Virtually all classes of phenolic compounds ranging from the simple phenolic acids (ferulic, caffeic, dihydrocaffeic, coumaric, sinapic, phloretic, protocatechuic, gentisic, gallic, vanillic, syringic, etc.) to relatively complex polyphenols (chlorogenic acid, rutin, catechin, epicatechin, quercetin, phloridzin, naringin, hesperidin, quercitrin, isoquercitrin, luteolin, epigallocatechin, epigallocatechin gallate, callistephin, esculin, delphinidin, cyanidin, pelargonidin, etc.) have been chemically, enzymatically, or chemoenzymatically modified to increase lipophilicity and functionality (Figuerola-Espinoza and Villeneuve, 2005; Chebil et al., 2006; Viskupicova et al., 2009; Gonzalez-Sabin et al., 2011; Laguerre et al., 2013; Crauste et al., 2016; de Araujo et al., 2017), albeit with widely varying results. However, despite the hundreds of available literature and novel studies in this important research area, there are only a handful of studies available where phenolic compounds were configured and evaluated as antioxidants for frying applications (Gertz, 2004; Catel et al., 2010, 2012; Aladedunye et al., 2012, 2015; Gruczynska et al., 2015; Aladedunye and Matthaeus, 2016). The reasons for these limited interests in the assessment of restructured or lipophilized polyphenolics for frying applications may be related to the erroneous extrapolation of data obtained for radical scavenging activity in chemical tests (DPPH, ORAC, etc.) or antioxidant activities under oxidative conditions (Schaal oven test, Rancimat, etc.), whereby the relatively bulkier, less polar, and more sterically hindered modified polyphenolic compounds understandably performed worse than their native counterparts (Lorentz et al., 2010; Ma et al., 2012; Milisavljevic et al., 2014). Indeed, it has been established that the activity of antioxidative compounds under ambient conditions using chemical assessments or during accelerate storage tests cannot correctly depict its performance during frying, considering the wide differences in operational conditions including: (1) temperatures; (2) oxygen pressure; (3) water content; (4) thermooxidative degradation of components and their interactions with antioxidative compounds; (5) volatilization, degradation, and thermal inactivation of antioxidants; (6) continuous changes in relative

**Figure 4** Synthetic modification of phenolic compounds to improve activity, lipophilicity, and thermal stability. Adapted from Catel, Y., Aladedunye, F.A., Przybylski, R., 2010. Synthesis, radical scavenging activity, protection during storage, and frying by novel antioxidants. *J. Agric. Food Chem.* 58, 11081–11089.

locations of antioxidant, oxidant, and substrates due to constant agitation during boiling; and (7) occurrence of parallel reaction mechanisms during frying that may as well be more important than radical scavenging mechanism, an activity solely assessed by DPPH and oxidative storage tests (Gertz et al., 2000; Gertz, 2004; Kochhar and Gertz, 2004; Aladedunye et al., 2012).

With regards to configuring polyphenolics for frying applications, Catel et al. (2010, 2012) reported the chemical synthesis of a series of trolox derivatives of selected hydroxybenzoic acids (p-hydroxybenzoic, syringic, gallic, vanillic, and protocatechuic) and dihydrocaffeic acid (Fig. 4) by esterifying the phenolic acids with trolox chromanol ring, which is regarded as the primary antioxidant active center for tocochromanols, the most abundant natural antioxidants in frying oils.

The new sets of antioxidants were evaluated for frying performance and were recorded to be significantly better than  $\alpha$ -tocopherol as measured by the amount of total polar compounds (TPC) formed under the experimental frying conditions. Further, the configured phenolic compounds were also reported more thermally stable than the natural chromanol-bearing  $\alpha$ -tocopherol. This is particularly important because one of the limitations to the application of phenolic compounds, especially simple phenolic acids, is their thermal lability, as they are readily thermally degraded or volatilized under the stringent conditions used for frying operations. The study, however, is limited in that it did not compare the performance of the newly composed antioxidants with their parent phenolic acids focusing more on the chromanol moiety rather than the phenoxyl unit.

In a related study, Aladedunye et al. (2012) reported the synthesis of 12 novel dihydrocaffeic acid amides (Fig. 5). The dihydrocaffeic acid derivatives were prepared in two-step synthesis from the corresponding aldehydes. Briefly, the aldehydes were reacted with the appropriate alkylamine in methanol, yielding the expected imines that were subsequently reduced with sodium borohydride to afford the corresponding amines. The amines were then coupled with dihydrocaffeic acid using (Benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate as a coupling reagent, generating a series of new dihydrocaffeic

**Figure 5** Synthetic modification of phenolic compounds to improve activity, lipophilicity, and thermal stability. Adapted from Aladedunye, F., Catel, Y., Przybylski, R., 2012. Novel caffeic acid amide antioxidants: synthesis, radical scavenging activity and performance under storage and frying conditions. Food Chem. 130, 945–952.

acid amides, each as a mixture of the two rotamers (Fig. 5). The length of the alkyl chain was adjusted to moderate the antioxidant's lipid solubility. In addition to being significantly more active at protecting frying oil from thermooxidative degradation, compared to  $\alpha$ -tocopherol, butylated hydroxytoluene (BHT), and, depending on the derivatives, the parent dihydrocaffeic acid, the newly configured phenolic antioxidants were much more thermally stable. For instance, at the end of the frying experiment, the TPC content of canola oil triacylglycerols fortified with dihydrocaffeic acid was at 18%, whereas the amount found in the configured phenolic compound 3a (Fig. 5) was 14%, and while no dihydrocaffeic acid was detected in the oil at the end of the frying period, about 20% of 3a still remained in the counterpart oil. Furthermore, a number of the structured antioxidants were found to possess better anticancer activity, effectively killing breast cancer cells, including on chemotherapy-resistant breast cancer cells and on oral squamous carcinoma cells without any negative effects on morphology and gene expression of normal human oral and gingival epithelial tissues (Kovalchuk et al., 2013).

