 2017](#)).

Qualitative methods can determine contents against a predetermined threshold through multiple control plans such as those used in seed quality control ([Kobilinsky and Bertheau, 2005](#); [Laffont et al., 2005](#); [Remund et al., 2001](#)).

#### Costs and Feasibility in Routine

Documentary traceability is a tried- and- tested method that can only be put in motion by the will of a few large operators such as supermarket chains who face the transparency demands of consumers ([Bertheau, 2013](#)). The market will do the rest ...

Traceability remains the selected method of supply chains for its ease of implementation, with or without blockchain as recently experimented in China by Carrefour, for its very low cost and control by operators, but it cannot protect consumers from frauds. Analytical controls and therefore the methods for detection and identification remain indispensable.

We have previously seen that methods for identifying NBT techniques exist and are already used in a similar form by breeders and seeds' companies. Routine detection methods are only simplified derivatives of this set of polymorphism's analyzes. These routine techniques, the majority of which use methods such as PCR or NASBA, which are well known to GMO control laboratories, can therefore be quickly taken over for validation by the EURL-GMFF, with the support of ENGL laboratories, and then directly applicable by all operators at all stages of the supply chains, thanks to the miniaturization of devices since 2001 ([Marx, 2015](#)).

To give an idea of the evolution of costs, it may be recalled that sequencing companies have recently announced they would provide in a short time full genome sequencing costs equivalent to the current PCR detection tests, i.e. 100 to 250 euros, list price, depending on the variant requested. Miniaturized amplification or sequencing devices such as the Oxford Nanopore MinIon allow field studies in the laboratory.

Legal and technical frameworks are all in place to ensure that the reference material is provided and analytical traceability of NBT products is quickly implemented as requested by consumers.

## Conclusion

Proof of concept of the ability to identify NBT techniques at the origin of certain products should be readily available as soon as the European Commission decides to provide the means as in the late 1990s with research programs on transgenesis issued GMOs.

As 30 years ago for transgenic GMOs, the analytical traceability and labeling of NBT products is technically accessible; it is part of a political choice and therefore partakes in the balance of power between stakeholders.

# Biogenic Amines in Food: A Review of Factors Affecting Their Formation

G Tabanelli, C Montanari, and F Gardini, Università degli Studi di Bologna, Campus of Food Science, Cesena, Italy

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Decarboxylases** enzymes which remove a carboxyl group from organic compounds, i.e. catalyzing the decarboxylation of amino acids leading to the production of the correspondent amines.

**Secondary metabolic pathways** Specialized metabolisms, which produce small molecules that are not required for microbial survival

**Non-thermal treatments** Food processing methods that are alternative to heat processing and which do not use heat to enhance microbial safety. These methods can reduce microbial contamination, while retaining the sensory attributes and nutrient content similar to raw or fresh products.

## Overview

Biogenic amines (BAs) are organic bases, which can be present in foods and cause several adverse reaction in the consumers. They are produced by microorganisms (mainly bacteria) through the action of decarboxylases, which are enzymes selectively acting on specific amino acids by removing the carboxyl group with the formation of the correspondent amine and CO<sub>2</sub>. The most important BA in foods and the relative precursors (shown in Fig. 1) are histamine, tyramine, 2-phenylethylamine, tryptamine, cadaverine and putrescine, being this latter a polyamine obtained through a direct decarboxylation of ornithine or through the agmatine deiminase pathway, which follow the decarboxylation of arginine to agmatine (Landete et al., 2008a; Marcobal et al., 2012; Wunderlichová et al., 2014). In addition, other polyamines (spermine and spermidine) can be produced with a more complex pathway that starts from putrescine (Bardócz, 2005).

The decarboxylative pathways are activated as cell response to acid stress, due to their contribution to maintain intracellular pH. In addition, BA production can lead to the energization of the membrane proton-motive force, with the transfer of a net positive charge outside the cell, bringing supplementary energy. In this framework, such decarboxylations belongs to the secondary transport systems responsible for electrogenic exchanges which can support the primary metabolism in environmental critical conditions (Konings, 2006; Pereira et al., 2009; Perez et al., 2015).

The presence of BA in food can constitute a risk for the consumer since they may cause severe health effects. Ingestion of food containing high amounts of BA is implicated in various pharmacological and toxicological reactions, i.e. headache, heart palpitations, vomiting and diarrhoea. Due to their relatively low threshold toxic levels and the severity of symptoms they may cause, the most dangerous BA are histamine and tyramine, which are responsible for symptomatology known as "scombroid fish poisoning" and "cheese reaction", respectively (Hungerford, 2010; McCabe-Sellers et al., 2006).

Several bacteria are able to produce BA. Among Gram negative, enterobacteria and pseudomonads have the greatest potential in the accumulation of histamine, putrescine and cadaverine (Landete et al., 2008a; Morii and Kasama, 2004; Wunderlichová et al., 2014). Anyway, BA are accumulated also by Gram positive bacteria. In fact, the decarboxylase activity has been described in members of several microbial groups, such as staphylococci, *Bacillus* spp. and, especially, Lactic Acid Bacteria (LAB). In particular, this latter group includes the most important tyramine producers (enterococci and some lactobacilli) (Marcobal et al., 2012). Moreover, the production of other BA (namely histamine and putrescine) has been observed in LAB strains (Landete et al., 2008a; Wunderlichová et al., 2014). It is also important to underline that, in many cases, the activities of decarboxylases are expressed independently of cell viability and that these enzymes are particularly resistant to harsh environmental conditions, even after the lysis of the cells responsible for their production (La Gioia et al., 2011; Rossi et al., 2011; Gardini et al., 2012).

The genetic organization of decarboxylase clusters has been reviewed for tyramine (Marcobal et al., 2012), histamine (Landete et al., 2008a) and putrescine (Wunderlichová et al., 2014). Generally, enzymes responsible for specific amino acid decarboxylation are organized in operons in which some genes are present, such as those responsible for the production of the decarboxylase, the antiporter permease (amino acid/BA) and a correspondent amino acid-tRNA synthetase.

## Occurrence in Foods

### Non-fermented Foods

The presence of BA is dependent on the precursor availability in food (proteins and/or free amino acids) and their contamination by decarboxylating microorganisms. In non-fermented foods, these compounds have been related to poor food hygienic quality because are associated with a massive growth of spoilage microorganisms (>7 log cfu g<sup>-1</sup>) with decarboxylating activity. For

**Figure 1** Most important biogenic amines in foods and their relative precursors.

this reason, several Authors proposed BA content as a microbial quality index, as indirect indicators of excessive microbial proliferation (Özogul and Özogul, 2006; Ruiz-Capillas and Jiménez-Colmenero, 2004).

In particular, scombroid fish (such as tuna, sardines, anchovies, mackerel, etc.) have been associated with cases of histamine intoxication because of their high histidine content and the proliferation of histidine decarboxylating Gram-negative bacteria (i.e. *Photobacterium* spp. *Enterobacteriaceae* such as *Morganella morganii*, *Enterobacter aerogenes*, *Raoultella planticola* and *Klebsiella oxytoca* and *Aeromonas hydrophila*) (Knöpe et al., 2014; Prester, 2011). Regarding fresh meat, when properly stored, it contains only low levels of spermine, spermidine and putrescine, which directly derive from the animal, but an improper storage can

promote the growth of an environmental Gram negative microflora that can produce high concentrations of cadaverine and histamine (Jairath et al., 2015).

### Fermented Foods

On the other hand, fermented foods are often characterized by the presence of different BA. The accumulation of these compounds is mainly caused by decarboxylase positive non-starter microflora, which can be present in the raw materials and in the environment and can massively grows when spontaneous fermentations occur or during the ripening period (when the selected starter cultures can be replaced by wild strains) (EFSA, 2011). BA, and in particular histamine and tyramine, can be accumulated in relevant amounts in dairy products, mainly in ripened cheese and in those obtained from raw milk. These products represent a suitable matrix for BA accumulation especially for the precursor availability (deriving from casein proteolysis) and the presence of wild microflora, which can prevail during ripening phases. BA concentrations up to 2000 mg kg<sup>-1</sup> has been detected (Linares et al., 2011).

Fermented sausages are another suitable substrate for BA accumulation. The presence of high precursor concentrations and, usually, the impossibility to eliminate the original spontaneous microflora are the reasons for high BA content, mainly tyramine, found in some cases in these products, especially in those obtained without the addition of starter cultures (Suzzi and Gardini, 2003; Latorre-Moratalla et al., 2010).

### Alcoholic Beverages

Differently from cheeses and sausages, the presence of precursors in wine and beer is relatively scarce. Nevertheless, the high amount of ethanol, which inhibits the action of the natural liver detoxifying enzymes for BA (amino oxidases), enhances the toxicity of BA. Then, also small amounts of these substances may have negative effects on people consuming alcoholic beverages (Ancín-Azpilicueta et al., 2008). The accumulation of BA, mainly histamine, cadaverine and putrescine, in wine is attributed to the metabolism of LAB and, for this reason, the activity of the bacteria responsible for malolactic fermentation has to be strictly controlled. Also fermented vegetables can be a favorable environment for the accumulation of BA. These aspects have been studied particularly in sauerkraut (Rabie et al., 2011) and in table olives (Medina-Pradas and Arroyo-López, 2015).

### Regulation aspects

Concerning the regulatory aspects regarding the presence of BA in foods, there is no legal regulation with the exception of fishery products, for which the maximum acceptable level of histamine is defined by several national and international Authorities. The European Commission Regulation (EC) 2073/2005 and successive amendments indicated a maximum histamine amount between 100 mg kg<sup>-1</sup> (m) and 200 mg kg<sup>-1</sup> (M) (n = 9, c = 2) in fishery products from scombroid species. The level is increased to 200 mg kg<sup>-1</sup> (m) and 400 mg kg<sup>-1</sup> (M) for fishery products subjected to enzyme maturation in brine (EC, 2005).

EFSA (2011) conducted a qualitative risk assessment concerning BA in fermented foods in the European Union. According to the conclusion of this investigation, no adverse health effects have been observed for the consumption of 25–50 mg of histamine per person per meal, even if smaller amount of this BA (few mg) can be dangerous for patients with histamine intolerance. The level of attention for tyramine is consistently higher (600 mg per person per meal). This dose is drastically lowered in individuals using third generation monoamino-oxidase inhibitor drugs, which should not be exposed to levels higher than 50 mg per person per meal.

### Factors Influencing the BA Formation in Foods

Several intrinsic and extrinsic factors can affect the formation of BA in foods (Gardini et al., 2016; Naila et al., 2010). Anyway, the first requirement to reduce the risks due to BA is related to the microbiological quality of the raw materials, and, in particular, to the absence or low presence of wild microorganisms with specific decarboxylases activities. In addition, amino acid decarboxylases responsible for BA production are generally stable and active under a wide range of environmental conditions, even when they are released in the medium after death and lysis of the cells that produced the enzymes. The increase of BA due to the presence of cell free extracts of culture able to produce decarboxylases has been demonstrated *in vitro* and in food such as cheeses (Gardini et al., 2016).

### Environmental Factors

The main environmental factors affecting microbial activities in foods are temperature, *a<sub>w</sub>* (and then salt concentration) and pH. These same factors affect BA formation by influencing both the metabolisms of microbial cells and/or the activity of decarboxylase enzymes independently on the cell viability.

Each microbial species presents its own optimum temperature and can grow in a more or less wide temperature range. This is obviously true also for decarboxylating microorganisms. Anyway, the better conditions for cell growth do not necessarily coincide with the optimum condition for BA production. In addition, the optimum conditions for BA accumulation by pure enzymes or cell free extracts do not always coincide with those characterizing living cells. The interaction between these two aspects is responsible

for the final BA amount. For example, in a tyraminogenic strain of *Enterococcus faecalis* inoculated in model system, after 24 h of incubation the maximum activity of the decarboxylating enzyme was detected at 37 °C, while the maximum tyramine content due to cell metabolism was found at 20 °C (Bargossi et al., 2015). This can be explained by the fact that the tyrosine decarboxylase is more active under harsh conditions for the cells, which require supplementary energy to counteracting stress conditions. In any case, the ability to produce BA is generally limited by the decrease of temperature and thus, the control of the cold chain during food storage and commercialization remains one of the main tool to avoid the accumulation of these undesired products after manufacturing. In the case of fermented foods, the temperature adopted in the first days of fermentation is crucial for the potential BA accumulation. In fact, in this first step of process, the members of the microbiota characterizing the ripening are selected (Gardini et al., 2008).

Increasing salt concentration significantly contributes to the limitation of the decarboxylating activities. However, the amounts of salt needed to control the BA production are often too high for food applications (Tabanelli et al., 2012). This is particularly true for LAB responsible for tyramine production (such as enterococci) and their decarboxylases, which can maintain their activity even at concentration higher than 20% (Bargossi et al., 2015). Gram negative aminobiogenetic bacteria are more sensitive to NaCl. Species belonging to *Photobacterium* spp. enterobacteria or pseudomonads are limited in BA production by salt concentration of 4%–5%, even if their decarboxylases are still active in these conditions (Morii and Kasama, 2004). Nevertheless, it has been demonstrated that initial salt concentrations of about 5%, which are added in some traditional meat fermented products, can significantly contribute to the limitation of BA production. However, such concentrations are not compatible with the trend of the industry to reduce NaCl in foods.

Since decarboxylation is a cellular activity to counteract acidic stress, several studies were addressed to exploit the relationship between pH and BA accumulation. Also in this case, the effect of pH is different if the decarboxylase activity of living cells, pure enzymes or cell free extracts is considered. From a genetic point of view, the transcription of many decarboxylase cluster genes is induced by low pH and favors the cell reaction to acidic stress (Marcobal et al., 2012; Perez et al., 2015). Tyrosine decarboxylases showed their maximum activities generally at pH comprised between 5 and 6 (Bargossi et al., 2015; Moreno-Arribas and Lonvaud-Funel, 2001). By contrast, the maximum tyramine accumulation of living LAB cells is always observed at pH lower than these values (between 4 and 5), as an active stress response. Optimum pH for histidine decarboxylase in Gram negative bacteria (*Photobacterium* spp and *M. morganii*) are close to the neutrality (between 6 and 7) (Kanki et al., 2007) while histidine decarboxylase of *Streptococcus thermophilus* has an optimum at pH 4.5 (Tabanelli et al., 2012).

As reported above, in general, the literature data indicate a great variability in the cell decarboxylase responses to the environmental factors. This is due not only to the intrinsic differences between bacterial metabolic pathways but also to the matrix considered and to great heterogeneity characterizing decarboxylase activity, even within strains of the same species.

Due also to this heterogeneity, in fermented foods the possibility to act on environmental factors in order to modulate BA production is often limited by the fermentation and ripening conditions and by health trends, as in the case of the reduction of NaCl content. For this reason, in this kind of product, the main tool to counteract BA accumulation is the choice of starter cultures without decarboxylating activity, able to rapidly and persistently colonize the environment and showing the capacity to inhibit or reduce the growth of aminobiogenetic wild microorganisms through a rapid acidification. Moreover, some starter cultures can produce antimicrobial compounds such as bacteriocins or other substances active against pathogens but also against aminobiogenetic bacteria. Recently, it has been demonstrated that the use of nisine producer strains of *Lactococcus lactis* can limit BA production by *S. thermophilus* and *E. faecalis* (Tabanelli et al., 2014).

### Technological Factors

Given that the ability to produce BA is often a strain rather than a species feature, in the last year a particular attention has been posed in the selection criteria of starter cultures, which are genetically and phenotypically screened to be sure of the absence of amino acid decarboxylase potential.

Linares et al. (2012) and Latorre-Moratalla et al. (2012) reviewed the use of selected starter cultures aimed to limit BA accumulation in dairy products and in fermented sausage production, respectively. In general, the use of the so-called autochthonous starter cultures, i.e. strains isolated from the same type of fermented product, reduced BA concentrations in these products. Also in wine, the choice of selected LAB strains unable to produce BA is essential for malolactic fermentation process in winemaking (Moreno-Arribas et al., 2003).

Beside to their role as a starter, some bacteria can be exploited for their potential in BA degradation. In fact, many microorganisms, among which LAB, can produce amino oxidases, which are the enzymes responsible for BA detoxification. Alvarez and Moreno-Arribas (2014) reviewed these aspects and reported this ability for some *Lactobacillus*, *Pediococcus* and *Oenococcus* strains, while Herrero-Fresno et al. (2012) showed that the use of two strains of *Lactobacillus casei* able to degrade histamine and tyramine could reduce the accumulation of these BA in Cabrales-like mini-cheeses. In matrix poor in BA precursors (such as wine) some Authors reached better results with the use of *Lactobacillus plantarum* able to deaminate BA (Capozzi et al., 2012).

However, it is well known that the use of selected starter cultures alone cannot be sufficient to assure the reduction or inhibition of BA production in fermented foods. For this reason, other technological factors can be considered for controlling amino acid decarboxylation, i.e. the use of antimicrobial substances and technological additives.

It is reported that BA accumulation is higher in nutritionally poor environments, being decarboxylative activities secondary metabolic pathways (Konings, 2006). Several authors tested *in vitro* BA production in relation to sugar supply. *S. thermophilus*

produced increasing amount of tyramine in the presence of limiting amounts of lactose (0.1%) (La Gioia et al., 2011) while increasing fructose and glucose concentration inhibited histamine accumulation of *Lactobacillus hilgardii*, *Pediococcus parvulus* and *Oenococcus oeni* (Landete et al., 2008b). In many fermented foods, the sugar amount added can modify the equilibrium among the microbial populations including decarboxylating bacteria. Bover-Cid et al. (2001) found that sausages produced without the addition of sugar in minced meat mixtures had significantly higher tyramine and cadaverine concentrations, concluding that sugar omission is detrimental for product quality and safety.

Preservatives can reduce the BA formation through the inhibition of biogenic bacteria growth and interfering with the equilibrium among microbial populations (Gardini et al., 2016; Naila et al., 2010). In fermented sausages, the presence of potassium sorbate, ascorbic acid and nitrites affects BA formation (Naila et al., 2010). Also sulphur compounds were used to control BA accumulation and, in particular, the addition of sulphur dioxide (SO<sub>2</sub>) in wine after malolactic fermentation prevented amine formation by aminobiogenetic LAB, due to the inhibiting effect on cell metabolism rather than to the repression of the decarboxylases activity (Landete et al., 2008b).

Natural antimicrobial compounds, such as essential oils and spices, could replace traditional additives in food since can exert antibacterial activities against many species, including decarboxylating bacteria. For this reason, these substances can be useful for the reduction of BA in foods (Komprda et al., 2004). In particular, essential oils containing eugenol, thymol and carvacrol reduced BA formation depending on their concentrations and bacterial species (Cai et al., 2015; Özogul et al., 2015). Also spices can influence BA accumulation in food, due to their content of several molecules among which capsaicin (in pepper), cinnamic aldehyde (in cinnamon) and allicin (in garlic) that exert antimicrobial and antioxidant activity (Naila et al., 2010).

Among technological factors, food packaging can influence both qualitatively and quantitatively BA production. In fact, the use of modified atmosphere and, specifically, the absence of oxygen inside packaging (obtained also through the use of oxygen scavengers) may delay or reduce the production of BA, selecting spoilage microorganism pattern and inhibiting microbial population endowed with decarboxylating properties (i.e. enterobacteria producing putrescine, cadaverine and agmatine). The presence of carbon dioxide (CO<sub>2</sub>) can act as bacteriostatic agent against many BA forming bacteria in refrigerated foods. In particular, high CO<sub>2</sub> concentrations have been tested in fish and meat and results showed a lower production of histamine, putrescine and cadaverine (Naila et al., 2010; Gardini et al., 2016).

Besides packaging, several non-thermal treatments could determine a lower BA content, due to the reduction or delay in microbial growth along the shelf life. Among these treatments food irradiation, pulsed electric fields (i.e. short electricity pulses that cause microbial inactivation with minimal detrimental effect on food quality attributes) and pressure treatments can be mentioned. Among these latter techniques, High Hydrostatic Pressure (HHP) up to 600 MPa can limit BA content by controlling decarboxylating microflora both in dairy and meat products (Novella-Rodríguez et al., 2002; Ruiz-Capillas et al., 2007). Also High Pressure Homogenization (HPH) can be an important tool to control the BA accumulation in dairy foods (Lanciotti et al., 2007).

## Conclusions

The negative effects of BA are strictly dependent on the conditions of the consumers. In other words, it is difficult to define limits associated with negative symptoms. Healthy consumers can ingest BA even in relative high amount without serious diseases because of the capacity of their organisms to detoxify them through the natural enzymes assigned to this function (amine oxidases). However, food industry has to face the request for a BA control of increasing segments of consumers less protected against BA (younger and elder people, immunocompromised, patients taking specific drugs). In addition, the presence of BA is undoubtedly a marker of improper procedures in the production and storage of foods. These considerations, such as the search for an always higher quality of foods, have brought several national and international food authorities to focus their attention on the content of BA in foods. If they should be absent in non-fermented foods, the question may be different for fermented foods, in which their presence could be, at some extent, unavoidable. Nevertheless, any effort to reduce BA concentration also in these products has to be done. As described here, there is not a unique or specific procedure to lower this risk, but a variety of actions can be taken to limit amine accumulation. An acceptable final result could be reached only modulating the factors considered above with the aim to inhibit the growth of decarboxylating microorganisms and the activity of their decarboxylases.

## Acknowledgments

The authors would like to thank Dr Tommaso Tabanelli for his contribution to the figure.

## Plant Alkaloids

**Birgit Dusemund, Bernd Schaefer, and Alfonso Lampen,** Department Food Safety, German Federal Institute for Risk Assessment, Berlin, Germany

### Overview

Natural sources of food are very well accepted by the consumer because of the positive image in regard to their secondary plant phytochemicals which may have for example anti-oxidative effects. However, plants (e.g. tea) or plant-based products such as food supplements may also contain natural contaminants. Since recently, therefore phytochemicals such as 1,2-unsaturated pyrrolizidine alkaloids (PAs), tropane alkaloids (TAs), and ergot alkaloids (EAs) are in the focus of Risk Assessment as examples for natural contaminations of food and feed. After rapid absorption upon oral intake these natural phytochemicals can induce very different tissue toxicity with acute and after long term ingestion chronic effects (e.g. PAs). Whereas EAs and TAs are believed to be non-genotoxic phytochemicals contain the PAs examples of derivatives that are proven to be genotoxic and carcinogenic in animal experiments. Therefore, PA exposure via common foods, contaminated with PA-producing plants or parts thereof raised concern, especially regarding the potential of genotoxicity and carcinogenicity of PAs. In summary, besides well-known classical contamination the contamination of food and food products with natural phytochemicals is a challenging food safety issue.

### Pyrrolizidine Alkaloids (PAs)

Over 500 different pyrrolizidine alkaloids (PAs) and their N-oxides are known and they are reported to occur in more than 6000 plant species (e.g. [Mattocks, 1986](#); [IPCS/INCHEM, 1988](#); [BfR, 2016](#); [EFSA, 2011](#)). PAs are secondary plant compounds and are undesirable substances in food and feed ([Fig. 1](#)). Plants containing pyrrolizidine alkaloids primarily belong to the Asteraceae, Boraginaceae and Fabaceae. PAs are esters of 1-hydroxymethylpyrrolizidine (necine base), which may bear a hydroxyl group at position 7, and aliphatic monocarbon or dicarbon acids (necine acids). PAs can occur as monoesters or diesters depending on the esterification of one or both hydroxyl groups. Cyclical diesters result from esterification with two carboxyl groups of a dicarbon acid.

**Figure 1** PAs as undesirable components in Foods.

Depending on the necine base, a distinction is primarily made between PAs of the retronecine, heliotridine, otonecine or platyne-cine type. PAs with 1,2-unsaturated necine structure esterified with at least one branched C5-carboxylic acid are associated with hepatotoxic, carcinogenic and genotoxic effects. This includes the unsaturated PAs of the retronecine, heliotridine and otonecine type but not the saturated pyrrolizidine alkaloids of the platyne-cine type (e.g. [Mattocks, 1986](#); [IPCS/INCHEM, 1988](#); [BfR, 2016](#); [EFSA, 2011](#)).

Food items that may contain unsaturated PAs include (herbal) teas, vegetables, honey, grain-derived products, eggs, milk and meat. The occurrence of PAs in food is mainly the consequence of contamination of food via PA-producing plants (e.g. [BfR, 2013a, b, 2016](#); [Mulder et al., 2015](#); [EFSA, 2011, 2016, 2017](#)).

PAs are generally rapidly absorbed upon oral intake. Following partial metabolism, excretion occurs primarily via the kidney and to a lesser extent in the faeces. In the organism unsaturated PAs are metabolised to pyrrole derivatives through hydrolysis, N-oxidation and dehydrogenation. N-oxide metabolites that are formed are highly soluble in water and are excreted extremely quickly in the urine, and this metabolic pathway is therefore seen as a detoxification pathway. However, the transformation of the uncleaved esters to toxic pyrrolic esters in the liver due to mixed-function oxidases, constitutes a toxification reaction. These pyrroles are highly reactive alkylating agents reacting with nucleic acids and proteins to form adducts and are considered active metabolites that are causing the hepatotoxic, hepatocarcinogenic and genotoxic effects (e.g. [Mattocks, 1986](#); [IPCS/INCHEM, 1988](#); [EFSA, 2011, BfR, 2016](#)).

The acute and chronic liver toxicity of unsaturated PAs is well known due to case reports in humans and animals and outbreaks of human poisonings by grain crops contaminated with seeds of unsaturated PA containing plants. Symptoms of acute PA poisoning are abdominal pain, ascites, vomiting, nausea, diarrhoea, oedema, jaundice and fever. The poisoning is typically associated with hepatic veno-occlusive disease (HVOD) involving obstruction of the small veins with sudden onset of hepatomegaly and ascites, and which may be lethal. A low long-term exposure to unsaturated PAs through the intake of food is known to yield chronic HVOD leading to cirrhosis of the liver. Full recovery from HVOD is possible. A chronic disease may develop among survivors of an acute HVOD or with longterm intake of small quantities of unsaturated PAs and result in liver cirrhosis. Other organs like the lungs (pulmonary hypertension) and the cardiovascular system (cardiac right ventricular hypertrophy) may be affected too. Unsaturated PAs exert foetotoxic and teratogenic effects in higher doses (e.g. [Mattocks, 1986](#); [IPCS/INCHEM, 1988](#); [EFSA, 2011, BfR, 2016](#)).

Some unsaturated PAs and corresponding plant materials have been evaluated by the International Agency for Research on Cancer (IARC). IARC classified lasiocarpine, riddelliine and monocrotaline to be possibly carcinogenic to humans (group 2B) ([IARC, 1976,1983,1987,2002](#)).

Several national and international bodies have carried out risk assessments of the intake of unsaturated PAs via food considering the toxic effects of PAs as cumulative ([COT, 2008](#); [BfR, 2013a, b](#); [EFSA, 2011, 2017](#)).

Regarding neoplastic lesions the British Committee on Toxicity of Chemicals in Food, [Consumer Products and the Environment \(COT\) in 2008](#) and the German Federal Institute for Risk Assessment (BfR) in 2013 and 2016 recommended to use a BMDL<sub>10</sub> (the lower confidence limit on the benchmark dose associated with a 10% response) of 0.07 mg/kg body weight (bw) per day derived from a 2 year carcinogenicity study of lasiocarpine in male rats as reference point to assess the exposure for any PA ([NCI, 1978](#); [COT, 2008](#); [BfR, 2013a, b](#); [EFSA, 2011, 2017](#)). A margin of exposure (MOE) of at least 10,000 was considered to be unlikely to be of high priority for risk management. PAs have also been evaluated as undesirable substances in food and animal feed by the [European Food Safety Authority \(EFSA\) in 2011 and 2017](#) ([EFSA, 2011, 2017](#)). In its latest evaluation EFSA established a new reference point of 0.237 mg/kg bw per day as BMDL<sub>10</sub> to assess the carcinogenic risks of PAs, based on a 2 year carcinogenicity study of riddelliine in female rats ([NTP, 2003](#); [EFSA, 2017](#)).

According to recent assessments dietary exposure to PAs may occur at levels that could be of concern with respect to carcinogenicity, especially for subpopulations which consume relatively large amounts of specific PAs-containing foods such as herbal teas. However, intake of PAs from the regular diet is not associated with risks of acute toxicity ([Mulder et al., 2015](#); [EFSA, 2011, 2016, 2017](#)).

## Tropane Alkaloids (TAs)

Tropane alkaloids (TAs) are natural components contained in certain plants such as henbane, thornapple and deadly nightshade. Tropane alkaloids-containing plants are found in numerous families, such as Solanaceae, Erythroxylaceae, Convolvulaceae, Brassicaceae, and Euphorbiaceae. A total of more than 200 different TAs have been identified in plants (e.g. [BfR, 2013c](#); [EFSA, 2013](#); [Mulder et al., 2016](#)). Some of these alkaloids are also used in medicinal products, for example atropine (a mixture containing equal amounts of the isomers (–)-hyoscyamine and (+)-hyoscyamine), (–)-hyoscyamine (–)-scopolamine and cocaine. In the modern food chain TAs, such as (–)-hyoscyamine (–)-scopolamine occur in food and feed, due to contamination with seeds of especially *Datura* spp. plants containing high concentrations of hyoscyamine and scopolamine (e.g. [BfR, 2013c](#); [EFSA, 2013](#)). In 2003, cases of domestic food poisoning with a typical syndrome of TA toxicity has been reported from Slovenia due to ingestion of a traditional dish made of buckwheat flour contaminated with *Datura stramonium* seeds. Outbreaks of acute toxicity due to contamination of crops with *Datura* seeds are also reported from Ethiopia and Botswana. Intoxications of children, teenagers and adults by TAs are reported mainly from abuses because of the hallucinogenic effects or from accidental exposure ([Perharič, 2005](#); [EFSA, 2013](#)).

Several tropane alkaloids are muscarinic receptor antagonists and used as powerful anticholinergic drugs. Some of them are hallucinogenic. Atropine, hyoscyamine, and scopolamine are used therapeutically for different medical indications, e.g. for treating spasms in the gastrointestinal tract, the biliary ducts or the urinary tract or for the prevention of kinetosis. The lowest single therapeutic dose for oral use is 1.4 µg/kg b.w. for (–)-hyoscyamine, 6 µg/kg b.w. for atropine (corresponding to approx. 3 µg/kg b.w. (–)-hyoscyamine), and 2.5 µg/kg b.w. for (–)-scopolamine (e.g. BfR, 2013c; EFSA, 2013). Known adverse effects of these alkaloids at the lowest oral therapeutic doses are slight cardiac slowing, dryness of the mucosa of the upper digestive and respiratory tract and reduced perspiration. At higher therapeutic oral doses an increased heart rate and mydriasis have been observed. Unlike (–)-hyoscyamine and atropine, (–)-scopolamine at levels of oral therapeutic doses causes a depression of the central nervous system (CNS) (e.g. BfR, 2013c; EFSA, 2013).

For risk assessment purposes, EFSA derived an acute reference dose (ARfD) as health-based guidance value of 0.016 µg/kg body weight (b.w.) for the sum of (–)-hyoscyamine and (–)-scopolamine (group ARfD). The derivation is based on observations in a study in healthy young male adults regarding the deceleration in the heart rate and CNS effects, such as drowsiness, headaches and nausea (Perharič et al., 2013a, b; EFSA, 2013).

Cocaine is a natural constituent of the coca leaf and it is a drug of abuse in many countries. It has local anesthetic properties. However, its therapeutic use nowadays is very limited. Cocaine affects in particular the central nervous and the cardiovascular systems and has the potential to induce mentally dependence. The BfR has undertaken a health risk assessment of the cocaine content of a coca leaf extract-containing soft drink and concluded that no health risk is to be expected from consumption of this product because of its low cocaine content. According to information in the scientific literature, the lowest dose that may lead to an adverse effect is a daily intake of 4800 µg cocaine per person. Assuming a high daily consumption of 1.7 L, the margin of safety between the consumed amount of cocaine and the amount upwards of which adverse effects may occur, is a factor of approximately 7000 (BfR, 2009).

## Ergot Alkaloids (EAs)

Ergot alkaloids (EAs) are found in the Western diet due to contamination with ergot. Ergot is the dried sclerotium of the fungus *Claviceps purpurea* developing mainly on rye, *Secale cereale*. More than 50 different EAs have been characterised. EAs are derivatives of lysergic acid (e.g. EFSA, 2012, 2017; BfR, 2013d).

Ergots contaminate flour or animal feed when harvested together with the grain (e.g. BfR, 2013d; EFSA, 2012, 2017).

Pharmaceutically ergotamine tartrate is used for the treatment of migraine, the usual oral dose being 1 to 2 mg. Not more than 6 mg should be given per day and the total weekly dose is limited to a maximum of 12 mg. Salts of ergometrine are used in the active management of the third stage of labour in oral dosages of 0.2 to 0.4 mg, 2 to 4 times daily. Ergometrine maleate causes intense uterine contractions in the range of the therapeutic dose (e.g. EFSA, 2012).

Ergotism is the disease caused by chronic consumption of rye infected by EAs, which is known since the Middle Ages in Europe, also as St. Anthony's fire. Ergotism exists in a convulsive (neurologic) and a gangrenous (vasoconstrictor) form. Convulsive symptoms are weariness, giddiness, dimness of sight, convulsions, muscle contractions, painful flexions of joints, tingling of the skin, headaches, fever, hallucinations, mania, and delirium followed by death. Gangrenous ergotism starts with tingling effects in the toes and fingers, is followed by dry gangrene of toes and limbs and may lead to loss of limbs. Typical adverse effects known from the medical use of ergotamine and ergometrine salts in high dosages include symptoms of ergotism (e.g. EFSA, 2012; BfR, 2013d).

EFSA (2012) derived a BMDL10 of 0.33 mg/kg bw per day for the incidence of tail muscular atrophy in a 13-week rat feeding study of ergotamine. Based on this reference point, which was considered representative of the vasoconstrictive effects of EAs, a group acute reference dose of 1 µg/kg bw and a group tolerable daily intake of 0.6 µg/kg bw per day were established. With respect to the uterus contracting properties of the ergot alkaloids, BfR considers pregnant women as a high risk group for high intake of cereals with high contamination of ergot alkaloids (EFSA, 2012; BfR, 2013d).

## Introduction

Pyrrolizidine alkaloids (PAs) are toxic secondary plant metabolites active against herbivores. It has been estimated that about 6000 plant species worldwide, representing 3% to 5% of all flowering plants, may contain PAs (EFSA, 2011; Smith and Culvenor, 1981). PAs are mainly found in the plant families of the *Boraginaceae*, *Asteraceae* (tribes Senecioneae and Eupatorieae) and *Fabaceae* (genus *Crotalaria*). The toxicity of a few PAs has been studied and they possess either acute or chronic toxic effects. PAs with a double bond in the 1,2-position are the most toxic PAs and are thus of special interest. The acute toxicological effects to livestock are known and described in the literature (Boppre, 2011; Fletcher et al., 2011; Molyneux et al., 2011; Molyneux, 2010; Wang et al., 2011; Wiedenfeld and Edgar, 2011). They lead to cirrhosis of the liver, and in case of acute intoxication it is well described that PAs cause the veno-occlusive disease (VOD) (Kakar et al., 2010; Prakash et al., 1999; Zhe and Ji-Rong, 2010). In addition, in experimental animals some PAs such as ridelliine and lasiocarpine have been tested and genotoxic, hepatotoxic and carcinogenic effects have been shown.

PAs are considered as contaminants or rather as plant toxins which can contaminate the food chain. From their behavior of contamination, e.g. their inhomogeneous distribution in the food or their concentration range, PAs are comparable to mycotoxins. The source of PAs is quite different. PAs enter the food chain at a very early state of the production chain due to harvesting of PA-containing plants. Examples are herbal infusions which can be contaminated with plant parts of PA containing weeds or Rucola which can be contaminated with ragwort (*Senecio jacobea*) during harvest. After harvesting it is almost impossible to sort out the PA containing plant parts which lead to a contamination of food and feed. Thus, the only possibility is to avoid foreign plants in the crop or to avoid harvesting the PA-containing plants. This is possible e.g. by applying a good and very strict agricultural practice.

## Chemical Structure of PAs

PAs have a common, so-called necine base (1, Fig. 1) of two fused nitrogen containing 5-membered rings as a backbone structure and this necine part can be esterified with miscellaneous acids (EFSA, 2011; Mattocks, 1986; Röder, 1995). This acidic part is called necic acid (B in Fig. 1). The necine base can either be saturated or can show one unsaturation in the 1,2-position.

The basic nitrogen of the condensed ring system can occur as a tertiary base as well as the corresponding N-oxide (PANO) (Fig. 1 (3)). In plants, the PANOs are the preferred form of the PAs. Furthermore, on C-2, C-6 or C-7 they can bear one or two hydroxy moieties which can lead to stereoisomers (Röder, 1995). Depending on the kind of the necic acid which is bound on the necine

**Figure 1** Chemical structures of pyrrolizidine alkaloids: (1) main necine base backbone of PAs including the typical numbering (R = H or –OH) (2) macrocyclic PA type senecionine ((A) necine base part (B) necic acid part) (3) senecionine-N-oxide (4) open chain diester type PA lasiocarpine.

base, the PA can occur as monoester, open chain diester and macrocyclic PA type forms. For this reason, a wide variety of different structures can arise in nature and as contaminants in food.

Moreover, these facts and the possibility of different stereocenters in the chemical structure of PAs lead to more than 600 known structures (EFSA, 2011; Kempf et al., 2010b; Kempf et al., 2008; Mädege et al., 2015). Also, for the toxicity of PAs, the structure is an important prerequisite. The PA toxicity is due to the existence of a carbon–carbon double bond in 1,2-position of the necine base. Furthermore, an ester functionality in position C-7 or C-9 or both positions is required. If these requirements are met, the PAs can undergo biotransformation, mainly by liver cytochrome P-450 monooxygenases, into the corresponding dehydropyrrolizidine alkaloids (pyrroles) (Jago et al., 1970; Kempf et al., 2010b, p. 159).