In a study similar to Choo et al. (2009), Gruczynska et al. (2015) described the preparation and frying performance evaluation of structured canola oil, incorporating ascorbic acid and selected phenolic acids (gallic, ferulic, caffeic, and *p*-hydroxyphenylacetic) into the triacylglycerol backbone through enzymatic interesterification using Lipozyme RM IM lipase from *Rhizomucor miehei* as a biocatalyst. Apart from the gallic acid derivative, the authors reported up to a threefold decrease in the rate of TPC formation in canola oil sample fortified with the structured phenolic compounds. The unexpectedly high level of TPC and polymers observed for the structured gallic acid canola triacylglycerols was attributed to the potential of galloyl moiety for self-polymerization, noting that none of the stability indices (TPC and polymers) could sufficiently differentiate between polymerized triacylglycerols and polymerized galloyl groups.

To circumvent the high cost of pure polyphenolic compounds, especially considering the relatively high amounts of antioxidants required per kg of frying oil, the direct modification of crude or partially purified polyphenolic extracts have been attempted (Stevenson et al., 2006; Hernandez et al., 2009; Ma et al., 2012; Aladedunye et al., 2015; Aladedunye and Matthaeus, 2016; Bernini et al., 2017). Using immobilized *Candida antarctica* B, Stevenson et al. (2006) reported a direct lipophilization of Penglai apple and blueberry polyphenolic extracts with palmitic, cinnamic, and phenylpropionic (PPA) acids and hydroxylated derivatives of PPA as acyl donors in the presence of 4 Å molecular sieves, using 2-methyl-2-propanol as solvent. The author reported the presence of several lipophilized anthocyanin glycosides, such as delphinidin-3-*O*-galactoside, delphinidin-3-*O*-glucoside, cyanidin-3-*O*-galactoside, petunidin-3-*O*-galactoside, petunidin-3-*O*-glucoside, malvidin-3-*O*-galactoside, and malvidin-3-*O*-glucoside from the blueberry extract, based on LC–MS analysis. Phloridzin esters were reported as the major lipophilized products from apple polyphenolic esters with palmitic acid being the best acyl donor, yielding up to 80% conversion rate. Hernandez et al. (2009) directly lipophilized coffee pulp's methanolic extracts using immobilized *C. antarctica* lipase B in supercritical  $CO_2$ /*t*-butanol solvent and heptanol as aliphatic chain donor. Heptyl chlorogenate (Fig. 6) was identified as the only product, recording a 65% conversion.

**Figure 6** Heptyl chlorogenate. Hernandez, C.E., Chen, H.H., Chang, C.I., Huang, T.C., 2009. Direct lipase-catalyzed lipophilization of chlorogenic acid from coffee pulp in supercritical carbon dioxide. *Ind. Crop Prod.* 30, 359–365.

Although none of these studies were applied to frying oils, they did provide the inspiration for subsequent studies by Aladedunye and his research group on the Canadian small fruits (Aladedunye et al., 2015; Aladedunye and Matthaeus, 2016). Enzymatic alkylation of rowanberry (*Sorbus aucuparia*) ethyl acetate extract was carried out in 2-methyl-2-butanol using octadecanol as the long chain alkyl donor and *C. antarctica* lipase B as a biocatalyst. Reaction bioconversion was monitored periodically by HPLC and the reaction was terminated at the end of the sixth day. Chlorogenic acid, which represented 87% of the polyphenolics in the rowanberry extract, was effectively lipophilized with about 70% conversion at the end of the fifth day. Assessments of the lipophilized polyphenolic extract for radical scavenging activity by DPPH assay did show them as poorer radical scavenger compared to the native extract containing unmodified chlorogenic acid, in agreement with other studies (Lorentz et al., 2010; Ma et al., 2012); however, the lipophilized extract containing predominantly octadecyl chlorogenate significantly outperformed the native extract by a factor of 1.3 as measured by the ability to limit polar and polymeric triacylglycerols formation during frying.

Furthermore, the stability and enhanced lipophilic nature of the structured chlorogenate was practically demonstrated by measuring its carry-through property that is related to the ability of the antioxidant to survive the stringent conditions of frying and gets transferred to the fried food, considering the extensive mass exchange between the food and the frying oil. The authors reported that the level of octadecyl chlorogenate found in the French fries (55.4 µg/g French fries, wet basis) was seven times higher than the amount of chlorogenic acid (8.1 µg/g French fries, wet basis) after deep frying in canola oil fortified with lipophilized and native phenolic extracts, respectively. It was also observed that due to its poor solubility in the frying oil, the major portion of the available chlorogenic acid did not dissolve in the frying oil or make it into the fried products, possibly “trapped” within the extraneous materials of the rowanberry extract.

Using the same conditions as in the above publication (Aladedunye et al., 2015), the authors extended the study to Canadian crabapple (*Malus baccata*), isolating phloridzyl octadecanoate (Fig. 7), which was reported to offer better protection against thermal and oxidative degradation of refined, bleached, and deodorized rapeseed frying oil, compared to the native unmodified polyphenolic extract (Aladedunye and Matthaeus, 2016).

Beside esterification reactions, enzymatic polymerization is another promising technique for configuring polyphenolic compounds to potentially improve their antioxidant/antipolymerization effects during frying. Unlike in esterification reactions where lipases are the most employed, peroxidases, laccases, tyrosinase, oxidases, and oxidoreductase are the typical biocatalysts for polymerizing polyphenolics (Racicot et al., 2012; Miao et al., 2015; Zheng et al., 2015; Sánchez-Mundo et al., 2016; Kocak et al., 2016; Gao et al., 2016; Reano et al., 2016; Muniz-Mouro et al., 2017). For instance, Racicot et al. (2012) reported the horseradish peroxidase-catalyzed synthesis and purification of polyepicatechin with improved antioxidant activity and thermal stability. Disentis-Mendoza et al. (2006) bioconfigured quercetin and Kaempferol using laccase and tyrosinase from *Ustilago maydis*, generating relatively low molecular weight polymers with improved antioxidant activity. Zheng et al. (2015) enzymatically polymerized

**Figure 7** Phloridzyl octadecanoate. Aladedunye, F., Matthaeus, B., 2016. Effective lipophilic antioxidant enzymatically derived from Canadian crabapple. *Eur. J. Lipid Sci. Technol.* 118, 919–927.

pyrogallol acid, resulting in sterically hindered phenolic antioxidants with markedly improved thermal and antioxidant activity against thermal degradation of polypropylene. Sánchez-Mundo et al. (2016) described the enzymatic polymerization of epicatechin, ferulic acid, quercetin, and phenolic mixtures isolated from fresh bell pepper using polyphenol oxidase isolated from bell pepper. According to the authors, regardless of aggregate sizes, all polymerized phenolics showed antioxidant activity better than their respective monomers.

Now, despite this opportunity, neither the technique nor the polymerized polyphenols obtained therefrom has been applied to the frying system/operation. Indeed, a natural nonextractable tannin-rich carob fiber has been reported to limit TPC and polymers formation in frying oil by up to 50% (Botega et al., 2009), highlighting the potential of polymerized polyphenols. Polymerization of polyphenols affects both the structure, texture, and other physical properties of the polyphenols, providing opportunity for a protective mechanism (antioxidant, antipolymerization, heat dispersal, oxygen barrier, etc.) different than that of the original monomer. Indeed it is highly likely that, with just the right aggregate sizes, polymerized polyphenolics may be able to protect frying oil with similar mechanism currently acknowledged for polydimethylsiloxane (PDMS), namely, creating oxygen barrier at the air-oil interface, in addition to other protective mechanisms.

## Conclusions

Indeed, frying is a unique method of food preparation, principally because the processing conditions are relatively more drastic, compelling unbridled physicochemical interactions among multitudes of components both from the frying oil and the food being fried in it. These stringent processing conditions often overwhelm conventional endogenous antioxidants such as the tocopherols and carotenoids, requiring external antioxidant fortification. Such exogenous antioxidants are expected to be effectively soluble in the oil, thermally stable, operating by more than one mode of antioxidative mechanisms, and preferably, naturally occurring. But for their poor lipophilicity and thermal lability, phenolic compounds are uniquely structurally designed to fit this role. Evidently, chemoenzymatic esterification and polymerization have the potential to expand the applications of phenolic compounds as frying oil antioxidants by enhancing lipophilicity and thermal stability. Although opportunities abound, currently, available studies in these directions are limited and localized within a very few research groups.

WPI	Whey protein isolate
WPNI	Whey protein nitrogen index

## Introduction

Bovine milk contains about 3.5%–4% proteins and their interactions govern the behavior of milk and form the basis for the manufacture of different milk products and their properties. Milk proteins are present mainly in the aqueous phase of milk either in soluble form or as colloidal suspensions. Although the proportion of these forms of proteins varies greatly among different species, their structure, general properties, and interactions remain largely similar. The following sections discuss some key chemical and physical properties of milk proteins and their interactions during milk processing.

## Caseins

The caseins form nearly 80% of the total protein in milk and are defined as phosphoproteins that precipitate out upon the acidification of milk to pH 4.6. Bovine milk consists of four major types of casein:  $\alpha_{s1}$ -,  $\alpha_{s2}$ -,  $\beta$ -, and  $\kappa$ -casein. Some of their key characteristics are shown in **Table 1**. The casein in milk exists as three-dimensional colloidal supramolecular structures called micelles. Three of the caseins,  $\alpha_{s1}$ -,  $\alpha_{s2}$ -, and  $\beta$ -casein, act as block copolymers and interact via noncovalent interactions into small nanoclusters, which in turn form the building blocks of micelles. The phosphate groups on the caseins from multiple nanoclusters bind calcium, resulting in calcium phosphate bridges between the nanoclusters resulting in a three-dimensional network or a micelle. The N-terminal region of  $\kappa$ -casein links in to the nanoclusters by hydrophobic interactions but, unlike other caseins,  $\kappa$ -casein does not have any phosphoserine cluster in its structure due to low levels of phosphorylation and therefore is unable to form the calcium phosphate nanocluster link. The C-terminal region of  $\kappa$ -casein is highly charged and instead contains carbohydrate moieties that extend into the aqueous medium, giving the micelle surface a 'hairy' appearance. This stabilizes the micelle by electrostatic repulsion and by steric effects arising from the bulky hairy layer. Fully assembled casein micelles are approximately 40–150 nm in size and hold up to 3.5–4 g water per g of casein. The stability of the casein micelle structure is governed by conditions that impact the protein–protein interactions and protein–calcium phosphate nanocluster cross-links. Factors that destabilize the micellar structure of caseins include temperature, lowering of the pH, sequestering of calcium ions, and the presence of cosolvents, such as ethanol, in the aqueous medium.

**Table 1** Key characteristics of different casein fractions in bovine milk

Parameter	$\alpha_{s1}$ -Casein	$\alpha_{s2}$ -Casein	$\beta$ -Casein	$\kappa$ -Casein
Content of total protein (g.L <sup>-1</sup> )	1.2–1.5	0.3–0.4	0.9–1.1	0.2–0.5
Fraction of total casein (%)	40	10	35	15
Amino acid residues	199	207	209	169
Molecular weight (Da)	23,599	25,206	23,973	19,052
Number of proline residues	17	10	35	20
Number of lysine residues	14	24	11	9
Isoelectric point (pH units)	4.42	4.95	4.65	5.6
Phosphorylated serines	8	11	5	3
Polymorphic forms	8	4	12	11
Disulfide bridges	-	2	-	2
Calcium sensitivity	++	+++	+	-
Unique structural features	Largely unstructured	Largely unstructured	Highly hydrophobic  Partial amphiphilic character	Glycosylated  Glycans of galactose, N-acetylglucosamine, N-acetylneuraminic acid

### Structural Properties of Caseins

Caseins have unique structural properties that make them particularly stable during processing. An important structural attribute of all casein fractions is their high content of proline residues, which are uniformly distributed throughout their sequence, limiting the formation of ordered secondary and tertiary structures. Hence, caseins are considered to be naturally denatured proteins or intrinsically unstructured proteins. The relatively open structure, in turn, imparts conformational flexibility or molten-globule-like character to caseins.