## The Pathway of PAs Into the Food Chain and Levels

The pathway how PA end up in the food chain was already described above. The main commodities in Western countries which are affected by PA contamination regarding chronic toxic effects are teas, infusions, honey, herbal drugs and medicines, phyto food supplements, herbs and spices and with lower prominence cereals and cereal products (Beuerle and Kempf, 2010; Boppré et al., 2008; Huxtable, 1980; Huybrechts and Callebaut, 2015; Kempf et al., 2009, 2010a, 2011a, 2011b; Oberlies et al., 2004).

PAs have regularly been determined in several commodities. Following a convention samples were analyzed on a spectrum either of 17, 21 or 28 individual PAs.

The levels are diverse and reach in herbal infusions from lower than  $10 \mu\text{g kg}^{-1}$  for the sum of 17 PAs up to more than  $3000 \mu\text{g kg}^{-1}$ . The occurrence in black and green tea is of lower importance because only a few highly contaminated samples have been reported (Bundesinstitut für Risikobewertung, 2013, 2016). For honey, especially for raw honey, high levels (more than  $600 \mu\text{g kg}^{-1}$  retronecine equivalents) of PAs are reported in the literature. For special *Jacobaea vulgaris* honeys levels up to  $12\,000 \mu\text{g kg}^{-1}$  have been reported (Kempf et al., 2011a,b). However, also for food supplements, PAs have been reported as a contaminant (Bundesinstitut für Risikobewertung, 2016).

When no grain cleaning processes are in place during food production, it is known that also acute intoxication of humans and animals can occur by consuming these products. As a consequence, liver diseases like VOD can occur (Kakar et al., 2010; Tandon et al., 1976; Wang et al., 2011). In general, the chronic toxic effects are the major concern regarding human health.

## Analytical Approaches for PAs

Analytical methods for PAs show a broad range of different techniques that were and still are used. In the literature, methods are described using chromatographic techniques like thin-layer-chromatography (TLC) methods (Bredenkamp and Wiechers, 1987; Mattocks and Jukes, 1987; MATTOCKS, 1967; Parvais, 1994), capillary electrophoresis, classical high-performance liquid chromatography (HPLC, LC) with ultraviolet (UV) or diode array detection (DAD) (Brown et al., 1994; Hösch et al., 1996; Xiong et al., 2009b; Yang et al., 2001; Yu et al., 2005), gas chromatographic approaches with nitrogen phosphorous detector (PND) or mass spectrometry (MS) (Joosten et al., 2010; Witte et al., 1993). During the past 10 to 15 years HPLC tandem mass spectrometric (MS/MS) techniques in the low concentration range ( $<10 \mu\text{g kg}^{-1}$ ) (Beales et al., 2004; Betteridge et al., 2005; Crews et al., 2009; Fu et al., 2010; Hoogenboom et al., 2011; Mulder et al., 2015; Zhou et al., 2010) are more frequently applied. These chromatographic techniques are used for structure elucidation but mostly for the quantification of PAs. Numerous methods are described in the literature to elucidate the level and the distribution of the different PAs. Likewise, some of them describe the levels of PAs in different commodities like tea, honey, pollen or flour.

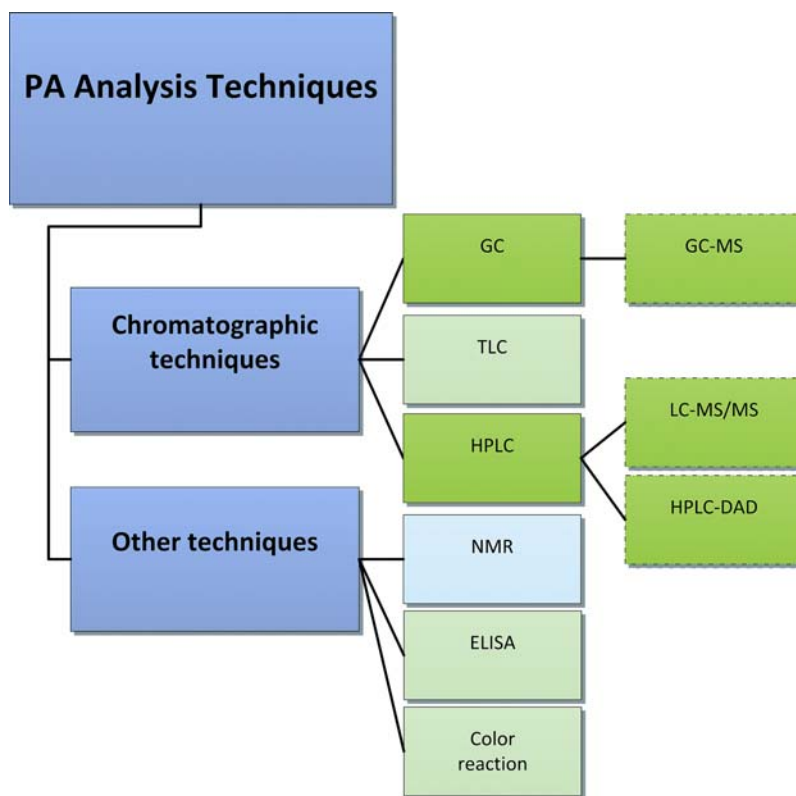

Besides chromatographic methods, techniques, such as enzyme-linked immunosorbent assays (ELISA) are also used for the analysis of PAs (Crews et al., 2010). The ELISA methods are more generic to detect PA structures, but it is known that these applications suffer from limited cross reactivities which prevent a broader use (EFSA, 2011). Additionally, none of them are commercially available.

Modern analytical methods for quantification use chromatographic techniques coupled with mass spectrometry. In the last ten years more and more sensitive and selective methods with mass spectrometric detection, tandem MS as well as high resolution MS, were established and described. Furthermore, the mass concentration range becomes nowadays much lower than before. Current analytical methods usually have a working range down to low  $\mu\text{g kg}^{-1}$ . LC-MS/MS is now the method of choice for detection and quantification of PAs followed by GC-MS methods.

## Analyzing PAs Using LC and GC Techniques

As described above, various analytical techniques can be used for analyzing PAs in different applications. In food and feed analysis, the quantitative chromatographic techniques are the most relevant applications, although with ELISA quantitative results can be obtained but only for the whole group of PAs, not for individual substances (Fig. 2).

A general problem for analyzing PAs is the limited number of commercially available standards. To date, around 50 substances out of more than 600 possible compounds are obtainable as reference standards.

**Figure 2** Overview of analytical techniques for PAs (dark green = quantitative, sensitive; light green = semi quantitative, not for individual PA; light blue = not quantitative).

The most relevant chromatographic techniques which allow the determination of individual PAs down to 0.5 to 2  $\mu\text{g kg}^{-1}$  and their challenges will be described in more detail below.

### GC-MS

For the analysis of PAs using GC-MS, first methods were described in the late 1980s and frequently applied in the following years. Different setups were described in the literature and the GC columns used differ from polar to unpolar stationary phases, such as OV-1, DB-1, DB-5, DB-17 and DB-1701. Modern capillary GC give satisfactory separation of several PA-isomers and existing retention indices relieve the identification of different PAs (Crews et al., 2010; EFSA, 2011; Witte et al., 1993).

A general limitation of GC methods for PAs is the fact that the PANO cannot be volatilized without destruction in the injection system of the GC. Thus, the tertiary bases of the PANOs need to be chemically converted. This is mainly done upstream by a reduction step using  $\text{Zn}/\text{H}^+$  (Witte et al., 1993, p. 188) (Kempf et al., 2008, p. 1194). This step is time consuming (3 hours (Kempf et al., 2011a, p. 335)) depart from the other steps of the sample preparation. Also, for some of the PAs, thermal decomposition and the formation of diesters from monoesters are described (Crews et al., 2010, p. 331).

By using GC methods, it is not possible to measure the analytes as they are, the PAs must be derivatized. Often used reagents are boronate derivatives, tetramethylsilane or a combination of both (Crews et al., 2010; Wretensjö and Karlberg, 2003).

For the detection, nitrogen-phosphorous-detectors (NPD) or flame-ionization-detectors (FID) in parallel are common (Joosten et al., 2010). But the most common detector for PAs is the mass spectrometric detector with electron-impact ionization (EI) mode. The mass spectrum is typical for PAs and shows unique signals for the necine base part of the structure. Characteristic fragments are e.g.  $m/z$  93, 120, 136 and 137 for retronecine type PAs, and macrocyclic PAs with a retronecine base typically show intense ions at  $m/z$  93, 119, 120 and 136 (Crews et al., 2010, p. 331). PAs do not show intensive molecular ion peaks (Schulzki, 2010).

In many cases GC-MS is used to compile a PA profile of the plant or e.g. of the phytopharmaceutical which shall be free of PA. In these cases, it is not the aim to quantify (LOQ 0.06 mg/kg) all the individual substances. It is rather the aim to identify the PA signal using typical  $m/z$  fragments and to quantify these signals by using one or two PAs for the calibration. For example, senecionine is used for retronecine type PAs and senkirine for otonecine type PA according to Schulzki (2010).

A completely different approach is to convert PAs into their basic structure moiety retronecine and quantify this compound (Fig. 3). This method is described by Kempf and Beuerle (Kempf et al., 2008).

This approach allows to detect and quantify most of the 1,2-unsaturated PAs as retronecine-equivalents. This represents a measurement of PAs as a single sum parameter. The PAs are extracted by means of acidic liquid extraction, a  $\text{Zn}/\text{H}^+$  reduction

**Figure 3** Conversion of PAs into their basic structure moiety retronecine during sample preparation (Kempf et al., 2008).

step and solid phase extraction (SPE) cleanup with a strong cation exchange material. Afterwards the essential reduction with lithium aluminum hydride to yield the necine base structure is performed. N-Methyl-N-(trimethylsilyl)trifluoroacetamid (MSTFA) is used as derivatization reagent. The di-TMS derivatives are quantified using an internal standard (ISTD). As ISTD heliotridine, a naturally occurring PA is used. Hence, all samples have to be analyzed a priori in duplicate to proof that no heliotridine is naturally occurring in the sample. A general lack is that all PAs of the otonecine type are not covered by this method. The method is very time consuming because the two reduction steps take 6 hours per sample, and the total analysis time is approx. 10 hours without chromatographic determination ([Kempf et al., 2011a](#)) ([Fig. 4](#)).

The typical concentration range for the GC-MS methods depends on the setup but it is usually in the range of  $10 \mu\text{g kg}^{-1}$  (retro-necine equivalents) for the sum parameter method described by Kempf et al. or for the PA profiles in the range of  $60 \mu\text{g kg}^{-1}$  (EFSA, 2011; Schulzki, 2010).

GC-MS/MS has not been used for PAs very often. Schoch et al. described a GC-MS/MS method already in the year 2000 but to date, where sensitive GC-MS/MS equipment is available in a number of laboratories, this technique has not gained increased importance for the determination of PAs (Schoch et al., 2000). A possible reason for this could be the limitations (no PANOS etc.) and the relatively complex cleanup procedure as described above.

**Figure 4** SIM mode chromatogram ( $m/z$  93, 183, and 299) of a PA positive honey sample (A) Without internal standard heliotridine and (B) after the addition of heliotrine (shown as di-TMS- heliotridine; RI [DB1] = 1632) (Kempf et al., 2008, p. 1197).

## LC-MS/MS

Liquid chromatography coupled with tandem mass spectrometry is a very widely used technique, especially for the target analysis of contaminants in food and feed. Generally, LC-MS/MS allows a very sensitive quantitative detection of contaminants, such as the PAs. It has a number of advantages compared to GC-MS based methods despite it is more cost-intensive than GC-MS equipment, both for purchasing and maintenance. Nevertheless, LC-MS/MS became the method of choice for separation and detection of PAs over the last approx. 15 years.

One of the main advantages of LC-MS/MS is the possibility of simultaneous detection of the tertiary forms of PAs and the PANOs. This is possible within one analytical run, allowing a substantially decreased time and effort for sample clean-up. The chemical reduction steps mentioned for GC based methods are not necessary by using an LC-MS/MS approach. Additionally, modern column materials allow to achieve a suitable separation of individual PAs and PANOs. Very often C<sub>18</sub> based separation columns are used. Chromatographic conditions both with acids (e.g. formic acid) or bases (e.g. ammonium hydroxide) as modifier for the aqueous eluent part and either methanol or acetonitrile for the organic eluent part can be set-up. Electrospray ionization (ESI) is the most frequently used method as ionization technique (Betteridge et al., 2005; Crews et al., 2009; Hoogenboom et al., 2011; Lucchetti et al., 2016; Xiong et al., 2009a,b). Atmospheric-pressure chemical ionization (APCI) is a good choice for PAs in their tertiary forms but it shows lower sensitivity for the PANOs (Beales et al., 2004). For ESI, most frequently H<sup>+</sup>-adducts are formed in the ion source.

For the specific and sensitive detection of PAs in food and feed matrices targeted MS methods are described by using single reaction monitoring (SRM) and multiple reaction monitoring (MRM). It lowers the effort for sample cleanup steps. For these purposes, ion trap or triple quadrupole (QqQ) instruments are used. For the sensitive and selective detection of the PAs, collision induced dissociation (CID) fragments of the adduct ions formed in the ion source is the method of choice. These CID fragments are typical for PAs. Characteristic CID fragment ions are m/z 94, 118, 120, 122, 138, 136, 150 and 168 for 1,2-unsaturated PAs/PANOs (Dubecke et al., 2011; Hoogenboom, 2010; Kempf et al., 2011a; Xiong et al., 2009a; Zhou et al., 2010).

Concerning sample preparation, it is very often the same approach of acidic conditions for the extraction of the sample material. To clean up the raw extracts, SPE is used either with strong cation exchange (SCX) or with a reversed phase material. This step usually leads to a concentration of the extract for a more sensitive detection. Hence matrix effects can be decreased by an appropriate dilution of the extracts, a better signal to noise ratio is the result.

Although LC-MS/MS has several advantages, also some challenges need to be faced. Due to the fact that LC-MS/MS is usually (due to sensitivity reasons) used as target approach one challenge is that only approx. 50 substances can be purchased commercially, but standards are required for quantitation. By using the typical CID transitions described above it is also possible to identify "unknown" PAs (where no standards are available), however with high uncertainty as the structure cannot be proven without an authentic reference compound. Furthermore, the typical CID transitions are in the lower m/z range and even below m/z 100. Measuring small molecules with MS/MS approaches is a general problem as the MS-transitions have a relatively high uncertainty and can be affected by e.g. matrix interferences. To overcome this problem, isotope labeled internal standards (ISTD) should be used, however to date no labeled standards are commercially available. Cramer et al. (2013) described a sum parameter method with the use of deuterated 7-O-9-O-dibutyryl-[9,9-<sup>2</sup>H<sub>2</sub>]-retronecine as ISTD. However, this standard is not commercially available. Owing to matrix effects in LC-MS/MS, which may lead to signal suppression or enhancement, these effects must be considered to get correct quantitative results. Alternative methods which can be used instead of an ISTD, are standard addition or matrix matched calibration. Both methods are not easy to handle in routine analysis. For matrix matched calibration, there is the need of suitable blank material, which is sometimes not possible. Standard addition is also complicated to perform because of the high price of reference standards and the high effort which is needed for the sample preparation.

The next important issue where attention must be paid are the mass transition itself, the ion ratio, and the chromatographic separation. Since there are a lot of stereoisomers within the group of PAs, this leads to isobaric compounds (same m/z values) which generate the same mass transition. To distinguish between the different isomers (e.g. intermedine/lycopsamine) a suitable chromatographic separation is needed. This can be managed by using modern UHPLC separation columns with 1.7 µm particle size. The advantage of this material is not so much a faster chromatography, which is often not possible with complex matrices like food and feed, but the high chromatographic resolution. However, not in all cases a sufficient separation can be obtained. In these cases, the result can only be calculated as a sum, as it is not possible to distinguish between the individual PAs.

Compared to GC-MS analysis, LC-MS/MS is more sensitive with reported limits of detection between 1 µg kg<sup>-1</sup> and 10 µg kg<sup>-1</sup> depending on the compound and the procedure of sample preparation (Bundesinstitut für Risikobewertung, 2014; de Nijs et al., 2014).

## LC-High Resolution Mass Spectrometry (HRMS)

As LC-HRMS is much more expensive, both in purchase and maintenance compared to GC-MS and LC-MS/MS, this analytical equipment is not available in many laboratories. The advantages of LC-HRMS as screening methods are enormous. But for quantification purposes, LC-MS/MS is still the method of choice.

Analyses searching for so called "known unknowns", which means PAs where no reference standard is available but the structure is known, can be performed by use of LC-HRMS based methods. Nevertheless, the challenges with the stereoisomers and the isobaric compounds remain. The identification using CID with PA-typical fragments as described above is possible with high

**Figure 5** Chromatogram of a honey sample spiked at 1 ng g<sup>-1</sup>: (1) monocrotaline; (2) monocrotaline-N-oxide; (3) intermedine; (4) lycopsamine; (5) retrorsine; (6) heliotrine; (7) seneciophylline; (8) retrorsine-N-oxide; (9) heliotrine-N-oxide; (10) seneciophylline N-oxide; (11) senecionine; (12) senecionine-N-oxide; (13) echimidine; (14) senkerkin; (15) lasiocarpine; (16) lasiocarpine-N-oxide. (Huybrechts and Callebaut, 2015)

resolution. But without any respective reference standard this is difficult to confirm, and quantitative results can only be obtained with a considerable uncertainty.

Structural screening for PA relevant substances ("non-target" screening) can be performed by using LC-HRMS as well as with LC-MS/MS approaches applying CID fragmentation on PA-typical *m/z* values. The major advantage here is to use the exact mass for the unequivocal identification of PA CID fragments.

## Conclusion

PAs are a broad group of natural plant alkaloids which can contaminate the food and feed chain. They exhibit a number of toxicological effects, of which chronic toxicity is most relevant. As PAs occur at low levels, analytical methods must be sensitive and specific allowing low LODs. There is still a lack of data regarding the exposure of humans with individual PAs though various food commodities. Therefore, a target approach for individual substances is of interest. Otherwise, a toxicological assessment cannot be performed because the PAs have a different toxicological potential depending mainly on their structure.

By applying chromatographic techniques for analyzing food and feed, a number of challenges must be considered. Since the past 15 years, LC-MS/MS became the method of choice. While there is a lack of isotopic labeled standards, only matrix matched calibration or standard addition is a possibility to take potential matrix interferences into account. Chromatographic procedures with a high resolution (e.g. UHPLC) are needed to achieve an optimized separation between the individual substances.

To date, it is uncertain whether all relevant PAs are covered as only around 50 reference standards are commercially available. Sum parameter methods cover a lot of relevant structures, but it must be proven that they produce reproducible results and even these methods do not cover all relevant structures. In addition, structural relevant information gets lost e.g. by hydrolysis and a toxicological conclusion cannot be drawn. The toxicological potential of a sample can even be overestimated by this approach.

Analyzing PAs needs experienced laboratories which know how to deal with natural substances. There can be numerous gaps and pitfalls which must be considered. Therefore, the analysis of PAs is to date not a routine method which can be implemented easily as a standard analytical procedure.

## Glossary

**Big data** Data sets whose size or type is beyond the ability of traditional relational databases to capture, manage, and process with low-latency.

**Blockchain** A digital ledger in which transactions are recorded chronologically.

**Food fraud** Deliberate and intentional substitution, addition, tampering, or misrepresentation of food, food ingredients or food packaging.

**Machine learning** A method of data analysis that automates analytical model building.

**Microbiome** The microbial composition of an environment.

**Predictive microbiology** Field of study which uses mathematical models to predict microbial response to various abiotic and biotic factors.

## Introduction

Big data and data analytics has evolved to become an indispensable facet across all industries, enabling new advances in management strategies, product development, and data insight that has never before been possible. A widely accepted definition of big data is inspired by a Meta (now Gartner) report (Douglas, 2001) from 2001 which never mentions Big Data and predates the popularity of the term and its widespread use. IBM analytics has defined big data as data sets whose size or type is beyond the ability of traditional relational databases to capture, manage, and process the data with low-latency (IBM: What is big data? - Bringing big data to the enterprise. <http://www-01.ibm.com/software/data/bigdata/>). And it has one or more of the following characteristics – high volume, high velocity, or high variety (Beyer and Laney, 2012).

However, the term big data encapsulates more than increased magnitude of data and includes statistical ideas that have revolutionized data analysis. This revolution in statistical analyses of vast amounts of various forms of data is how big data has permitted disruptive innovation across seemingly unrelated fields and has generated revolutionary ideas that has changed the course of entire industries. Traditionally, scientists have approached scientific questions by formulating a hypothetical model and carefully designing experiments to accept or reject the proposed model. The more modern statistical method, fueled by the revolution of big data, is to refrain from relying on hypothetical models and allow the data itself to identify pertinent variables and patterns that shape the observed outcome. Closely related is the development of artificial intelligence (AI) and Machine learning in which machines, via algorithms, learn from input data, predict for future data, and perform tasks guided by the data (Bishop, 2006; Hastie et al., 2009; and Mohri et al., 2012).

A simplistic view of the process for creating models from big data is represented in Fig. 1. A more realistic view, however, looks more like the scheme in Fig. 2. Big data problems are often categorized into supervised learnings and unsupervised learnings. Supervised learnings deal with data that is accompanied by a label, also referred to as response, target variable, or dependent variable. Labels are the variables that need to be predicted. A label can be quantitative, a regression problem, or categorical, a classification problem. In contrast, features, also referred to as inputs, independent variables, or predictors, are individual measurable properties or characteristics observed in every instance. Unsupervised learnings, on the other hand, deals with unlabeled data, where the goal is to find hidden patterns and structure in the data from the observed features.

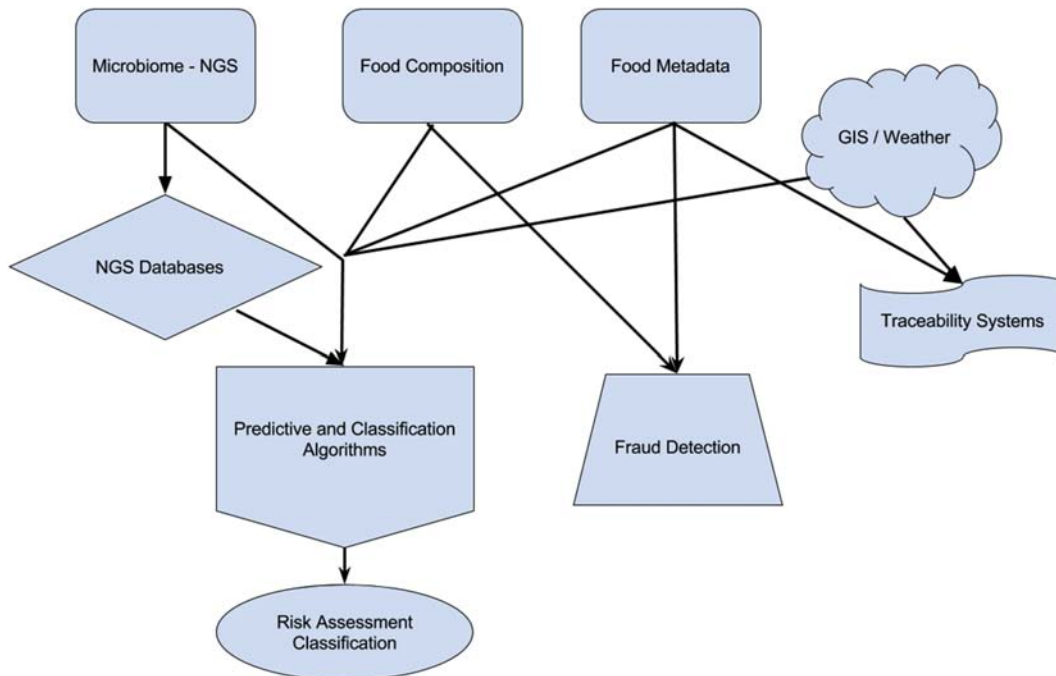

A significant feature of modern statistical platforms and what brings intelligence to these algorithms, is the ability to update the model and continue learning as newer data is collected. In fact, many applications include a feedback line that keeps training and testing the model with the updated set of data and monitors the performance of the model continuously.

The following sections describe the workflow of general predictive algorithms with a focus more in supervised learnings, as unsupervised learnings are generally more challenging to formulate, train, and evaluate.

Figure 1 Analysis of data, general schema.

**Figure 2** General schema for a supervised learning problem.

### Data Collection, Cleaning and Storage

Collection of the data is the first step for any big data application. Even though in big data the emphasis seems to be on quantity, very often quantity cannot cover the lack of quality. In particular maintaining diversity while avoiding bias is an important aspect of good data collection. The unbiased choice of data does not mean equal numbers of data points from different sectors, but numbers that are close to proportional to the population of each sector. Cleaning and preprocessing is another essential step when dealing with large quantities of data. This is more the case since larger and larger quantities of new data are unstructured.

Data storage and security of data create further challenges of collecting and analyzing data. The issue of data security is a hot topic. The data related to food safety, on one hand ties to liabilities of the public and private sector, and on the other hand is connected to medical and health data which are among the most sensitive categories of data.

### Splitting Data, Feature Reduction, and Normalization

In supervised learning problems, the data has to be divided into training and test data. The test set is generally a smaller subset which needs to be kept separated from the training process and all aspects of model selection.

Often the data used in a problem is highly dimensional and contains too many features. Keeping all the features not only creates performance deficiencies but may lead to overfitting, which is a major concern in all prediction problems. To help, a step for feature selection and feature extraction is added where some features are eliminated and some others are merged into smaller number of features (Blum and Langley, 1997). The feature extraction is often accompanied by dimensionality reduction algorithms. Finally in the normalization step, features are brought to the same scale, which often improves the performance of the final model significantly.

### Training and Model Selection

Training of the model involves first choosing the type of model and then training the model using the training dataset (Claeskens and Hjort, 2008). Once a model is chosen the test set is used to evaluate the predicted performance of the model on future data. One common pitfall when choosing a model is heavily reliance on the training data set (James, 2003). In this case, the trained model may perform very well on the training set and fail miserably on the test set or the future data due to what is called overfitting (Hawkins, 2004 also Burnham and Anderson, 2002).

A common remedy to the overfitting problem is to seek models with more consistent performance on the training data (Brodely and Friedl, 1999). Another approach, called cross-validation, is a further splitting of the data outside the test set to training set and the cross-validation set (James et al., 2013). Then the cross validation set is used to minimize overfitting and select the main architecture of the model.

## Evaluation and Metrics

When training of the final model is complete, it is evaluated against the test set which has not been used in any of the steps for development of the model. Mean squared error and the coefficient of determination, i.e., R-squared-error, are important metrics for regression problems. For classification problems, accuracy score is the most common metric, and precision, specificity, and recall, sometimes referred to as sensitivity, scores are other notable metrics.

## Big Data and Food

The use of big data in the food industry is still new. There are four general categories of such applications which are briefly explained below and expanded with more specific examples in the remainder of the chapter.

- Predictive models: Applications that can be used to provide food safety and quality risk assessments, including pathogen risk prediction, shelf life prediction, and precision agriculture.
- Classification algorithms: Applications determining presence or absence of pathogens, pesticides, or existence of any other major modification that affects the food
- Anomaly detections: Detection of fraud or any isolated defect among samples of the same product or samples of products in the same category.
- Accessible large datasets: Having organized, comprehensive data sources by itself is an asset and can be implemented in many applications. Traceability technologies rely on such data collections. Other examples of ever expanding major data sources related to food are the GenomeTrakr, NCBI genomic database, and NARMS.

## Agriculture

Big data-enabled technology has an increasing adoption rate in agriculture and is expected to continue to become more widespread in the coming years. In the agricultural sector, big data is used in numerous aspects of farming and crop production such as precision agriculture (soil conditions, yield monitoring, field mapping, crop scouting, weather forecasting, etc.), decision making tools, and in emerging areas of on-farm food safety. Pre-harvest food safety hazards can be assessed through the use of geographical information systems technology (GIS) and geo-referenced data systems to identify associations between the environment and a pathogen (Strawn et al., 2013).

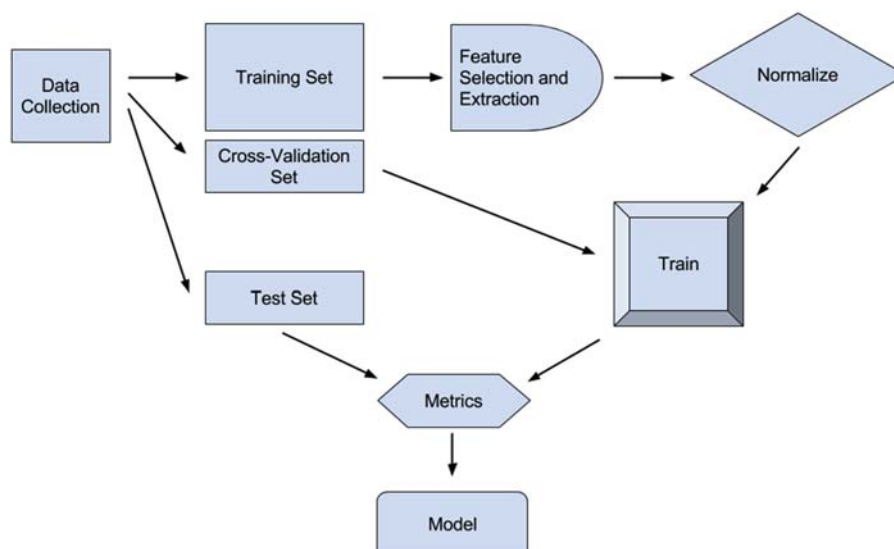

Similarly, by monitoring the conditions of crops in the field, areas with an increased incidence of aflatoxins can be identified before entering the food chain (Armbruster and MacDonell, 2014). Quantitative models have also been developed to predict the contamination of the mycotoxin deoxynivalenol (DON) on wheat in northwestern Europe using a variety of data, including weather data (van der Fels-Klerx et al., 2012). Phytobiome and soil microbiome analysis can be used to identify microbial communities that are vital to plant health by imparting increased abiotic (e.g. drought tolerance) and biotic (e.g. disease resistance) stress tolerance. By gathering a vast amount of phytobiome and soil microbiome data, machine learning tools can be used to identify those microbial communities that may play a role in crop disease resistance/suppression, yield increase, and drought tolerance, and harness that information to develop new agricultural products (Marasco et al., 2012). There are several pioneer companies breaking new ground in this field including Indigo and AgBiome located in Boston, MA and Research Triangle Park, NC, respectively.

As big data analytics continues to disrupt and revolutionize a multitude of industries, it is possible that the future of big data applications in the agricultural sector will bridge data associated with crop production, including weather, soil, environmental conditions, pest management strategies, phytobiome composition, and nutrient availability into one all-encompassing system, allowing the agricultural sector to make more informed decisions that will lead to higher yields, greater nutritional value, and decreased production costs (Fig. 3).

## Food Authenticity

With the rise of consumer demand for food transparency, consumers are more concerned than ever with where their food comes from and expect companies to provide clear, accurate and useful food-related information for the products they purchase. The Center for Food Integrity conducted a study in 2015 that revealed that consumers not only want transparent food product labeling and ingredients, they want companies to be transparent about their business practices as well (CFI, 2015). Big data has played a major role in allowing companies to ensure authenticity and detection of food fraud in the products they sell. Advances in sequencing technologies and the availability of public databases has enabled the development of genomics-based authenticity and food fraud detection tests with greater accuracy than previously available.

Since the 2013 horse meat scandal in which foods advertised to contain beef was found to contain undeclared horse meat, consumers have a heightened level of concern about food authenticity and adulteration (Lawrence, 2013). Sequencing-based tests enable high-throughput analyses using curated, proprietary, or publicly available databases which allow companies to verify suppliers, ensure product integrity, and reduce the risk of food adulteration and contamination. Such tests include, but are not

**Figure 3** The use of big data applications in food safety and quality to create a FSQA system.

limited to, GMO detection, pesticide residue, allergen contamination, missing ingredients, halal validation, antibiotic detection, heavy metals, animal species identification, and hormones (Ellis and Goodacre, 2016).

### Composition Trends to Enhance Quality Control

One way of monitoring food authenticity is by tracking product composition trends. Monitoring the relative abundance of each component within a product is an effective way of identifying unexpected changes that may be problematic or cause the product to become out of compliance with standard specifications. This approach provides monitoring which is flexible and can be different for different products, and even different part of the product's content, and also it can evolve and update when there are gradual changes in the production. Additionally, if monitored over time, composite trends can also be used to show long-term trends and even potentially identify seasonal trends.

An example of this type of monitoring system is implemented by Clear Labs Inc., where NGS technology is used to quantify and identify the DNA content of food samples. Using data generated from numerous samples of the same product, composition trends are monitored and appropriate alerts are automatically generated when something unusual is observed. However, while it is useful to be able to quantify sample components to facilitate a detailed analysis of products, monitoring DNA composition trends do not require any DNA/Mass model conversion and are effective to monitor for product specification compliance and enhance quality control systems.

### Fraud Detection

Food fraud can be a major economic and public health threat. Some of the earliest cases of food fraud, dating back thousands of years, involved olive oil, tea, wine, and spices. Although the vast majority of fraud incidences do not pose a public health threat, there have been some cases that have harmed or had the potential to harm the public. One of the most well-known cases of economically-motivated adulteration (EMA) involved the addition of melamine to high-protein feed and milk-based products to artificially inflate protein values in products (Johnson, 2014). Similar to methodologies previously described to investigate composition trends, monitoring similar products across brands and suppliers can be used to identify these fraudulent products at any point throughout the supply chain process. These compliance specifications may include many parameters such as ingredient substitution, GMO percentage, presence and quantities of allergens, toxic, and toxigenic organisms, and matching with label claims. This big data approach to fraud detection can enable high-throughput, reliable analysis for fraud and adulteration detection. Such analysis will have additional advantages of providing specifications that depend on the product, help to identify sources of adulteration, and establish industry standards for manufacturer or suppliers.

### Traceability

Tracking down contaminated food has historically been a very time-consuming process, sometimes requiring weeks for food companies and retailers to identify what products they need to pull from the store shelves. The advent of blockchain-based systems, however, has the ability to reduce that time to seconds. A blockchain is a continuously growing list of records protected from revision and tampering. In the food safety world, blockchain technology can be used to digitally record the distribution of products

throughout the farm to fork continuum (Ahmed and Broek, 2017). Walmart, Unilever, Dole, Nestlé, and several other food giants have already partnered with IBM to explore how to use blockchain technology as a data management system across a complex network that includes farmers, broker, distributors, processors, retailers, regulators, and consumers (Yiannas, 2015).

### **Predictive Microbiology via Microbiome Analysis**

Predictive microbiology is an established field which studies the responses of microorganisms to various factors that may impact growth (e.g. temperature, water activity, pH, humidity, matrix, etc.) using mathematical models to make statistically sensible predictions (Perez-Rodriguez and Valero, 2013). Big data, however, has expanded these applications far beyond their historical boundaries. Classical predictive models relied heavily on imperfect prior assumptions of the distribution of data. However, in the new world of AI and machine learning, those assumptions are unnecessary and the distribution is pushed among the unknowns which are discovered and updated by the machine and the data to create models with greater accuracy than ever before.

#### **Shelf Life**

Traditionally, shelf life estimation begins with the hypothesis that the shelf life of a product follows a standard mathematical model, often an exponential model. Subsequently, through regression analysis and statistical goodness of fit tests, the model and its parameters are generated based on the limited number of available observations. Such predictions are often limited to known models of spoilage and a completely new model is required if newer data suggests a different model, or if the product varies over time.

Additionally, another way to predict shelf life for a wide range of food products is through analysis of the microbial composition of the food as measured by the food microbiome.

There are many intrinsic and extrinsic factors that influence food quality and shelf life including, but not limited to, food storage conditions, packaging, pH, temperature, water activity, and nutrient availability. Traditionally, microbiologists have relied on culturing techniques to measure the microbial composition of foods and make deductions about spoilage potential and shelf life. In contrast, utilizing a metagenomics approach to measure the microbial composition of foods via sequencing analysis will help recover some of those missing pieces and provide a more complete picture.

Recent advances in next-generation sequencing (NGS) technologies enable affordable high-throughput sequencing that has never before been available. This level of resolution enables the use of big data analytics to paint a more complete picture of the microbial composition of foods and how those microbial communities are influenced by intrinsic and extrinsic factors. While it is impractical to analyze the microbiome of every food product, it is possible to analyze enough samples to facilitate the development of more accurate predictive models, which use the observed (or expected) microbiome profile of the fresh product and estimate its remaining shelf life. Additionally, microbiome data can be used to measure the effectiveness of control measures such as refrigeration, modified atmosphere packaging (MAP), and preservatives used to extend the shelf life of foods. Furthermore, utilizing food microbiome data for shelf life prediction will also lead to the identification of new and more accurate spoilage indicators.

#### **Predictive Risk Assessment**

In addition to using microbiome data to predict quality parameters and shelf life of a product, the data can also be used to predict safety parameters and create a predictive risk assessment. Unique signatures can be identified within the microbial composition of products that do not contain a pathogen compared to those that are contaminated with harmful pathogens, which will allow for AI algorithms to assess the risk of a product through the microbial composition. Utilizing metadata derived from contaminated and non-contaminated sources to curate a microbiome database enabling machine learning tools to predict contamination of a product will facilitate a more holistic approach to food safety management. Industry and government will be able to use this big data approach to assess the food safety risk of a product with confidence - the question changes from "Is this pathogen/microbe/toxin present in the sample?" to "what does the microbial community indicate about the safety of this product?". In this way, big data can be used to revolutionize the food safety industry and potentially reduce the number of recalls, foodborne illnesses, and deaths.