The primary structures of  $\alpha_{s2}$ - and  $\kappa$ -caseins have cysteine (Cys) residues that can form strong covalently linked disulfide bonds, which assist in polypeptide folding or the formation of cross-links with other proteins.  $\alpha_{s2}$ -Casein possesses two cysteine residues (Cys36 and Cys40) in its sequence, which form inter- and intramolecular disulfide bonds with other  $\alpha_{s2}$ -casein monomers. In comparison,  $\kappa$ -casein possesses two cysteine residues (Cys11 and Cys88), which participate in the disulfide-linked oligomerization of  $\kappa$ -casein in untreated raw milk. Upon the heat treatment of milk, the Cys residues of  $\kappa$ -casein react with those of whey proteins, which affects the quality of processed milk for the manufacture of different dairy products.

A structural feature that is common to all caseins is the proximity of amino acid residues with similar properties in their primary structure. This results in the formation of clusters of hydrophobic, charged, and hydrophilic regions on the polypeptide chain, which are responsible for several important properties of caseins, such as their ability to form micelles, their association tendency, their interactions with calcium, and their unique functional properties, including emulsification and foam stabilization. One of the key clusters that imparts unique properties to caseins is formed by phosphates that are bound to the serine and threonine residues of caseins. These phosphorylated clusters increase the negative charge density in the region and contribute to the structural stability of caseins because of high electrostatic repulsion. The phosphoserine clusters also form bridges with calcium resulting in a three-dimensional casein micelle structure and during aggregation, such as during the second phase of rennet action in cheese manufacture.

The clusters of hydrophobic and charged hydrophilic regions result in a strong tendency for the caseins to self-associate into multimers or oligomers via noncovalent interactions. The self-association tendency of  $\beta$ -casein has important implications for the properties of the casein micelle structure, as discussed below in the chilling and thermal processing of milk. The hydrophobic patches, together with the phosphoserine clusters, impart an amphiphilic character to caseins, which is responsible for their emulsifying, foam-stabilizing, and chaperone-like properties. The chaperone-like activity of proteins is defined as their ability to assist in the noncovalent assembly or folding of other proteins without being a part of their structure or interactions during their biological action. Different forms of casein, such as sodium caseinate, micellar casein, and pure casein solutions, possess chaperone-like activity by preventing the aggregation of several enzymes.  $\beta$ -Casein and  $\alpha_s$ -casein have been shown to bind to the hydrophobic surfaces of unfolded globular proteins and to prevent their heat-induced aggregation.

### Sensitivity of Caseins to Calcium

The negatively charged clusters of phosphoserine residues in caseins can bind to calcium, which can affect the stability of micelles by two different phenomena. The calcium ions first bind to the phosphoserine residues of caseins by electrostatic interactions, lowering the stabilizing electrostatic repulsion. This may induce a conformational change in the casein polypeptide ( $\alpha_{s1}$ -casein) structure. In the absence of low electrostatic repulsion between monomers, the casein–calcium complexes reversibly interact with each other by noncovalent interactions such as hydrogen bonding and hydrophobic interactions, resulting in their aggregation.

The different casein fractions possess various sensitivities to calcium-induced precipitation, with  $\kappa$ -casein being the least sensitive. The  $\alpha_{s1}$ - and  $\alpha_{s2}$ -caseins are particularly sensitive to calcium and can precipitate from solution at calcium concentrations from 3 to 8 mM and <2 mM, respectively. The ability of these caseins to bind calcium has important implications during the processing of milk and milk products, e.g. during the manufacture of concentrated milks, dried milks, and fermented milks and in the second stage of rennet action during cheese manufacture. In comparison,  $\beta$ -casein displays temperature-dependent stability in the presence of calcium, with up to 400 mM calcium required for its precipitation at low temperature (<18 °C) but only up to 15 mM calcium required at 37 °C. As the binding of caseins to calcium is electrostatic in nature, factors that screen charges, such as pH, ionic strength, dephosphorylation of phosphoserines, and deamination of arginine residues in the primary structure, greatly affect the calcium–casein interactions.

## Whey Proteins

The whey proteins represent a heterogeneous group of proteins in milk that remain soluble after its acidification to pH 4.6 or after rennet coagulation. They have a well-defined globular structure and include  $\beta$ -lactoglobulin ( $\beta$ -Lg),  $\alpha$ -lactalbumin ( $\alpha$ -La), bovine serum albumin (BSA), and immunoglobulins (Ig). Whey proteins form up to 20% of the total protein in milk and some of their key characteristics are listed in Table 2. Unlike caseins, the whey proteins are devoid of any bound phosphorus or glycan chains in their structure. Some key properties of whey proteins that govern their interactions are discussed below.

### Globular Structure of Whey Proteins and Factors Affecting Their Structural Stability

The unique composition of the amino acid residues in the polypeptide allows it to assume specific conformations with well-defined secondary and tertiary structures. In a globular structure, the hydrophobic residues are buried deep in the core whereas the hydrophilic residues cover the surface. The formation of the globular structure is facilitated by hydrogen bonding, van der Waals' bonds, electrostatic interactions, and disulfide bonds; its stability is maintained by the interactions of the side-chain residues with solvent molecules (termed preferential interactions) and is a net result of forces that oppose unfolding and forces that induce a conformational change. Any alteration to this delicate balance between the forces that maintain stability results in non-native conformations that minimize the free energy. These non-native structures of a globular protein under the new equilibrium conditions are called the denatured state of the protein. The common unit operations that denature whey proteins are thermal processing, high shear, and high pressure treatment. Although the denaturation of globular proteins can theoretically be considered to be a reversible process, this is seldom true in practice because the denatured proteins rapidly assemble into aggregates. Thus, unless stated otherwise, the term denaturation or denatured protein, used henceforth in this chapter, refers to the irreversible denatured state of the protein.