#### **Detecting Pesticides and Chemicals**

A different potential for the use of big data is to utilize a large database of microbiome compositions and comprehensive metadata, to detect additives, pesticides, or treatments of a food sample. Distinguishing conventional and organic produce is an example of such problems where traditional tests are not successful. A number of recent studies have shown how microbiome composition can provide such an avenue. A PCOA graph from a small forthcoming study of organic vs conventional apples conducted at Clear Labs is presented in Fig. 4. (For similar results and studies see Abdelfattah et al., 2016 and Shetty et al., 2016). With larger collection of data and sophisticated analysis broad and accurate predictions like this are not very far (Fig. 5).

**Figure 4** Composition trend as means of monitoring product quality.

**Figure 5** Spatial view of microbiome data, organic vs. conventional apples (via PCOA to appear in forthcoming Clear Labs study).

## Databases

Reference databases make it possible to use metadata and machine learning tools to build much of the predictive models that have been discussed throughout this chapter. Databases such as GenomeTrakr have been accumulating large collections of data on safety outbreaks. The data has many applications including, but not limited to, the following:

- Trace the source of the outbreak using the geographic information, strain typing, and other metadata that connect groups of reported outbreaks.
- Evaluate risk for each kind of outbreak based on time, location, and matrix and as a result help with resource allocation in facing such incidents.
- Help with establishing preventive measures suggested by identifying factors that contribute to higher rates of outbreaks.

**Figure 6** Total number of sequences in the GenomeTrakr database over the past four years (FDA, 2017).

Other useful databases include National Antimicrobial Resistance Monitoring System (NARMS), Resistome Tracker, PulseNet and FoodNet. NARMS reports resistance genotypes of *Salmonella* isolated from retail meats, food-producing animals, and humans. WGS is then used to further characterize the isolates for bacterial speciation and serotyping. Furthermore, Resistome Tracker is an interactive research and data visualization tool for antibiotic resistance genes in *Salmonella*. Both PulseNet and FoodNet databases are used more for outbreak and foodborne illness surveillance and identifying trends associated with illness occurrences (Fig. 6).

## Future of Big Data

Advances in genomics, data analysis, computer processing and digital technologies are re-shaping the way consumers and producers think about and make decisions regarding food purchases and production practices. The once untapped potential of big data and advanced data analytics applications in food safety and quality is gaining more and more attention as tools become available making it easier to apply these technologies. Big data can be used to drive more informed safety and quality decisions, such as shelf-life prediction, improved sanitation and supply chain decisions (identification of resident vs. transient contamination), and predictive risk assessment among many other applications. However, although the field of food safety and quality has made strides in the use of big data to drive improvements, the possibilities are endless with regards to the potential to revolutionize the entire food system. An important next step in fully utilizing all that big data has to offer the food safety and quality world is to gain a better understanding of how to analyze complex datasets in a way that is unbiased and meaningful.

## Foodborne Disease, a Global Burden

Over millennia our food supply has been constantly affected by multiple issues and serious challenges. Many of these challenges would and continue to be the result of key human developments such as agriculture, urbanisation, industrialisation, and leaps in technological innovation. More recently this includes globalisation, whereby advances in worldwide transportation and rapid digital communication technologies have led to food supply chains/networks becoming increasingly more complex, and fragmented; that is to say, the supply chain is rarely horizontal but is a multidimensional network where many participants within that network only have knowledge of their immediate supplier and who they supply. These more recent challenges have included issues such as the intentional adulteration or deliberate misrepresentation of food products for economic gain, so-called food fraud; an issue first highlighted in the scientific literature during the industrial revolution and now again affecting many countries worldwide (Ellis et al., 2012). Of course food fraud falls within the scope of one of the major contemporary challenges of food supply, namely, food security, where serious nutritional disparities exist between developed and developing countries (as well as communities within all countries dependent on socio-economic status), when people do not have constant and sufficient access to a safe and nutritious food supply (FAO, 1996). However, despite these challenges within our food supply system changing over time, one constant and major challenge throughout human history and still affecting all communities worldwide today is the impact and burden of foodborne disease.

Foodborne disease is a serious and largely preventable public health challenge, specifically described as a global burden in the World Health Organisation's (WHO's) first global estimate of the effects of eating contaminated food published in 2015 (WHO, 2015). Illness and deaths caused by foodborne disease have also been described as a constant threat not only to public health but also as a significant impediment to socio-economic development worldwide (Havelaar et al., 2015). Results from the most recent WHO global estimate showed that every year, almost 1 in 10 people across the world become ill following the ingestion of contaminated food, and these numbers are likely to be under reported. Results also showed that 420,000 deaths result from foodborne disease annually, with significant regional variation worldwide, and with children below 5 years of age accounting for 125,000 deaths, almost one-third of the total (Kirk et al., 2015). Some 31 agents are known to cause foodborne disease including bacteria, parasites and viruses, as well as chemicals and toxins. Over half of the fatalities, 230,000, are the result of diarrheal disease, with diarrhoea caused by the ingestion of raw or undercooked fresh produce contaminated either by norovirus, or a range of bacterial pathogens mainly including *Salmonella* spp., *Campylobacter* spp., and *Escherichia coli* 0157, amongst many others (Table 1). Interestingly, foodborne bacterial pathogens have also been observed to have regional variation and different impacts related to socio-economic status: with Africa and South-East Asia having the highest overall incidence and death rates; whilst pathogenic strains of *E. coli* are more prevalent in low-income countries; *Campylobacter* is said to be an important pathogen in high-income countries. By contrast, non-typhoidal strains of *Salmonella* are a major public health concern across all regions and all incomes.

It is these types of information which allows for the targeting of resources for the detection and reduction of these important foodborne pathogens, as well as increasing our knowledge in several areas such as 'pathogenomics' (Hain et al., 2007), food safety, risk monitoring and reduction (Brul et al., 2012), epidemiology, and antibiotic resistance in food chains (Ramos et al., 2016). It is also apparent that there is a constant need to develop new methods, as well as refine existing approaches, for the detection and analysis of foodborne bacterial pathogens and food disease outbreaks, especially so with the emergence and global threat of antibiotic resistant strains (Ramos et al., 2016), in order to reduce the burden of foodborne bacteria. With the largest ever recorded *Listeria monocytogenes* outbreak in South Africa, multi-State foodborne outbreaks of *Salmonella* in the USA, *Salmonella* found in baby formula in France, and continued concerns over *Campylobacter* in Europe, reinforcing this view. Here, in this short overview we offer a brief background introduction to the potential role of omics approaches and look at some of the recent research undertaken using these methods for the analysis of some of the most important foodborne bacterial pathogens.

## Omics, a Short Introduction

We define the neologism omics as a suffix to a molecular target in order to suggest that many of the potential molecules within that molecular target class are collectively characterized or measured. The development of various omics approaches and advancements in their technologies and potential applications (Ellis and Goodacre, 2016; Ellis et al., 2016) has enabled the high-throughput detection and quantification of various bio-molecules at different cellular levels, which has provided us with a deeper understanding of different biosystems and bioprocesses, including of course those directly related to and involving pathogenic foodborne bacteria (Bergholz et al., 2014) and food microbiology in general (Walsh et al., 2017). These can generally be divided into four main areas, namely: genomics, proteomics, metabolomics, and lipidomics. It is perhaps also worth noting at the onset, that no single omics analysis alone can fully reveal and characterize the complexity of a biological system. Thus, application of

**Table 1** A range of important foodborne bacterial pathogens and their known symptoms and potential impact

Bacteria	Symptoms and potential impacts
<i>Campylobacter jejuni</i>	Responsible for most campylobacter-related infections. Common symptoms include inflammatory watery diarrhoea which maybe bloody sometimes, abdominal pains, nausea and vomiting and fever. Symptoms usually manifest between 2 and 7 days following ingestion of food contaminated with <i>C. jejuni</i> and may last for a week. In immunocompromised people (e.g., those living with HIV/AIDS), the pathogen may cause fatal bacteremic conditions.
<i>Clostridium botulinum</i>	The spores of this soil bacterium produce a highly toxic biological chemical called botulinum which is usually transferred to vegetables and intestines of fish, birds and other herbivores which feed on vegetation. Symptoms may appear between 6 and 36 hours, but may sometimes delay until 10 days after eating contaminated food. Botulinum affects the nervous system leading to neurological complications such as slurred speech, dry mouth, blurred vision and muscle weakness. May paralyse muscles and even lead to death if no therapeutic strategies (antitoxins) are administered in the early stages of the symptoms.
<i>Clostridium perfringens</i>	Within 6–24 hours of clostridium infection nausea, diarrhoea and strong abdominal cramps appear. Immunocompromised people are at higher risk of developing serious health complications following infection which may even lead to death if it is left untreated.
<i>Cryptosporidium</i>	Nausea, mild to severe watery diarrhoea leading to body dehydration and weight loss, vomiting and stomach cramps appear within 10 days of infection and may persist for 14 days. Usually children under 5 years old and adults with weak immune system are at higher risk of serious illnesses.
<i>Escherichia coli</i> O157:H7	Most people infected with this pathogen start feeling sick after 7 days following ingestion of contaminated food or drinks. Early symptoms may appear in 3–4 days which include severe watery diarrhoea (often bloody), vomiting, weight loss and abdominal cramps. Prolonged exposure causes potentially life-threatening health complications including haemolytic uremic syndrome (HUS). HUS may cause kidney failure if no treatment is administered on time.
<i>Listeria monocytogenes</i>	Common symptoms include fever, diarrhoea; muscle ache and nausea are reported from 1 to 4 weeks after swallowing infectious dose of the pathogen. Pregnant women, elderly and people with weak immune system are at higher risk. In addition to common symptoms pregnant women experience fever, fatigue and if the pathogen spreads beyond the gut it may lead to premature birth, miscarriage or stillbirth. People other than pregnant women suffer severe convulsions, headache, stiff neck and loss of balance. Ultimately may lead to death if no timely therapeutic intervention is made.
<i>Salmonella</i> (over 2300 types)	Diarrhoea, stomach cramps, fever, and life-threatening body dehydration. Symptoms develop between 12 and 72 hours after eating contaminated food. People with healthy immune system recover within 4 to 7 days without any treatment. The elderly and immunocompromised (e.g., cancer, AIDS) people may develop life-threatening illnesses.
<i>Shigella</i> (over 30 types)	Watery diarrhoea, abdominal pain, fever and tenesmus appear in 1–2 days after becoming infected and last for 5–7 days in people with healthy immune system. If the pathogen enters the digestive system, it would lead to HUS which is usually accompanied by bloody diarrhoea.
<i>Staphylococcus aureus</i>	Early symptoms include diarrhoea, severe nausea, vomiting and abdominal pains. Symptoms appear as early as 30–60 minutes after swallowing food infected with <i>S. aureus</i> but disappear after 1–3 days in healthy immune system. People with weak immune system and those who have had severe skin trauma are at higher risk for invasive staphylococcal infections. If left untreated it may lead to severe and life-threatening illnesses including septic arthritis, pneumonia and sepsis.
<i>Vibrio vulnificus</i>	Symptoms vary depending on the immune system; healthy individuals experience diarrhoea, vomiting and abdominal pains whilst people with weak immune system have fatal illnesses including dangerously low blood pressure, blistering skin lesions, sudden chills and fever which may lead to death within 2 days of infection on average.

Adapted from the USDA, Food Safety and Inspection Service (USDA, 2013).

multi-omics approaches (Burnum-Johnson et al., 2017) may provide a clearer picture, and allow for a more precise conclusion to be made. A typical omics workflow is depicted in Fig. 1.

Genomics can be described as the study and assessment of variability and function of DNA sequences (Aebersold and Mann, 2016; Stefanovic et al., 2017). During the past two decades, the unprecedented advancements in DNA sequencing technologies and computational-based annotation (bioinformatics) techniques has revolutionised the fields of genomics and transcriptomics (Andjelkovic et al., 2017; Valdes et al., 2013). These fast evolving technologies provide detailed information on genome structure, gene function, and various metabolic networks and pathways. However, unlike the genome which is considered more static, and does not show significant response to short-term external changes, the transcriptome allows for the detection and quantification in gene expression levels in a dynamic manner (Zhang et al., 2010).

Proteomics (Martinovic et al., 2016) is the study of the structure, function and abundance of different proteins and peptides (or complexes) in a system. Proteins are important parts of cells and are involved in various processes and regulatory mechanisms. The proteome is also considered highly dynamic, which under different environmental or physiological conditions will result in changes in its properties, such as: protein abundance, structure, localization, synthesis, degradation and modification (Larance and Lomond,

**Figure 1** A typical omics workflow from experimental design to biological interpretation.

2015). Therefore, understanding the changes in the proteome requires the identification and detection of changes in protein abundance, interactions, structure and properties. Subdivisions of proteomics include the fields of peptidomics (Giacometti and Buretic-Tomljanovic, 2017; Giacometti et al., 2013; Korte and Brockmeyer, 2017) and secretomics (He et al., 2015; Sibbald et al., 2006). Many proteins are also modified by post-translational modifications (PTM) including (for example) glycosylation (50% of the proteins in man contain glycans) and phosphorylation which are known to change the function of the protein. It is therefore also important to have information about the protein as well as its PTM.

Metabolomics (Dunn and Ellis, 2005; Ellis et al., 2007) is the comprehensive and systematic study of low molecular weight compounds (metabolites) in a system. The metabolome generally refers to the complete set of small molecules involved in metabolism (metabolites) present in a cell that contributes to metabolic reactions which are required for the maintenance, growth and normal function of a cell in a particular physiological or developmental stage (Fiehn, 2002). The metabolome is considered one of the main components within systems biology (Patti et al., 2012), linked to other cellular processes such as: gene expression, post-transcriptional and translational events and physiological changes. This field encompasses a range of approaches such as metabolic profiling (Li and Zhu, 2017), metabolic fingerprinting (Ellis et al., 2007, 2012; Muhamadali et al., 2016a), metabolic footprinting (Kaderbhai et al., 2003; Kell et al., 2005) and multiple technologies such as a range of mass spectrometry (MS) (Singhal et al., 2015; Ouyang and Cooks, 2009), NMR (Garcia-Perez et al., 2017; Wright et al., 2009), and vibrational spectroscopy (Ellis et al., 2017; Black et al., 2016). The field of fluxomics (Brul et al., 2012; Yadav et al., 2018), which uses isotope tracing to monitor fluxes, is a subdivision of metabolomics.

Lipidomics (German et al., 2007; Jain et al., 2007) is a growing area of study, also originally considered a subdivision of metabolomics, and can be described as the study of pathways and networks of different lipid species in a system. Lipids are considered highly complex and crucial metabolites with important and diverse functions in biological systems, such as extremely important components of cellular membrane and barriers, signalling, and interconnecting various metabolic pathways (Rolim et al., 2015). However, detection and quantification of such a diverse and complex class of compounds requires robust analytical tools. So-called hyphenated methods, where MS (usually tandem and MS<sup>n</sup>) is/are coupled to chromatographic separation-based techniques for example, such as liquid chromatography (LC), and are considered the dominating analytical platforms in the field of lipidomics (Cajka and Fiehn, 2016).

### Recent Omics Studies of Foodborne Pathogens

At the time of writing, the largest recorded outbreak of foodborne bacterial disease is underway in southern Africa with a total of 973 victims and 183 deaths to date (March 2018). Caused by *L. monocytogenes*, this record outbreak is thought to involve ready-to-eat meats such as polony, a regionally very popular form of low-cost sausage typically made from highly processed meat. The ST6 sequence strain has been confirmed at production facilities in South Africa, and the outbreak is beginning to spread to neighbouring countries such as Namibia (reported this month in (Heiberg, 2018; Rosa, 2018)). It is large-scale and lethal foodborne disease outbreaks such as these, that bring the potential effects of pathogenic bacteria present within highly industrial modern food supply chains sharply into focus. Here we very briefly describe a selected range of recent omics studies involving some of the most well-known foodborne bacteria and also direct readers to several reviews of interest in this important area of food safety.

So-called pathogenomic studies of *Listeria* spp. have been undertaken for some considerable time in order to explore data from multiple omics approaches (genomics, transcriptomics, proteomics) to understand better the genomic diversity and evolution, and

the physiological aspects related to the metabolomics, of this deadly genus when these bacteria are exposed to and grow in diverse environments (Hain et al., 2007). Furthermore, this particular genus has recently gained its own omics suffix with the publication of listerionics (Becavin et al., 2017), as well as already being a distinct area of study within microbiology termed listeriology (Lebreton et al., 2016). In addition, one could state that a commonality between many, if not all, of the omics approaches is that they are data rich, generating and subsequently requiring the analysis of large and very highly complex datasets (Gromski et al., 2015), with them once being described as “producing bounteous data floods” (Goodacre et al., 2003) (more on this below).

The listerionics project appears to be no exception, with this very recent study comprising an eponymous web-based platform integrating the complete genomes (>80), transcriptomes (~350) and proteomes (25) published to date, with various tools for omics data analyses (Becavin et al., 2017). These multiple tools are said to allow for an integrative systems biology (Kell, 2004) approach, which the interested reader can find here: <https://listerionics.pasteur.fr/Listerionics/>. This platform includes an interactive genome viewer allowing for the display of gene expression arrays, tiling arrays, sequencing, proteomics, and genomics data sets; a protein and expression atlas to connect genes, RNA, or proteins with the most relevant omics data; a protein conservation exploration tool; and a co-expression network tool. Allowing for what the authors state to be the ability to study and browse multiple mechanisms in this important pathogen such as host–pathogen interactions, RNA regulation and this organisms adaptations to stress (Becavin et al., 2017). Another computational-based and related, if less comprehensive, approach is termed the *Salmonella* food-borne syst-omics database (SalFoS), <https://salfos.ibis.ulaval.ca/>. This consortium-led database hopes to improve food safety via the reduction of salmonellosis. With an analytical pipeline of genomic and phenotypic metadata on genome evolution, antibiotic resistance and virulence, its aims are to improve the accuracy of diagnostic methods, identify prognostic markers to aid surveillance and epidemiology, as well as develop in-field control methods (Emond-Rheault et al., 2017).

Any further development of in-field control methods is very encouraging, as large-scale outbreaks of foodborne disease involving pathogenic bacteria, such as the devastating South African Listeriosis outbreak, always have the potential to remain undetected for some considerable time. Whilst the specific source(s) of a foodborne outbreak remain undetected, this can obviously result in an increase in the incidence and spread of disease through communities and increased mortality rates. Therefore there is an obvious and urgent requirement to be able to attribute the source of foodborne disease rapidly and on-site/in-field, which in itself has been said to be leading towards a trend for more so-called culture-independent diagnostic tests (CIDs) (Forbes et al., 2017), which can link clinical cases both to each other and of course directly to food products. These can include metagenomics approaches (also referred to as environmental genomics) such as next-generation sequencing (NGS) which is increasingly being used for whole genome sequencing (WGS), as well as other omics methods and single cell technologies which have been stated to have the potential to revolutionize the fields of food safety and public health (Forbes et al., 2017).

Some envision that data from genomics and related omics tools could lead to a paradigm shift in contemporary and future food safety similar to those already underway in human medicine (Kambouris et al., 2018; Chen et al., 2012; Wishart, 2016) and the veterinary field (Van Borm et al., 2015). With precise pathogen detection, characterization and identification, leading to highly accurate risk assessments and the foundation for evidence-based food safety surveillance and monitoring decision making, a truly systems level approach (Capra and Luisi, 2014) which Kovac and co-workers term “precision food safety” (Kovac et al., 2017). Others agree, and also that a transition is underway at the molecular level, from traditional molecular biology-based methods currently seen as gold standard, to omics technologies, such as WGS, NGS tracking, as well as high resolution technologies such as CRISPR-based typing methods which constitute practical and powerful alternatives and will provide valuable insights into problematic food-associated bacterial pathogens (Barrangou et al., 2016).

Others have investigated the role of multiple omics methods and in particular the growing role of proteomics for the detection of specific microbial toxins (Martinovic et al., 2016; Josic et al., 2017). Microbial toxins can be placed in foods deliberately of course as a form of bioterrorism (Wein and Liu, 2005), and one recent study investigated the potential of proteomics methods in detecting toxins predominantly isolated from known bacterial food pathogens, namely *Clostridium perfringens*, *Staphylococcus aureus*, *Shigella dysenteriae*, enterohemorrhagic *E. coli* strains, and cytotoxic distending toxin from *Campylobacter jejuni*. With the goal being to develop an antibody-free proteomics assay to improve the multiplexing capacity of foodborne toxins. Antibody-free sample preparation was followed by LC-MS/MS, a targeted proteomics approach also known as LC-SRM (selective reaction monitoring), with highly specific detection and quantification enabled through the use of isotopically labelled protein references spiked into food matrices. The sensitivity of the assay for multiple toxins was lower than the oral LD<sub>50</sub> likely to be used to contaminate the food supply, and whilst initially developed to improve food defense (Manning et al., 2005; Manning and Soon, 2016), this antibody-free proteomic assay could also be applied to food quality control and public health monitoring (Gilquin et al., 2017). For a recent review of sensors used to detect specific pathogens and identify toxin-contaminated foods and beverages the reader is directed to Alahi and Mukhopadhyay (Alahi and Mukhopadhyay, 2017).

Metabolomics has grown exponentially as a field over the last decade with what has been said to be exciting applications across a wide range of biosciences (Putri et al., 2013), including multiple applications to food (Ellis et al., 2012; Cevallos-Cevallos et al., 2009; Nychas et al., 2008; Scalbert et al., 2014; Vrhovsek et al., 2012) and foodborne bacterial pathogens (Pinu, 2016; Cevallos-Cevallos et al., 2011; Xu et al., 2010; Ellis et al., 2002). With far less lipidomics studies relating to food (Hyötylainen et al., 2013; Murphy and Nicolaou, 2013) and even less so to foodborne bacterial pathogens (Dubois-Brissonnet et al., 2016), it is not surprising to find very recent food-related research which integrates both metabolomics and lipidomics approaches (Trivedi et al., 2016).

Interestingly, one of these integrated approaches specifically involved species of bacteria belonging to the well-known foodborne pathogen *Campylobacter*. This study primarily used metabolic fingerprinting approaches utilizing Raman and high-throughput

Fourier-transform infrared (FT-IR) spectroscopies, and matrix-assisted laser desorption ionisation-time of flight-mass spectrometry (MALDI-TOF-MS), with confirmation by 16S rRNA gene sequencing, for the differentiation of 11 strains of *Campylobacter* from six species. These six species included the most common foodborne pathogens from this genus, *C. jejuni* and *C. coli*, as well as *C. lari*, *C. hyointestinalis*, *C. fetus*, and *C. consisus*. Analysis of data from these three methods not only showed successful differentiation of all isolates, but also discrimination of two phylogenetically very closely related subspecies of *C. fetus* by FT-IR and MALDI-TOF-MS, which was found to be partly as a result of information from the lipid region of each rapid method. Subsequently, targeted lipidomics using LC-MS was used to further explore this and confirmed the findings from both fingerprinting methods, revealing major differences in the intensities of several classes of lipids between the two subspecies of *C. fetus* including phosphatidylcholine, phosphatidylethanolamine and phosphatidic acids. These results were said to show the potential of these rapid high-throughput techniques for the simultaneous detection and differentiation of different *Campylobacter* spp. down to subspecies levels (Muhamadali et al., 2016b).

Furthermore, as studies such as those by Muhamadali et al. (2016b) involve rapid methods; they also have the potential to be undertaken with field deployable instrumentation, or on/at-line within food production facilities. Field deployable instrumentation has much promise for the future. With methods such as handheld Raman (Ellis et al., 2017) and other forms of optics and spectroscopy (Crocombe, 2018), as well as developments in miniature MS (Ouyang and Cooks, 2009; Gao et al., 2006) and other sensors (Seo et al., 2016), which can be deployed on-site and/or coupled with smartphone technology (Gallegos et al., 2013) for rapid detection of bacteria on food, as recently demonstrated by Pearson et al. (Pearson et al., 2017, 2018).

## Outlook

Here, we have very briefly discussed the global burden of foodborne disease, provided a short background to the main omics approaches, and showed the potential of these approaches applied to the study of a range of common bacterial food pathogens. The reader will note that the final applied section began with two large data analytical studies, on *Listeria* and *Salmonella* respectively, using web-based platforms, followed by examples from genomic, proteomic, metabolomic and lipidomics approaches and their respective technologies. As already inferred above and by many others previously, it is important to highlight the data rich nature of all omics approaches and therefore the pivotal and indeed crucial role of a range of computational methods employed to analyse highly complex datasets generated by the omics.

What Kell once termed “data floods” over a decade and a half ago (Goodacre et al., 2003) could now quite accurately be described as data reservoirs. Data reservoirs which can not only store but are also able to analyse the massive volumes of data captured from multiple omics sources, with a range of built-in tools and functionality (as per listerionomics above). With these data reservoirs populated with primary data generated by omics, now having the additional potential to be accessed anywhere in the world to be utilised, analysed, or augmented by researchers in the field during and following food disease outbreaks. In order to influence decision-making, reduce the potential risk and impacts, or aid the rapid, accurate, on-site analysis of foodborne pathogens within food production facilities as well as in communities.

Omics can be said to have much potential for the detection of foodborne pathogens, as well as monitoring contamination and disease outbreaks, particularly when integrated with each other but especially so when incorporated within emerging and vitally important current and future technologies and resources such as the Internet of Things (IoT) (Seo et al., 2016; Badia-Melis et al., 2015) and Cloud-based computing (Gorelick et al., 2017; Tzounis et al., 2017).

# New Analytical Frontiers in Mycotoxin Research

Laura Righetti and Chiara Dall'Asta, University of Parma, Parma, Italy

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Mycotoxins are one of the major food contaminants, causing important losses on the agricultural market, as well as being a great concern for food safety due to their toxicity. Indeed, more than 400 mycotoxins with widely different chemical structures have been identified so far, and their number is expected to increase further due to climate changes. The Food and Agriculture Organization (FAO) estimates that 25% of the world's food crops are affected by mycotoxin-producing fungi. Faced with this threat, a legal framework is gradually being set up to establish standards defining the maximum acceptable level of mycotoxin in foodstuffs.

Currently, only maximum levels for aflatoxins (AFs), deoxynivalenol (DON), zearalenone (ZEN), ochratoxin A (OTA), fumonisins (FBs), and patulin in various foodstuffs have been set in the EU countries. Recently, the European Commission fostered the release of two guidance documents concerning the identification criteria for mycotoxins and relating to the estimation of the limit of detection (LOD) and quantification (LOQ) for several classes of contaminants. Moreover, the European Food Safety Authority CONTAM Panel set a group tolerable daily intake (TDI) based on relative potency factors, calculated for the parent mycotoxins and its modified forms. Following their indications, the contamination should be expressed as the overall amount of parent compound and its modified forms. Using the established group, TDI would overestimate any risk of modified forms, structurally altered forms of the parent mycotoxins by plants and other living organisms (i.e., fungi, bacteria, mammals).

As a result, enforcing such standards requires appropriate analytical tools to detect and quantify mycotoxins and to identify new hazardous metabolites. In this frame, it should be mentioned that determination of mycotoxins is a challenging task because of their low occurrence levels and the complexity of the matrices.

Rapid, sensitive, and accurate analytical methods for determination of these mycotoxins in unprocessed cereals and cereal-based products are highly required to properly assess both the relevant toxicological risk for humans and animals, as well as to ensure that regulatory levels fixed by the European Union are met.

Several analytical techniques have been developed for different purpose, having different accuracy and sensitivity. The most widely used methods to monitor mycotoxins are chromatographic and immunological methods. Both approaches are useful when gathering surveillance data to determine the overall amount of legislated mycotoxins. However, they meet the current demands coming from two different stakeholders. Indeed, ongoing developments in the field of mycotoxin analysis polarized between the two approaches on opposite sides of the analytical spectrum to meet the demands of both regulatory authorities and research scientists for mycotoxin detection.

The first has been the development of rapid screening methods for a variety of analytes based on immunochemical techniques, such as ELISA or lateral flow devices. The second is the development of highly advanced multianalyte methods based on liquid chromatography coupled with high-resolution mass spectrometry for identification and simultaneous quantification of a wide range of contaminants.

Rapid screening methods based on ELISA system are user friendly, enable testing of large numbers of samples, and thus potentially represent a powerful tool for point of sampling in all parts of the food processing chain providing semiquantitative results. By contrast, the multicontaminant mass spectrometric methods require highly skilled laboratory staff, and enabling quantification with confirmation of the analytes of interest is spreading rapidly as a promising technique for simultaneous screening, identification, and quantitative determination of a large number of mycotoxins. Taking advantage of the improvement offered by high-resolution mass spectrometry instruments (HRMS), in the past few years, mycotoxin analysis has been moving from the targeted analysis of individual mycotoxins to the analysis of hundreds of contaminants in one run. In addition, omics strategies started to be exploited for the mycotoxin issue, and their applications have been recently reviewed. The increasing number of successful metabolomic approaches suggests that this new omics could soon play a major role in many aspects of food safety.

## Rapid Screening Methods

For farmers and small industrial producers, mainly fast screening tools for monitoring regulated mycotoxins are of interest. This is both due to the need of high-throughput analysis and due to the lack of resources to own expensive instruments and hire highly skilled laboratory staff. On this account the availability of portable devices is highly preferred to permit rapid on-site analysis by importers, traders, and companies. Hence, one of the major challenges is to minimize the detecting instruments to move detection methods from the lab to the field.

Rapid methods based on immunochemical reactions in various arrangements with different types of signal detection continue to attract commercial interest because they are cost-effective, rapid, and easy-to-handle. The most well-known and widely used methods are enzyme-linked immunosorbent assay (ELISA) and lateral flow immunoassays (LFIA). Immunoassays rely on the reaction between the specific antibodies and the analyte and therefore present such advantages as high sensitivity and selectivity.

An upcoming trend appears to be the development of immunoassays, which are able to determine several mycotoxins. For instance, the use of an ELISA kit as a promising group detection tool for the accurate evaluation of deoxynivalenol (DON) and

its modified forms, expressed as sum of DON, DON-3Glc, and 3Ac-DON, in soft wheat and maize, has been investigated (Righetti et al., 2016). Recently, a membrane-based flow-through test was presented, which was able to accurately screen zearalenone (ZEN), DON, aflatoxin B1 (AFB1), and ochratoxin A (OTA) in a variety of cereal-based feedstuffs.

The cross-reactivity phenomenon is one of the critical issues of immunochemical methods. However, if it is strictly under control and related to, modified mycotoxins or other similar mycotoxins might be desirable. Indeed, these kits may be helpful in the routine practice for a mycotoxin-group detection, as recommended by the recent EFSA opinions.

Despite the availability of several commercial ELISA there is still a lack of rapid screening methods, which require minimal sample preparation and can be used for on-site monitoring. In this frame, analytical methods using spectroscopy-based system, routinely used for the detection and identification of molecular constituents, are nowadays started to be applied to mycotoxin analysis. Their applications for rapid analysis for mycotoxin-contaminated commodities have been recently reviewed. Rather than to quantify a single mycotoxin, these methods are useful to classify commodities as compliant or noncompliant against a decision limit fixed by the European Union. Therefore, multivariate data evaluation and classification strategies (i.e., chemometrics) are fundamental for establishing appropriate classification and quantification schemes. Successful applications of NIR spectroscopy have been employed to predict DON and fumonisins levels in corn. Hyperspectral imaging allowed to discriminate between contaminated grain for OTA as well as OTA-producing *Penicillium verrucosum* strains.

A step toward a spectroscopy-based system intended to be used as the first-line-control method was described by Sieger et al. (2017). The authors proposed an on-site analysis by using infrared laser spectroscopy to classify peanuts as compliant or noncompliant for levels of AFB1 ( $8 \mu\text{g kg}^{-1}$ ). Furthermore, biosensor array is also a good option for fast screening of mycotoxins. The field of microfluidics holds great promise for the development of simple and portable lab-on-a-chip systems. Very recently, a capillary chip portable device has been tested, enabling the simultaneous detection of OTA, AFB1, and DON. Results were acquired using a standard smartphone camera and analyzed with a simple gray scale quantification procedure.

This scenario is moving fast toward a lab-on-mobile-device platform, and it is also facilitated by the launch from many companies of mobile reading app that have excellent potential for allowing performance of analysis and interpreting results. Despite this technology is still in the early development stage, results are promising. Sensitive and high accurate measurements are reported and also compared to HPLC data.

Mobile phones are now so widespread and accessible that this technology has been proposed for mycotoxins monitoring in developing countries. Smartphone rapid diagnostic readers have been tested in field trials in Africa to control and reduce aflatoxin contamination.

Proposals for rapid analytical methods for legislated mycotoxins, based on chemical molecular recognition, represent still a major fraction of newly published articles. The reduction of instrumental complexity and the development of user-friendly devices for point-of-need analyses allowed the spread of these methods. Miniaturization to foster on-site analysis is the key trend, and multianalyte detection is highly preferred. However, the main drawbacks are the number of false positives (because of cross-reactivity and matrix-dependence) or false negatives (because of low sensitivity), in comparison with chromatographic methods. Therefore, these methods are insufficiently precise to satisfy the legal requirements for making decision.

Future work will be required also on detection and quantification of modified mycotoxins, whose importance is discussed in the recent published EFSA opinion on modified mycotoxins.

## Liquid Chromatography–Mass Spectrometric Methods

### Low- and High-Resolution Mass Spectrometric Methods

In the first section, the many possibilities of rapid methods for mycotoxin analysis were reviewed. Immunological methods can detect most of the mycotoxins, but they are mainly used for screening.

However, mycotoxin analysis is also frequently achieved by chromatographic techniques. Primarily liquid chromatography (LC) coupled with ultraviolet/diode array detection and fluorescence detection was used.

Subsequently, in the last two decades, LC–MS/MS became the method of choice, in particular, for its ability to allow the development of multiresidue and multiclass methods. The first low-resolution multitoxin method was developed in 2006 for the quantitative determination of 39 parent and modified mycotoxins.

Despite having become a well-established technique, the triple quadrupole (QqQ) method setup is time-consuming when aimed at determining a large number of substances. Likewise, this technique presents limitation on the number of compounds that can be analyzed in one run. In addition, only targeted analytes can be detected, making necessary the use of an analytical standard, which is a critical issue in the modified mycotoxin field.

With new development in mass spectrometric instrumentation and with the introduction of benchtop high-resolution mass spectrometry instruments (HRMS), such as Time-of-Flight (ToF) and Orbitrap, full-scan techniques started to be investigated as complementary approach for the QqQ-based methods on the basis of increased resolution power and detectability. While the use of HRMS for the quantification of one or few analytes does not pose any significant advantage compared with MRM-based methods, multicontaminant methods seem to be the most promising approach for food and feed surveillance in the coming years. In particular, the availability of sensitive LC–MS instruments that are less prone to matrix effects allows to oversimplify the sample preparation and to avoid cleanup steps. Thus, the general tendency is to avoid any cleanup steps exploiting the selectivity and

sensitivity of MS technique. Dilute and shoot and the injection of raw extract, without any cleanup, is now commonly performed in multiresidue LC–MS analysis.

The enhanced selectivity and sensitivity provided by HRMS allowed the development of methods that cover a wide range of co-occurring contaminants (i.e., pesticides, mycotoxins, plant toxins) with different physicochemical properties.

The major advantage of using HRMS over MS/MS techniques for the targeted analysis is actually due to the possibility to perform retrospective data analysis, thus enabling the possibility to reconsider analytical results for stored data. The measurement of accurate MS and MS/MS spectra (resolution <5 ppm) allows the determination of compounds without previous compound-specific tuning, to carry out retrospective analysis of data and to perform structural elucidation of unknown or suspected compounds. This is particularly worth noting when modified mycotoxins are considered.

Besides the quantitative analysis, HRMS' major benefit is related to the qualitative analysis and it is due to the possibility to perform structural elucidation of newly discovered mycotoxins and phase I and phase II metabolites. As an example, the identification of new trichothecene conjugates such as FUSX-glucoside and NIV-glucoside, or acetyl-T2, was allowed on the basis of accurate mass measurements. LC coupled to Quadrupole Orbitrap MS was also adopted for the identification of acetylated metabolites of ZEN in wheat and of neosolaniol-glucoside (NESGlc) and diacetoxyscirpenol-glucoside (DASGlc) in maize.

From the abovementioned examples and application, it is clear that HRMS is gaining increasing interest in both research and routine laboratories. Targeted and routine quantification as well as qualitative research analysis can be performed with the same instrument. This situation is also facilitated by the launch from many MS companies of the latest generation of HRMS instrumentation designed for routine analysis and equipped with user-friendly dedicated data processing software.

### Advanced High-Resolution Ion Mobility Spectrometry Applications

The great increases in sensitivity and selectivity of LC–MS instruments have made a significant contribution in qualitative and quantitative determination of mycotoxins in food commodities. However, matrix effects, isobaric interference, and maintaining confidence in the assignment of identity are still the major limitations for LC–MS methods used for the quantification and identification of mycotoxins.

In this frame, the ion mobility–mass spectrometry (IM-MS) is explored as a new promising approach that can overcome the abovementioned HRMS limitation, making it an ideal candidate for improving confidence in the identification and separation of structurally closely related isomers. IMS is a gas-phase electrophoretic technique that provides a new dimension (3D) of separation based on size, shape, and charge of ions. Comprehensive reviews addressing, in detail, the various ion mobility techniques have been presented.

In addition, IMS allows the measurement of collision cross-section values (CCS), which is a unique orthogonal molecular descriptor that, when used in addition to retention time and mass-to-charge ratio ( $m/z$ ), offers the opportunity to further improve and support the identification process. This allows CCS to be used alongside the traditional molecular identifiers.

At first, this interest was primarily oriented in separating structurally related isomers. As an example, DON-oligo-glucosides were analyzed using drift tube ion mobility spectrometry (DTIMS) enabling the detection of one more DON-di-Glc and two more DON-tri-Glc peaks separated by their drift time, compared with LC–HRMS results. These additional peaks were tentatively attributed to the linkages, 1–4 or 1–6, between the sugar moieties and the mycotoxin, as the bounding position was confirmed by HRMS-MS/MS. Therefore, IMS-MS allowed the detection and subsequently the characterization of new isomeric DON-oligo-Glc, also increasing confidence in results.