### Disulfide Exchange Reactions of Whey Proteins

The unfolding of whey proteins results in the opening-up of the structure, giving a highly reactive molten-globule state that can aggregate readily via different pathways. At neutral pH, the unfolded polypeptide aggregates mainly via intermolecular thiol–disulfide exchange reactions and, to a lesser extent, by hydrophobic interactions. The unfolded polypeptides of the whey proteins  $\beta$ -Lg and  $\alpha$ -La readily interact with  $\kappa$ -casein, resulting in disulfide-linked whey protein– $\kappa$ -casein complexes, although BSA and lactoferrin have also been reported to form disulfide linkages with  $\alpha_{s2}$ -casein in ultra-high-temperature (UHT)-processed milk. The disulfide exchange reactions of whey protein and  $\kappa$ -casein are of technological importance because they affect several processes, including the UHT processing of milk, cheese and yogurt manufacture, and the fouling of evaporators during concentration.

**Table 2** Key characteristics of whey proteins in bovine milk

Parameter	$\beta$ -Lactoglobulin	$\alpha$ -Lactalbumin	Bovine serum albumin	Immunoglobulins
Content of total protein (g/mL <sup>-1</sup> )	0.32–0.35	0.12–0.15	0.04–0.06	0.08–1
Fraction of total whey proteins (%)	50	20	8	10
Amino acid residues	162	142	582	–
Cysteine residues in sequence	2 (1)	4	35	–
Molecular weight (Da)	18,281	14,176	66,267	150,000–900,000
Isoelectric point (pH units)	5.4	4.8	5.4	
Thermal denaturation temperature (°C)	75	60–63	85–87	80
Unique features	Absent in human, rat and guinea pig milks	Aids in lactose biosynthesis in golgi apparatus of cells	Also present in blood	Higher content in colostrum (up to 10%, w/v)

The heating of whey proteins ( $>60^{\circ}\text{C}$ ) at low pH ( $\text{pH} < 3$ ) results in the formation of highly ordered amyloid-like nanofibrils. The disulfide exchange reactions are significantly reduced mainly because of the protonation of free sulfhydryl groups; the main pathway for the aggregation of unfolded whey proteins under these conditions is by hydrophobic interactions.

## **Milk Protein Interactions During Unit Operations of Milk Processing**

The casein micelle structure is remarkably stable during routine processing operations, except during cheese and yogurt manufacture. The technology for the manufacture of milk products is largely a manifestation of a change in the equilibrium conditions that stabilize the micelles. In comparison, the whey proteins undergo extensive changes during milk processing, as discussed above, and their interactions with the casein micelles affect the suitability of milk for the manufacture of dairy products, affecting their yield and their final properties. The following sections discuss the interactions of milk proteins during the manufacture of milk products.

### **Chilling and Thermal Processing of Milk**

Chilling is one of the most common operations to which milk is subjected on farms and in processing plants, to arrest bacterial growth. Chilling brings about changes in the salt equilibrium and causes solubilization of micellar calcium phosphate, affecting the stability of the micelles. This may affect further processing of the milk, e.g., an increase in the rennet coagulation time during cheese manufacture.

At temperatures employed for the chilling of milk,  $\beta$ -casein undergoes a highly cooperative and reversible temperature-dependent self-association. At low temperatures ( $0$ – $5^{\circ}\text{C}$ ) and in relatively dilute solutions ( $0.03$ – $0.07\%$ ),  $\beta$ -casein exists as a monomer but gradually self-associates into multimeric structures as the temperature is increased to  $20^{\circ}\text{C}$ . These structures have been referred to as micelles that are similar to those in detergent solutions. In chilled milk ( $0^{\circ}\text{C}$ ), approximately 50% of the total  $\beta$ -casein in the micelles has been known to reversibly dissociate from the casein micelles, which increases the viscosity of milk. This effect is reversible and, upon heating to approximately  $40^{\circ}\text{C}$ , the  $\beta$ -casein migrates back into the casein micelles. The dissociation of  $\beta$ -casein from the casein micelle has important implications for the quality of untreated milk because dissociated  $\beta$ -casein is prone to proteolytic cleavage by the enzyme plasmin (EC 3.4.21.7), resulting in  $\gamma$ -casein (residues 29–209). The  $\gamma$ -casein fraction has been reported to play a detrimental role in the stability of UHT milk.

The heating of milk at  $50$ – $60^{\circ}\text{C}$  results in the interaction of  $\beta$ -Lg with plasmin, blocking its action on the caseins and thus improving the quality of milk for the manufacture of UHT milk. The heating of raw whole milk to  $60$ – $65^{\circ}\text{C}$  results in denaturation of the proteins associated with the milk fat globule membrane (MFGM) and their subsequent interactions with the whey proteins by thiol–disulfide exchange reactions. The whey proteins are relatively stable at  $< 65^{\circ}\text{C}$  and the free-thiol-mediated disulfide exchange reactions are driven primarily by the thiol groups of the denatured MFGM proteins, which may cross-link with  $\kappa$ -casein during more intense heating. Alternatively, some  $\kappa$ -casein on the casein micelle surface may also interact with the MFGM proteins.

The most important changes in milk occur during heating in the temperature range  $80$ – $90^{\circ}\text{C}$ . At these temperatures, the thiol-mediated reactions cause the generation of compounds that are responsible for the cooked flavor of heated milk. The whey proteins  $\beta$ -Lg and  $\alpha$ -La unfold and interact with  $\kappa$ -casein by thiol–disulfide exchange reactions, forming complexes on the casein micelle surface. A more severe heat treatment results in a greater extent of whey protein– $\kappa$ -casein complexation and thus a stronger anchoring of the complex to the micelles. The formation of the whey protein– $\kappa$ -casein complex affects the properties of milk and milk products during subsequent processing, e.g. a delay in the rennet clotting time, change in rheological properties of yogurts and milk powders.

Another major effect of the heat treatment of milk is Maillard or nonenzymatic browning because of the interactions of the milk proteins with lactose. The  $\epsilon$ -amino groups of lysine and arginine residues interact covalently with the carbonyl group of lactose to form a Schiff base that undergoes a series of degradation reactions to form complex advanced glycation end products (AGEs). The Maillard reaction translates into the loss of color and flavor, nutritional value of the product, changes in the functional properties of the proteins, and the formation of AGEs that have detrimental effects on human health.

Continued heating at high temperatures ( $120^{\circ}\text{C}$  for 90 min) results in dephosphorylation of the caseins, with as much as 65% of the casein phosphate being solubilized by a heat treatment of  $130^{\circ}\text{C}$  for 60 min. In addition, the heating of milk decreases its pH because of the release of organic acids resulting from the thermal degradation of lactose, the precipitation of calcium phosphate from the micelles with a concomitant release of  $\text{H}^{+}$  ions, and dephosphorylation of the caseins. In milks with  $\text{pH} > 6.7$ , heating results in  $\kappa$ -casein dissociation from the micelle surface, which exposes the calcium-sensitive  $\alpha_s$ - and  $\beta$ -caseins to the calcium-rich aqueous phase. A combination of one or more of these effects lowers the heat stability of milk and results in coagulation of the caseins upon prolonged heating.

The interactions of whey proteins with caseins during heating at low pH is an area that has largely remained unexplored, perhaps because of the disintegration of the micellar structure and the poor stability of the caseins under these conditions. The high acid and high temperature conditions of heating bring about the heat-induced acid hydrolysis of whey proteins at peptide bonds involving aspartic acid (Asp) residues. In pure protein solutions and at relatively dilute concentrations, the interaction between  $\beta$ -Lg and  $\beta$ -casein during heating ( $80^{\circ}\text{C}$ ) at low pH ( $\text{pH} 2$ ) was recently reported to be minimum except at lower molar ratios.

## Renneting of Milk

The manufacture of cheese exploits the structural features and the properties of the casein micelles, discussed above. Gelation of the caseins during cheese manufacture is a result of two separate reactions: enzymatic cleavage of the 'hairy'  $\kappa$ -casein layer stabilizing the micelle, followed by aggregation of the casein micelles into a three-dimensional network. The primary phase of rennet coagulation consists of enzymatic cleavage of  $\kappa$ -casein by the enzyme chymosin (EC 3.3.23.4). This enzyme cleaves the peptide bond between residues 105 (Phe) and 106 (Met), resulting in the removal of the hydrophilic region that is referred to as caseinomacropeptide (CMP) or glycomacropeptide (GMP) (because of the presence of glycan chains). The optimum pH for the activity of chymosin is 5.5–5.3; at lower pH, the proteolysis becomes more and more nonspecific, resulting in cleavage of the  $\alpha_{s1}$ -,  $\alpha_{s2}$ -, and  $\beta$ -caseins, an important phenomenon that occurs during the ripening of cheese.

In the second phase of rennet coagulation, the para-casein forms a three-dimensional gel via calcium-mediated interactions. The cleavage of GMP from the casein micelles reduces their net charge (by up to 50%) and the steric-stabilizing effect of GMP, resulting in the aggregation of para-casein by calcium, van der Waals' forces, and hydrophobic interactions of the  $\alpha_s$ - and  $\beta$ -caseins. Nearly 70% cleavage of the  $\kappa$ -casein is necessary for the para-casein micelles to interact with each other and coagulation occurs only after nearly all of the GMP has been released from the micelles. These extensive changes in the structure of the casein micelles leads to the formation of clusters that aggregate through hydrophobic and electrostatic interactions to form a three-dimensional gel network.

The rennet gel physically entraps a considerable amount of water, which is released rapidly during cutting; disturbing the gel causes shrinkage of its volume by up to 2–2.5 times the initial volume. During subsequent processing operations, the casein particles undergo a complex and dynamic process of disruption and reformation of casein–casein linkages, with the expulsion of water resulting in their fusion. The fused particles are interlinked by hydrophobic and calcium bridges and envelop the fat phase in the matrix.

The pH of the cheese curd, which affects the colloidal calcium phosphate (CCP) content (the lower is the pH, the lower is the CCP content), greatly affects the microscopic and macroscopic properties of the matrix, affecting subsequent operations such as shreddability, slicing, stretchability, chewiness, and melting of the cheese. Transformation of the para-casein curd network into a cheese mass with a characteristic flavor occurs during ripening or curing. The residual rennet and proteases of microbial origin hydrolyze the para-casein into peptides and amino acids. The simultaneous action of lipases on the fat, producing free fatty acids, aldehydes, and alcohols, imparts a characteristic flavor to the matured cheese. In addition, the continued drop in pH alters the calcium phosphate levels within the para- $\kappa$ -casein network, which may in turn affect the water-holding capacity and result in swelling of the network.

The preheat treatments of the cheese milk prior to renneting greatly affect the gelation time and the characteristics of the gel. The whey protein– $\kappa$ -casein complexation in high-heat-treated milk blocks access of the enzyme to its site of action (Phe105 and Met106), resulting in delayed rennet coagulation. The whey-protein-coated casein complexes pose challenges during fusion of the casein micelles because of steric effects, resulting in a poor texture in the final product. In addition, high heat treatment of cheese milk causes solubilization of CCP from the casein micelles. The net effect of these phenomena affects important properties of the cheese curd, including reduced shrinkage of the curd upon cutting, poor matting and fusion of the curd particles, and a higher moisture content in the final product.

## Acidification of Milk

The acidification of milk, either by the addition of acid externally or by the generation of lactic acid by lactose-fermenting starter cultures, reduces the net charge on the casein micelles (–20 mV at pH 6.7) and collapses the 'hairy' layer of  $\kappa$ -casein. At pH 5.5–5.0, the voluminosity of the casein micelles and their dissociation is greatly increased by the irreversible loss of CCP. With nearly all the CCP in micelles being solubilized at pH 4.9, the micelles lose their integrity. The dissociation of the caseins during acidification is markedly temperature dependent, with virtually no dissociation at 30 °C but up to 40% of the micelles being disrupted at 4 °C and pH 5.5. This facilitates protein–protein interactions between casein particles, resulting in clusters that form a three-dimensional gel network. Acid gelation involves mainly noncovalent linkages rather than hydrophobic interactions, because the storage modulus of the gel increases at low temperature, where hydrophobic interactions are weaker.