Apart from the isomeric separation, IMS is starting to be successfully employed in routine screening analysis. Indeed, CCS values can be routinely measured as an integrated part of LC–HRMS experiments and used alongside the traditional molecular identifiers (i.e., precursor ions, accurate masses, fragment ions and isotopic patterns, retention times) to reduce the number of both false positive and false negative of targeted analysis. Recently, the potential of CCS as an additional identification point (IP) for residue analysis has been discussed, in consideration of the precision and the robustness of the CCS measurement. Their reproducibility across multiple samples and instruments has been demonstrated by analyzing more than 100 CCS values of parent and modified mycotoxins. The measurements showed high reproducibility (RSD <2%) across different instrumental settings as well as several complex cereal matrices (i.e., malt, rye, corn flakes, maize feed, wheat), showing a mean intermatrix precision of RSD <0.9%. The database was applied to the analysis of several spiked as well as naturally incurred cereal-based samples, demonstrating that no matrix effect is interfering with the IMS separation.

Thus, it is an argument in favor of considering CCS as valuable parameter in food safety control. Population of databases with CCS values for mycotoxins is pivotal to implement the CCS comparisons and thus to support the inclusion of CCS values as a new identification point.

CCS values may also be estimated computationally if the 3D structure is known. A comparison of the theoretically and experimentally derived collision cross-sections can be used for the accurate assignment of isomeric metabolites when analytical standards are not available. This approach has been recently applied to elucidate glucuronide metabolites of DON, ZEN, AOH, and AME. Indeed, the authors demonstrated a good correlation between theoretical and experimental CCS, suggesting the potential of the CCS matching in supporting the annotation procedure. The use of theoretical CCS values offers a unique means of characterization to overcome the lack of analytical standards and the limitation of HRMS when fragmentation pattern of two isomers is not useful in discriminating.

IMS is spreading rapidly as a promising technique for simultaneous screening, identification, and quantification of a large number of mycotoxins. As for LC–HRMS, both research and routine analysis can be performed in the same instrument. With this perspective, CCS database must be populated to widen the range of contaminants that can be present in food samples.

### Metabolomics Approaches to Study Mycotoxin Metabolism

In the recent years, the tremendous progress in high-resolution mass spectrometry and software tools facilitate the spread of metabolomics approaches also in the contaminants field. Indeed, novel research in mycotoxin analysis has been moving from the targeted analysis of individual mycotoxins to untargeted analysis to detect not only the mycotoxins itself and their biotransformation products but also all the metabolites that are involved in plant–fungi interactions.

Metabolomics is going to open new avenues into safety evaluation of foods and food components. Two different strategies can be distinguished within this approach: metabolomics profiling, focused on a predefined group of structurally related compounds, and untargeted metabolomics, which aim to record MS features of all detectable compounds.

Metabolic profiling strategy has been in depth applied with the aim to elucidate the biotransformation pathways of a determined mycotoxin in plant. Therefore, the major method used in this area is based on *in vivo* stable isotope  $^{13}\text{C}$  labeling (SIL) and subsequent measurement of biological samples by full-scan high-resolution LC–MS. The spectra comparison and metabolite identification are supported by the use of a dedicated software able to monitor pairs of corresponding nonlabeled and labeled precursor. This powerful approach simplifies the identification of novel unknown compounds (i.e., feruloyl-T2) or novel mycotoxin metabolites. So far, the abovementioned approach has been employed to understand the metabolic fate of HT-2 toxin and T-2 toxin in barley and oats and DON in wheat.

Not only profiling but also untargeted metabolomics starts to be widely applied. This approach represents the golden tool for understanding the biological pathways involved in mechanisms of plant resistance against fungal attack.

The main advantage provided by the nontargeted nature of the method is based on the possibility of detecting new metabolites involved in the resistance mechanisms helpful in deciphering new pathways, enabling the detection of hundreds of small molecules in one run. Such an approach requires advanced analytical instruments as well as strong knowledge of chemometric tools.

On the other hand, the main constraint is related to the complexity of the plant metabolome. Seeking for all plant metabolites simultaneously is extremely challenging because of the high chemical diversity. Currently no extraction protocol combined with a single analytical technique allows considering the entire metabolome, and consequently, the data delivered by metabolomic studies only cover a fraction of the metabolome.

This promising method allowed to improve our limited understanding of the roles of plant pathogen cross-talk at the molecular level. Most of the recent findings are deeply described in a comprehensive review.

The advent of “omics” in the mycotoxin research field is also stressed by the inflationary use of this term. “Mycobolome” and “Xenobolomics” have been used to refer to the whole set of fungal metabolites, while “Maskedome” includes all the possible modification. With the aim to estimate the human exposure toward toxic compounds, also the “exposome” has been defined. Although risk assessment is commonly based on the targeted quantification of mycotoxin urinary biomarkers (i.e., glucuronides and sulfate metabolites), the use of untargeted HRMS will theoretically enable the investigation of the whole individual exposure, linking dietary exposure to the outcome of specific diseases.

### Summary and Future Outlook

Over the last few years, the mycotoxin scientific community has experienced a shift from classical LC–MS analysis based on QqQ to the use of HRMS, in particular, for multianalyte applications. The analytical potential of high resolution, accurate mass, and acquisition in full scan permits a retrospective analysis using extensive databases of hundreds of analytes. In addition, studies based on untargeted approaches are becoming more popular, especially for the analysis of biomarkers of exposure, under a “human exposome” approach. Therefore, HRMS is undoubtedly going to redefine the analytical scene for quantitative and qualitative mycotoxin analysis. On the other hand, simple and rapid tools for screening are becoming the golden standard for qualitative routine analysis, when a clear cut-off for acceptance or withdrawal of batches can be set. In this field, the scenario is moving fast toward multitoxin systems, biosensors able to return a response in terms of “cocktail,” and ICT-driven solutions that can be easily managed in remote with cloud data storage.

## Glossary

**Amplicon sequencing** Sequencing of targeted PCR products (e.g. 16S rDNA sequencing).

**Next-generation sequencing** Also called high-throughput sequencing; high-throughput nucleotide sequencing technologies that can sequence many DNA strands in parallel.

**Read** Sequenced base pairs generated from a DNA fragment.

**RNA sequencing (RNA-Seq)** Sequencing of an entire transcriptome, using cDNA synthesized from RNA.

**Sanger sequencing** Also referred to as first-generation sequencing; a low-throughput nucleotide sequencing method which relies on the incorporation of fluorescently-labelled, chain-terminating dideoxynucleotide triphosphates (ddNTPs) by DNA polymerase during the elongation step of PCR. The resulting strands are separated using capillary gel electrophoresis, and the emission spectra of the fluorescently-labelled ddNTPs are determined using laser excitation.

**Shotgun metagenomic sequencing** Untargeted sequencing method that employs NGS technologies to sequence all DNA extracted from an environmental sample, including food or other complex matrices.

**Shotgun metatranscriptomic sequencing** Untargeted sequencing method that employs NGS technologies to sequence cDNA synthesized from RNA extracted from an environmental sample, including food or other complex matrices.

**Whole-genome sequencing (WGS)** Sequencing of an entire genome of a single organism.

## Nomenclature

**List of nomenclature used including all definitions and units.**

**16S rDNA** 16S ribosomal deoxyribonucleic acid

**bp** base pairs

**cDNA** complementary deoxyribonucleic acid

**cgMLST** core genome multi-locus sequence typing

**DNA** deoxyribonucleic acid

**Kb** kilobase pairs

**MLST** multi-locus sequence typing

**NGS** next-generation sequencing

**PCR** polymerase chain reaction

**PFGE** pulsed-field gel electrophoresis

**RNA** ribonucleic acid

**RNA-Seq** ribonucleic acid sequencing

**RT-qPCR** quantitative reverse-transcription polymerase chain reaction

**SBL** sequencing-by-ligation

**SBS** sequencing-by-synthesis

**SLST** single-locus sequence typing

**SMRT sequencing** single-molecule real-time sequencing

**SNP** single-nucleotide polymorphism

**wgMLST** whole genome multi-locus sequence typing

**WGS** whole-genome sequencing

## Overview

*Next-generation sequencing* (NGS) encompasses sequencing technologies that are capable of sequencing many DNA strands in parallel, resulting in higher throughput than can be achieved using *Sanger sequencing*. As NGS has become cheaper and more accessible, it has been used to address an expanding range of biological problems, including many relevant to food safety and quality.

## Next-Generation Sequencing Technologies

Contemporary NGS sequencing platforms employ either a (i) short-read, or (ii) long-read sequencing approach (Table 1). Short-read sequencing approaches typically yield read lengths of up to 700 base pairs (bp), which tend to be shorter than those produced by Sanger sequencing (Goodwin et al., 2016; Liu et al., 2012). Currently, sequencing-by-synthesis approaches (SBS) to NGS are the dominant paradigm in short-read sequencing. These approaches (e.g. Illumina sequencing, Roche 454 pyrosequencing, Ion Torrent semiconductor-based sequencing) rely on the use of DNA polymerase in their respective methods (Goodwin et al., 2016). SBS approaches to short-read sequencing can be contrasted with the sequencing-by-ligation (SBL) approach employed by the SOLiD (Small Oligonucleotide Ligation and Detection) platform, which employs DNA ligase to join fluorescently-labelled probe and anchor sequences to a DNA strand (Goodwin et al., 2016). Among the SBS approaches and short-read sequencing methods as a whole, Illumina sequencing has emerged as the dominant technology (Goodwin et al., 2016), in which fluorescently-tagged nucleotides are added in complement to amplified strands of DNA. Upon the addition of a single nucleotide, the fluorescent dye is imaged, and the identity of the corresponding base is recorded (Goodwin et al., 2016).

While short-read sequencing technologies have been the workhorse of NGS, they are not without limitations; many genomic features, such as long, repetitive regions or copy number variations, cannot be readily resolved using short reads (Goodwin et al., 2016). Long-read sequencing technologies have been able to bridge the literal gaps that their short-read counterparts have been unable to resolve, relying on either (i) synthetic long-read approaches or (ii) single-molecule long-read sequencing approaches (Pacific Biosciences and Oxford Nanopore) (Goodwin et al., 2016). Synthetic long-read sequencing approaches employ existing short-read sequencing platforms, but use barcoding during library preparation to link fragments (Goodwin et al., 2016). Single-molecule long-read sequencing approaches, however, yield “true” long reads that can span kilobases, with the approach most commonly employed as of late 2017 being the Pacific Biosciences (PacBio) single-molecule real-time (SMRT) approach (Goodwin et al., 2016). SMRT sequencing uses a DNA polymerase fixed to the bottom of a well in a specialized flow cell through which a DNA strand is passed (Goodwin et al., 2016). Upon the incorporation of a single, fluorescently-labelled nucleotide by the polymerase, light is emitted and recorded by a camera to determine the identity of the nucleotide (Goodwin et al., 2016). This can be contrasted with the aforementioned short-read SBS approaches, which rely on DNA polymerase traversing the DNA template to which it is bound (Goodwin et al., 2016). In addition to the PacBio platform, the small and highly portable MinION platform from Oxford Nanopore Technologies also employs a single-molecule long-read sequencing approach, during which a strand of DNA is passed through a protein pore along with an electric current (Goodwin et al., 2016). As different combinations of nucleotides are passed through the pore, shifts in the electric current are recorded (Goodwin et al., 2016).

Long-read sequencing is becoming increasingly popular for many applications, including gap closure in reference genomes, characterization of long genomic structures, and the generation of closed chromosomes or transcriptomes (Goodwin et al., 2016). A notable consideration when comparing short-read and long-read sequencing methods is the relatively high error rates of long-read sequencing platforms (Goodwin et al., 2016). For example, the PacBio RS II, which yields average read lengths of 10–15 Kb, has an error rate as high as 15% for a single pass through a molecule of DNA (Goodwin et al., 2016). However, this error rate can be reduced to one that rivals that of Sanger sequencing by increasing sequencing coverage through multiple passes; after 30 passes (i.e. at 30X coverage), the accuracy of the consensus is greater than 99.999% (<http://www.pacb.com/smart-science/smart-sequencing/accuracy/> and <https://www.pacb.com/uncategorized/a-closer-look-at-accuracy-in-pacbio/>) (Goodwin et al., 2016).

**Table 1** Overview of next-generation sequencing technologies discussed in this article<sup>a</sup>

Sequencing technology	Sequencing mechanism	Read length <sup>b</sup>	Error rate (type of error)
<b>Sequencing-by-ligation (SBL)</b>			
SOLiD	Ligation; 2-base encoding	50–75 bp	≤0.1% (AT bias) <sup>c</sup>
<b>Sequencing-by-synthesis (SBS)</b>			
454	Pyrosequencing	Up to 1000 bp	1% (indel) <sup>d</sup>
Illumina	Illumina SBS	25–300 bp; can be 100 Kb if synthetic long-read library preparation is used	0.1% to 1%, depending on platform/output (substitution)
Ion Torrent	Hydrogen ion detection	Up to 400 bp	1% (indel)
<b>Single-molecule long-read</b>			
Oxford Nanopore	Nanopore	Up to 200 Kb	12% (indel)
Pacific Biosciences	Single-molecule real-time sequencing	8–20 Kb	13% for a single pass (indel)

<sup>a</sup>Summarized from reviews of NGS technologies by Goodwin et al., Liu, et al., and Glenn (Goodwin et al., 2016; Liu et al., 2012; Glenn, 2011).

<sup>b</sup>bp, base pairs; Kb, kilobase pairs.

<sup>c</sup>AT, adenine and thymine.

<sup>d</sup>indel, insertion/deletion.

## NGS Data Analysis

Processing and analysis of NGS data is dependent on the sequencing technology used, as well as the experimental goals. Regardless of sequencing method or experimental design, the first steps in the analysis of NGS data usually involve an assessment of read quality, using metrics such as the total number of reads, the distribution of read lengths, sequence quality scores, etc. This can be followed by trimming of adapters and/or low-quality bases, filtering out low-quality reads, and filtering of contaminant DNA, steps for which a number of programs are available (Breitwieser et al., 2017). After these pre-processing steps, data analysis can be carried out according to the goals of the experiment, with possible food science-relevant applications discussed below (Table 2).

## NGS Applications: Whole-Genome Sequencing of Microbial Contaminants

Traditionally, microbial contaminants isolated from food undergo various organism-specific phenotypic or biochemical tests (e.g. testing for motility, toxin production, growth at various temperatures) to elucidate or confirm their identity (FDA, 1998). These tests may be supplemented with additional typing methods, such as serotyping, pulsed-field gel electrophoresis (PFGE), Sanger sequencing of a single taxonomic marker gene or genomic region (i.e. single-locus sequence typing; SLST), or Sanger sequencing of multiple loci used in a multi-locus sequence typing (MLST) scheme (Kovac et al., 2017; Sabat et al., 2013). However, the per-isolate cost of *whole-genome sequencing* (WGS) has decreased to the point at which it is comparable, and even below, the price of many of these traditional subtyping methods (Kovac et al., 2017), making it an increasingly popular method for characterizing microbial contaminants isolated from food matrices, food-associated environments (e.g. farm environments, processing environments), and, in the case of pathogenic microbes, from hosts (e.g. in human- or animal-clinical settings) (Kovac et al., 2017). Furthermore, many of these typing methods (e.g. serotyping, SLST, MLST) can be performed *in silico* using WGS data, with the advantage that one can query the majority of a microbial genome from a single data set, rather than just a small fraction of it (<0.01% for a traditional 7-gene MLST scheme) (Kovac et al., 2017). In addition to *in silico* subtyping, WGS data from microbial contaminants can be used to predict functional characteristics of isolates, query genes or genomic elements of interest within a genome (e.g. plasmids, bacteriophage, and genes contributing to antimicrobial resistance or virulence), and, in the case of pathogenic microorganisms, detect and track outbreaks (Kovac et al., 2017).

After sequencing the genomic DNA and pre-processing the resulting reads from a microbial isolate (see “NGS Data Analysis” section above), possible analysis steps that may be taken include (i) *de novo* genome assembly of the reads into contiguous stretches of sequence (contigs) (Giordano et al., 2017; Liao et al., 2015; Ekblom and Wolf, 2014), (ii) mapping reads back to a reference genome, (iii) identifying single-nucleotide polymorphisms (SNPs), insertions, and deletions (indels) in NGS data through variant calling (Olson et al., 2015), (iv) constructing phylogenetic trees to assess the evolutionary relationship of multiple isolates, (v) assigning allelic types at a genomic scale using core genome or whole genome multi-locus sequence typing (cgMLST and wgMLST, respectively), and (vi) locating genes and features in NGS data via genome annotation (Richardson and Watson, 2013;

**Table 2** Overview of food science-relevant next-generation sequencing applications discussed in this article

Next-generation sequencing application	Number of organisms queried	Nucleic acid extracted/sequenced	Genomic elements queried	Current food science-relevant applications
Whole-genome sequencing (WGS)	1	DNA/DNA	Entire genome	Characterization of food-relevant organisms at the genomic level
RNA sequencing (RNA-Seq)	1	RNA/cDNA reverse-transcribed from RNA	Entire transcriptome	Characterization of food-relevant organisms at the transcriptional level
High-throughput amplicon sequencing (e.g. 16S rDNA sequencing, DNA-barcoding)	≥1	DNA/DNA	Selected amplicon(s) present in sample (usually 16S rDNA for bacterial/archaeal communities; other loci for eukarya)	Taxonomic characterization of food-relevant microbial communities (usually bacterial/archaeal communities); authentication of eukaryotic food matrices (e.g. seafood, meat products)
Shotgun metagenomic sequencing	>1	DNA/DNA	All genomes present in sample	Characterization of food-relevant communities at the genomic level (queries eukarya, bacteria, archaea, and viruses)
Shotgun metatranscriptomic sequencing	>1	RNA/cDNA reverse-transcribed from RNA	All transcriptomes present in sample	Characterization of food-relevant communities at the transcriptional level (queries eukarya, bacteria, archaea, and viruses)

Mudge and Harrow, 2016; Yandell and Ence, 2012). These data can be used to characterize isolates at high resolution, making it possible to compare isolates geospatially and temporally at the whole-genome scale.

WGS is becoming an increasingly valuable tool for characterizing microbial contaminants—particularly pathogens—isolated from food and food processing environments. A notable example of the utility of WGS can be seen in the multi-agency collaboration in the US to sequence all *Listeria monocytogenes* isolates from human patients, food, and the environment (Jackson et al., 2016). Since its implementation in 2013, the WGS-based surveillance program detected more listeriosis clusters and solved more outbreaks each year, relative to the previous year (Jackson et al., 2016). Similar findings have been seen for *Salmonella enterica* serotype Enteritidis (*S. Enteritidis*); retrospective sequencing of 55 *S. Enteritidis* from clinical and environmental sources allowed isolates from known outbreaks to be differentiated from sporadic isolates at greater resolution than PFGE (Taylor et al., 2015). These examples showcase how WGS can be used to not only characterize foodborne pathogens at high resolution, but also the outbreaks associated with them.