The formation of gel networks is greatly influenced by the interaction of whey proteins and  $\kappa$ -casein on the micelle surface. Preheat treatment (85–95 °C for 10–15 min) of milk modifies the characteristics of the casein micelle surface by the complexation of whey proteins with  $\kappa$ -casein. As whey proteins have a higher isoelectric point than caseins, gelation in such milks occurs at higher pH. In addition, the strength of the resulting networks is enhanced by additional hydrophobic interactions involving whey proteins and disulfide cross-links. The whey protein– $\kappa$ -casein complexes bind significant quantities of water, preventing 'wheying off' or syneresis in yogurts.

## Concentration of Milk

Commercially, the concentration of milk is achieved either by thermal concentration or by membrane processing. Thermal concentration, or evaporation, involves heating milk at temperatures between 50 and 70 °C under vacuum in a falling film multi-effect evaporator to obtain a final total solids (TS) content of 50% (w/v). Under these conditions, the risk of heat denaturation of the

wey proteins is minimized, and the extent of denaturation of the whey proteins in the final condensed product is essentially a result of preheat treatments employed prior to concentration.

However, the concentration of milk brings about changes in the salt equilibria by converting the soluble calcium phosphate into a colloidal form. In addition, there is a simultaneous release of the hydrogen ions during concentration, which decreases the pH from pH 6.7 in un-concentrated milk to 6.3 in the concentrate at approximately 20% TS. All these changes affect the characteristics of the casein micelle, such as an increase in the size of the casein micelles and an increased tendency to aggregation. A decrease in the pH during the concentration of milk solids will also decrease the negative charge on the casein micelles and whey proteins, lowering the electrostatic repulsion between the two groups of proteins and facilitating their interaction via noncovalent interactions. Many of these changes are reversible upon dilution of the milk.

An alternative process for the concentration of milk is to pass it through membranes of different pore sizes to separate different components; this is widely used to produce milk protein ingredients, such as milk protein concentrates (MPCs) and whey protein isolates (WPIs). Under the influence of a pressure gradient, the milk is separated into permeate, which flows through the membrane, and retentate, which is retained after release of the permeate. As membrane processing involves minimal thermal treatment, the casein micelles and the whey proteins retain their respective structural features prior to concentration. In addition, the extent of Maillard browning reactions is greatly reduced in membrane-concentrated milks.

The interactions of caseins and whey proteins can be exploited to concentrate different fractions in the retentate. Skimmed milk, when subjected to ultrafiltration (UF), allows concentration of the micellar casein and the whey proteins, retaining the same ratio as that in milk, resulting in MPCs. The size of the casein micelles in ultrafiltered milk is largely similar to that in the original milk and the different salts associated with the micelles are retained in the concentrate. In comparison, diafiltration (DF) causes the dissociation of CCP, loosening of the micellar structure, and swelling of the micelles. The whey proteins may be separated from the casein fractions by the microfiltration (MF) of skimmed milk at 50 °C. The casein-rich fraction may be subjected to cooling to < 4 °C, to allow  $\beta$ -casein dissociation from the micelles, and then subjected to a second MF to obtain  $\beta$ -casein-depleted casein micelles. Similarly, when subjected to MF, heated skimmed milk will result in a casein- $\beta$ -Ig-rich retentate and a permeate that is rich in  $\alpha$ -La.

### Drying of Milk

The dehydration or drying of milk is widely used commercially for the storage and shipping of milk solids and is commonly achieved by spray drying. As the drying of milk is essentially a process of water removal, the changes brought about during drying are akin to the effects of concentration, i.e., the conversion of soluble calcium phosphate into a colloidal form and a lowering of the pH. The characteristics of the casein micelle are largely conserved during drying, implying that the properties of reconstituted milk are similar to those of the milk before drying. This implies that changes to the proteins and their interactions are governed by the pre-treatments given to the milk before concentration.

For skimmed milk that is intended for drying, it is common to preheat the milk to temperatures ranging from 72 °C for 15 s to 120 °C for 2 min before concentration to 48–50% (w/v) TS. These conditions cause denaturation of the whey proteins and their complexation with the casein micelles, as discussed earlier. The temperature of the concentrated milk droplet, which undergoes heat and mass transfer during drying, is maintained at < 70 °C and this, combined with its sufficiently low residence time in the drying chamber, ensures that any additional denaturation of the whey proteins during the drying process is minimal.

The extent of denaturation of the whey proteins in the final dried milk powder [skimmed milk powder (SMP)] can be measured in terms of the whey protein nitrogen index (WPNI), which is defined as the amount (mg) of denatured whey proteins per g of milk powder. Although the WPNI does not account for the initial whey protein concentration in the milk, which varies with the season and with the stage of lactation, it is a useful guide for deciding the suitability of a milk powder for a given application. The heat classification of SMPs based on their WPNI and their applications is shown in Table 3.

Although the casein micelles in spray-dried milk powder retain native-like characteristics upon reconstitution, in high protein powders, such as MPCs, the casein micelles have been reported to fuse with each other and to form a shell around the dried powder. This prevents the penetration of water to the interior of the powder particle, resulting in poor solubility at low temperatures.

**Table 3** Heat classification of skimmed milk powders (SMPs), their functional properties, and their applications

WPNI <sup>a</sup>	Heat classification	Pre-warming conditions	Functional properties	Applications
> 6	Low heat	71–74 °C for 15 s	Solubility, flavor	Cheese manufacture, recombined milk
1.5–6	Medium heat	85–90 °C for 30–60 s	Emulsification, foaming, water absorption, viscosity, color and flavor	Recombined evaporated milk, UHT milk, ice cream
< 1.5	High heat	120 °C for 2 min, 90 °C for 5 min	Heat stability, water binding, gelation and texture, viscosity	Bakery and confectionery applications

<sup>a</sup>Whey protein nitrogen index.