### NGS Applications: RNA Sequencing (RNA-Seq) of Food-Relevant Organisms

While WGS can be used to characterize the genome an organism at unprecedented resolution, it offers no information on whether a genomic element of interest is being actively transcribed or not. This is particularly important within a food safety context; for example, the mere isolation of a pathogen from a food matrix does not necessarily mean that particular isolate is viable, or that it is transcribing the genes necessary to cause infection or intoxication in a human host. Traditionally, quantitative reverse-transcription PCR (RT-qPCR) has been employed to quantify or detect shifts in transcript levels of loci of interest. For this method, reverse-transcription PCR (RT-PCR) is used to obtain complementary DNA (cDNA) from a RNA template, and the resulting cDNA can be quantified using quantitative PCR (qPCR). In a food science context, RT-qPCR has been proposed as a method for detecting viable microorganisms, quantifying virulence, toxin, or stress response gene transcription, and quantifying microbial growth in food matrices (Postollec et al., 2011). Studying transcription at a genome-wide scale, however, was made possible with cDNA microarrays, which have been used to study the stress responses of various foodborne pathogens, as well as their transcription of toxin and virulence genes (Postollec et al., 2011; Roy and Sen, 2006; Rasooly and Herold, 2008). As NGS has become more feasible, however, it is now possible to query the transcriptome of an organism in its entirety at low cost: RNA sequencing (RNA-Seq) employs NGS technologies to sequence cDNA reverse-transcribed from RNA that has been extracted from an organism of interest (Wang et al., 2009). RNA-Seq allows one to quantitatively survey transcribed regions of an entire genome, improving upon microarrays in both cost and flexibility (i.e. the ability to characterize any organism that can be sequenced, rather than relying on the availability of an array for a particular organism), which is particularly valuable for studying organisms or genomic regions that may not be well-characterized.

After employing NGS to sequence cDNA from an organism of interest, and determining that the quality of sequencing reads is adequate, reads are usually aligned to a reference genome or an assembled transcriptome (McClure et al., 2013; Conesa et al., 2016). After assessing mapping quality and determining that it is appropriate, reads mapping to various genes or genomic regions can be quantified and normalized, taking into account biases such as gene length (Conesa et al., 2016; McClure et al., 2013). After quantification and normalization, analyses can be carried out according to the experimental goals (e.g. differential transcription under various conditions). Within the realm of food safety, RNA-Seq has been applied to pathogenic and toxin-producing microorganisms to identify differentially-transcribed genes during growth in various food matrices (Tang et al., 2015; Deng et al., 2012; Galia et al., 2017), after exposure to various stressors (e.g. acid, starvation, or antimicrobial stressors) (Zhang et al., 2014; Casey et al., 2014; Butcher and Stintzi, 2013; Jia et al., 2017), and during the infection of a host (Avraham et al., 2016).

### NGS Applications: High-Throughput Amplicon Sequencing

WGS and RNA-Seq have allowed food-associated microorganisms to be characterized at unprecedented resolution. However, these methods typically require the microorganism in question to be in pure culture or isolated via culture-based methods, a process which involves the use of organism-specific enrichment media, selective media, and isolation protocols (Kovac et al., 2017). Metagenomics, which involves sequencing DNA directly from an environmental sample, attempts to bypass the isolation step, making it possible to survey an entire community simultaneously (Kovac et al., 2017).

Until recently, NGS-based metagenomic methods have primarily involved high-throughput *amplicon sequencing*. Also referred to as “metataxonomics”, “meta-genetics”, or “marker gene metagenomics”, high-throughput amplicon sequencing employs NGS technologies to sequence targeted PCR products (amplicons) to characterize particular communities. When surveying bacterial and archaeal communities, the 16S ribosomal DNA gene (16S rDNA) is usually the amplicon of choice, as it is present in all bacterial and archaeal species. 16S rDNA sequencing has been used to survey the microbiota of various foods (De Filippis et al., 2017; Kergourlay et al., 2015; Ercolini, 2013), including fermented foods (De Filippis et al., 2017) and food matrices subjected to pathogen-specific enrichments (Jarvis et al., 2015; Lusk et al., 2012), as well as to monitor bacterial community shifts in food processing environments (Stellato et al., 2016; Hultman et al., 2015).

One of the strengths of 16S rDNA amplicon sequencing is that there are many open-source bioinformatics tools and pipelines available for data analysis and visualization of results (e.g. QIIME, Mothur). A typical workflow for analyzing NGS data from high-throughput 16S rDNA experiments may include pre-processing of the raw reads, clustering of sequences into operational

taxonomic units (OTUs) based on sequence similarity, and taxonomic assignment of sequences using a database of 16S rDNA genes (e.g. RDP, Greengenes, SILVA) (Oulas et al., 2015; Siegwald et al., 2017).

In addition to querying bacterial and archaeal communities, the same principals of amplicon sequencing can be applied to characterize eukarya. DNA-barcoding, a practice in which a specific region of a genome is sequenced, is a commonly-used method for food matrix authentication along the food supply chain (Ellis et al., 2016; Galimberti et al., 2013). For this approach, a genetic marker (i.e. a “barcode”) present in a range of taxa, but variable enough to be capable of discriminating between taxa of interest, is sequenced (Galimberti et al., 2013), similar to the way the 16S rDNA gene is used to survey bacterial/archaeal communities. When querying animal DNA in a matrix (e.g. for seafood or meat authentication), the cytochrome *b* (*cytB*) and cytochrome *c* oxidase subunit 1 (*COI*) genes are common amplicons of choice. For fungi, the internal transcribed spacer (ITS) region of the genome is the locus of choice (Schoch et al., 2012), while a number of loci have been proposed for querying plant DNA present in a matrix (Hollingsworth et al., 2011, 2016). The sequences of these genes are then compared to the barcodes of known taxa, such as those found in the Barcode of Life Database (BOLD) (Ratnasingham and Hebert, 2007) or the National Center for Biotechnology Information’s (NCBI) GenBank database (Benson et al., 2013). Applications of DNA-barcoding within the realm of matrix authentication and contaminant detection along the food supply chain have included authentication of and contaminant detection in seafood (Carvalho et al., 2015; Armani et al., 2015; Pardo et al., 2016; Kim et al., 2015; Chang et al., 2016; Carvalho et al., 2017), meat (Kane and Hellberg, 2016; Hellberg et al., 2017; Naaum et al., 2018), poultry (Hellberg et al., 2017), dairy products (Galimberti et al., 2013), olive oil (Kumar et al., 2011), and spices (Swetha et al., 2017; De Mattia et al., 2011; Galimberti et al., 2013).

Until recently, DNA-barcoding was limited by the low-throughput that Sanger sequencing provides; however, NGS has emerged as a low-cost, high-throughput alternative (Ellis et al., 2016; Shokralla et al., 2014) that has been used for characterizing both raw ingredients and processed foods (Galimberti et al., 2013). In this high-throughput approach, sequencing reads are mapped to sequences in an appropriate database (often BOLD or GenBank) after determining that read quality is appropriate. The proportion of reads mapping to a particular species in the database corresponds to the proportion of that particular species in the matrix. A notable example of the application of high-throughput sequencing for food matrix authentication is provided by Carvalho et al. (Carvalho et al., 2017), in which mislabelled cod products in Brazilian stores and restaurants were identified by targeted sequencing of the *cytB* and *COI* genes present in processed cod products using NGS (Carvalho et al., 2017). In addition to identifying mislabelled products, the composition of blended products composed of multiple fish species could be determined by sequencing the selected loci (Carvalho et al., 2017).

## NGS Applications: Shotgun Metagenomic and Metatranscriptomic Sequencing

Although high-throughput amplicon sequencing has offered a higher-resolution glimpse into food and food-associated microbiomes, it has numerous limitations that are particularly relevant within the realms of food safety and food quality, perhaps most notably the inability to query organisms that do not possess the amplicon of choice (e.g. eukarya in a community cannot be queried if 16S rDNA amplicon sequencing is performed; see “NGS Applications: High-Throughput Amplicon Sequencing” section above). For 16S rDNA amplicon sequencing of bacterial/archaeal communities, additional drawbacks include (i) difficulty achieving species-level resolution (Janda and Abbott, 2007; Rossi-Tamisier et al., 2015) and reliably distinguishing pathogenic bacteria from non-pathogenic species (e.g. *L. monocytogenes* from *Listeria innocua*, human pathogens *Bacillus anthracis* from *Bacillus cereus* and biopesticide *Bacillus thuringiensis*), (ii) PCR amplification and primer bias (Brooks et al., 2015), and (iii) inability to query functionally-relevant genomic elements directly, such as virulence or antimicrobial resistance determinants (Kovac et al., 2017).

An increasingly-popular alternative to amplicon sequencing is *shotgun metagenomic sequencing*, an approach in which all DNA present in a sample is sequenced, rather than solely an amplicon. By sequencing all DNA present in a sample, the amplification bias and low taxonomic and functional resolution issues which plague amplicon sequencing can typically be bypassed (Kovac et al., 2017). In addition to sequencing all of the bacterial and archaeal DNA present in a sample, all viral and eukaryotic DNA is sequenced; this is particularly relevant when the community of interest is derived from a eukaryotic matrix (e.g. from a host or from food), as the majority (as much as 99%) of DNA will come from the eukaryotic matrix itself (Noyes et al., 2016; Kovac et al., 2017). While large quantities of host DNA may not be a problem if the experimental goal is to assess the composition of the food matrix itself, it may hinder the sequencing and detection of many microbial species. As a result, when extracting DNA from a matrix containing high amounts of host DNA, additional steps may be taken to deplete any background DNA originating from the matrix itself to increase the proportion of microbial DNA that is sequenced (Kovac et al., 2017). After sequencing the extracted DNA, analysis of the resulting sequencing reads is carried out according to the experimental goals, which may include taxonomic assignment (Sharpton, 2014), metagenomic assembly, functional annotation (Sharpton, 2014), and/or conducting a metagenome-wide association study by associating community data with a particular phenotype (Wang and Jia, 2016; Lynch and Pedersen, 2016).

As with all genomic approaches, shotgun metagenomic methods can offer insight into the genomic composition of a community, but cannot offer information as to which genes are being transcribed and possibly translated and expressed as protein products (Kovac et al., 2017). Similar to the way RNA-Seq can be used to complement WGS of a bacterial isolate, metagenomic approaches can be supplemented with *shotgun metatranscriptomic sequencing*, which involves sequencing cDNA reverse-transcribed from RNA (typically messenger RNA) extracted from an entire community (Kovac et al., 2017).

Analysis of shotgun metagenomic and metatranscriptomic data usually begins with pre-processing steps such as assessing read quality and trimming adapters (Breitwieser et al., 2017). This can be followed by (i) assembly of the reads into contigs, or (ii) taxonomic or functional classification directly from sequencing reads (Breitwieser et al., 2017). For a review of methods for metagenomic data analysis, see Breitwieser et al. (Breitwieser et al., 2017).

The use of shotgun metagenomic and metatranscriptomic approaches to survey communities in foods has been undertaken only recently (De Filippis et al., 2017). Goals of these studies have included characterization of the microbiomes of various foods in the presence of foodborne pathogens and/or spoilage organisms (Jarvis et al., 2015; Ottesen et al., 2013), tracking foodborne pathogens and antimicrobial resistance genes along the food supply chain (Yang et al., 2016; Noyes et al., 2016), characterizing eukaryotic food matrices composed of multiple species (Ripp et al., 2014), and characterizing the microbiomes of various food matrices during processes such as fermentation (De Filippis et al., 2017; Kergourlay et al., 2015; Alkema et al., 2016; Valdés et al., 2013; Lessard et al., 2014; De Filippis et al., 2016; Monnet et al., 2016). A notable example of the application of shotgun *meta*-omics approaches to identify the cause of a food quality anomaly is provided by Quigley et al. (Quigley et al., 2016); using high-throughput 16S rDNA sequencing followed by shotgun metagenomic sequencing, *Thermus thermophilus* was proposed (and later confirmed) to be the cause of a pink discoloration defect in Continental-type cheeses (Quigley et al., 2016).

## Conclusions

NGS technologies are being employed increasingly in food science-relevant realms, with applications ranging from surveying microbial communities involved in food processing, to rapidly characterizing bacterial isolates from foodborne outbreaks. As sequencing costs continue to decrease, it is likely that whole-genome and *meta*-omics approaches will be applied routinely at various points along the food supply chain.

## Introduction

### Dioxins

Polychlorinated dibenzo-p-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) are two classes of organic environmental contaminants that are often together termed “dioxins”. They have no use, were never produced industrially, but are formed as unwanted and often unavoidable by-products in a number of thermal and industrial processes. Dioxins are generally not formed as single compounds but as complex mixtures which can give valuable hints on the generating sources. Although they were already formed thousands of years ago, especially during forest fires, their levels in the environment substantially increased in parallel with the start of the growing chlorine industry in the 1940s.

Depending on the number and position of the chlorine atoms at the two rings, 75 PCDDs and 135 PCDFs, termed “congeners” can be distinguished (Fig. 1). They are resistant against acids, show low water solubility but high lipophilic properties. The best studied dioxin is 2,3,7,8-tetrachloro-dibenzo-p-dioxin (2,3,7,8-TCDD) which exhibits also the highest toxicity of the 210 congeners. Well-known pollution episodes are the spraying of the defoliant Agent Orange in the Vietnam War and the release of 2,3,7,8-TCDD in 1976 in Seveso/Italy, both causing high contamination in the environment and the humans living in the affected areas. Agent Orange was composed of the two herbicides 2,4 D and 2,4,5-T. The latter contained 2,3,7,8-TCDD as a by-product from the synthesis of the intermediate chlorinated phenol. The synthesis of chlorinated phenols was also the reason for the release of huge amounts of 2,3,7,8-TCDD in Seveso when a reaction vessel burst in a chemical factory.

From a toxicological point of view, those congeners that are 2,3,7,8-chlorine substituted are toxic and thus are of special concern. At high concentrations following poisoning or exceptional accidental or occupational exposure, they may cause chloracne. At much lower levels, *inter alia* effects on the immune and reproductive system in humans were reported. The biological half-life of TCDD in humans is 7–10 years and even longer for some higher chlorinated congeners.

### PCBs

In contrast to dioxins, PCBs had found wide-spread industrial use. It is estimated that more than 1.5 Million tons were produced since their first commercial introduction in 1929. They were generally manufactured as technical mixtures containing 40%–60% chlorine, and were marketed under trade names, such as Clophen, Arochlor, Phenoclor, Fenclor and Kaneclor. PCBs have excellent dielectric properties, are thermally stable, and resistant against acids, bases and oxidation. Due to these favourable properties, they were widely used as insulating material in electric equipment, such as capacitors and transformers, and as hydraulic fluids in mining. Although these applications are considered as “closed” systems, PCBs were released into the environment due to leakages, accidents and/or destruction of the electrical equipment. Besides the application in “closed” systems, PCBs were also used in “open” systems. This encompassed addition to lubricants and putty, use as plasticizers, paper surface coatings, flame retardants, carrier for pesticides and others. The application in “open” systems is banned in the Western World since the late 1970s, and also the use in “closed” systems was strictly regulated in the past. Nevertheless, it is estimated that several ten thousand tons of PCBs still remain in the environment today.

Depending on the number and position of the chlorine atoms at the two rings, 209 different PCBs can be distinguished, which are also termed “congeners” (Fig. 2). Those congeners that carry none or one chlorine in the ortho-position of the two rings (2, 2', 6, 6') can adopt a spatial orientation comparable to dioxins, exhibit similar toxic properties and thus are termed “dioxin-like PCBs (DL-PCBs)”. PCB congeners with two or more chlorine atoms at the ortho-position show different toxic properties and are called “non dioxin-like PCBs (NDL-PCBs)”. Within the subgroup of NDL-PCBs, the congeners with IUPAC numbers 28, 52, 101, 138, 153, and 180 are considered as “indicator-PCBs”. While the PCBs 28, 52 and 101 are rapidly metabolized in mammals, and thus would indicate a fresh contamination if determined in a food sample, the other three PCBs are highly persistent and generally contribute the most to the sum of PCBs in food stuffs of animal origin and in humans.

**Figure 2** Structure of PCBs;  $Cl_x + Cl_y = 1-10$ .

### Toxic Equivalency Factors (TEFs)

Within the group of dioxins, the 2,3,7,8-chlorine-substituted congeners are of special importance due to their high toxicity in animals and humans. As the DL-PCBs exhibit similar toxic properties as the above mentioned dioxin congeners, both groups of environmental contaminants are generally considered together. Although the toxicity of the individual congeners varies substantially, the toxic effects of all these compounds are mediated through the aryl hydrocarbon receptor (AhR) in the cells. Based on the results of *in vivo* and *in vitro* studies, the diverse toxicity of the individual congeners can be expressed in terms of the most toxic dioxin, 2,3,7,8-TCDD which arbitrarily is assigned a toxic equivalency factor (TEF) of 1. The TEFs for the other toxic congeners are  $\leq 1$ . By summing up the concentrations of the analytically determined congeners multiplied with their individual TEFs, one obtains the toxic equivalent (TEQ) of a sample, which provides the total toxic potency in terms of 2,3,7,8-TCDD.

An important prerequisite of the TEF system is persistence and accumulation of the compounds in the food chain, additivity of effects, binding to the Ah receptor and eliciting AhR mediated toxic responses. Several different TEF systems have been established by national and international organizations in the past decades. The derivation of a TEF underlies the progressive scientific knowledge. New studies e.g. performed with highly purified reference standards may lead to a re-evaluation of the factors and consequently to updated TEFs. From this, it becomes clear that a meaningful comparison of analytical data can only be performed when they are based on the same TEF system. **Tables 1** and **2** show the TEFs that were established by WHO 1998 and 2005 (Van den Berg et al., 1998, 2006). TEQs derived with the WHO<sub>2005</sub>-TEFs are currently the basis for the legal appraisal of dioxins and DL-PCBs in feed and food.

### Health-Based Guidance Values

In 1998, the World Health Organization (WHO) established a Tolerable Daily Intake (TDI) of 1–4 pg WHO<sub>1998</sub>-TEQ/kg body weight. Based on the WHO 1998 assessment, the Scientific Committee on Food (SCF) published an opinion in 2000 (SCF, 2000) which was updated in 2001 (SCF, 2001). The SCF found it more appropriate to express the health based guidance value (HBGV) on a weekly rather than on a daily basis, and established a Tolerable Weekly Intake (TWI) of 14 pg WHO<sub>1998</sub>-TEQ/kg body weight. This TWI is still valid in the European Union. In 2001, the FAO/WHO Joint Expert Committee on Food Additives

(JECFA, 2001) re-evaluated the earlier risk assessments on dioxins and DL-PCBs and concluded that the tolerable intake should be assessed over a period of at least one month, and thus established a Provisional Tolerable Monthly Intake (PTMI) of 70 pg WHO<sub>1998</sub>-TEQs/kg body weight. The US-EPA published its reanalysis of dioxin toxicity in 2012 (US-EPA, 2012) and established an oral reference dose (RfD) of 0.7 pg TCDD/kg bw per day. The oral RfD is defined as “an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime”. Currently, the European Food Safety Authority (EFSA) is performing a re-evaluation of dioxins and DL-PCBs. The outcome of this risk assessment is expected for summer 2018.