## Concluding Remarks

This chapter has discussed the key properties of milk proteins, casein and whey proteins, that form the basis for the manufacture of different dairy products. The in-depth understanding of the structural aspects of milk proteins and their interactions has opened up new opportunities for the development of milk protein-based ingredients. Recently a new casein-based ingredient Ferri Pro™ fortified with iron was developed using the structural principles of casein micelles. Similarly, by careful selection of membrane separation it was possible to manufacture dairy ingredients with protein composition similar to that in human milk (a lower casein: whey protein ratio) from skimmed milk. The denaturation conditions of whey proteins have been explored in detail to produce ingredients such as microparticulated whey proteins (Simplese™) that have been used as fat replacers in different food products. In addition, approaches such as enzyme cross-linking of milk proteins have a huge potential to develop new functional ingredients. Another avenue that has been explored to modify the properties of milk proteins for commercial applications is the use of novel processing techniques. High-pressure treatment or high-pressure homogenization of milk improve the texture of yoghurts by their effect on casein micelle structure and resulting interactions during gelation.

Thus, interactions of milk proteins continue to be explored for improving the functional properties of conventional dairy products and manufacture of protein-based ingredients with novel functionalities. The current research in this domain aims to understand the impact of milk protein interactions on the digestibility of dairy products in the human gastro intestinal tract using *in vitro* and *in vivo* systems.

### Glossary

**Caramel** Brown material formed by heating carbohydrates in the presence of acid or alkali; also known as burnt sugar. It can be manufactured from various sugars, starches and starch hydrolysates and is used as a flavor and color (E-150) in a wide variety of foods.

**Coagulation** A process involving the denaturation of proteins, loss of their native, soluble, structure, so that they become insoluble; it may be affected by heat, strong acids and alkalis, metals and various other chemical agents. Some proteins are coagulated by specific enzymic action. Denaturation is due to the breaking of hydrogen bonds that maintain the protein in its native structure. As the process continues, there is considerable unfolding of the protein, and interaction between adjacent molecules, forming aggregates which reach such a size that they precipitate.

**Gelatinization** The addition of gelatin or a similar substance to a food to turn it into a gel or Formation of a water-retentive gel by expansion of starch granules when heated in moist conditions.

**Interesterification** Exchange of fatty acids between triacylglycerols in order to modify the properties of the fat; may be achieved by heat treatment or using fungal lipase

**Maillard reaction** Non-enzymic reaction between lysine in proteins and reducing sugars, leading to a brown color. A similar reaction occurs in the glycation of proteins in diabetes mellitus. The first step in the reaction is the formation of a Schiff base (aldimine) between the aldehyde group of the sugar and the  $\epsilon$ -amino group of lysine, followed by isomerisation (Amadori rearrangement). May also occur with other amino acids at the amino terminal of a protein. It takes place on heating or prolonged storage and is one of the deteriorative processes that take place in stored foods. It is accompanied by a loss in nutritional value, since the amino acid that reacts with the sugar is not available.

**Organoleptic** Sensory properties, i.e. those that can be detected by the sense organs. For foods used particularly of the combination of taste, texture and astringency (perceived in the mouth) and aroma (perceived in the nose).

**Pathogenic** a bacterium, virus, or other microorganism have ability to causing disease.

**Retrogradation** Cooked starch has an amorphous structure; the staling of bread and other starchy foods is due to crystallization of the starch, so that crumb loses its softness, a process that can be delayed by addition of emulsifiers (crumb softeners) such as polyoxyethylene and fatty acid monoglycerides. Many modified starches are used to slow the process of retrogradation.

### Introduction

Foods are treated thermally in order to enhance palatability, increase shelf life, destroy pathogenic microorganisms and improve sensory quality (Sun, 2012). Heating method generally depends upon food matrix type, microbial load, heating medium and final product characteristics. Various conventional and innovative thermal treatments are currently being employed for processing of foods including pasteurization (Bornhorst et al., 2017b), sterilization (Sevenich et al., 2014), canning, blanching (Malmgren et al., 2017; Datta et al., 2002), induction heating (El-Mashad and Pan, 2017), ohmic heating (Ramaswamy et al., 2014), radio frequency dielectric heating (Ahmed et al., 2010; Awuah et al., 2014), microwave assisted (Guo et al., 2017; Bornhorst et al., 2017a), pressure-assisted (Ahn et al., 2007; Wang et al., 2017), and pH-assisted thermal processing (Palop and Martinez, 2006). There is an increasing concern regarding the effect of thermal processing treatments and their combinations on properties of different foods and their components (Sun, 2012). Heat treatments can induce chemical changes in foods i.e. hydrolytic decomposition (hydrolysis of fats, proteins) (Nawar, 1969), oxidative rancidity (Frankel, 1998), denaturation of proteins (decomposition and modification of amino acids) (Anema, 2014), color degradation (Suh et al., 2003; Medina-Meza et al., 2015), enzymatic degradation (Oerlemans et al., 2006), caramelization of carbohydrates, and interactions between proteins and organic molecules. Other chemical changes include homofermentative or heterofermentative reactions, emulsion breakdown and production of ethanol (Clark et al., 2014). These changes can result in either desirable or undesirable effects (e.g. increase in shelf life or nutritional losses respectively) (Ling et al., 2015). Some of the effects of heat treatment on physicochemical and organoleptic characteristics of major food components as well as various food groups are summarized in following sections.

## Effect of Heat on Major Food Components

Foods mainly comprise of four major components including water, carbohydrates, proteins and fats. Starch and sugar are among the most common types of carbohydrates present in plenty of food products. When sugar is exposed to heating, it starts melting and converts to concentrated syrup. With increasing temperature, its color changes from clear to yellow (Chen and O'Mahony, 2016). Further increase in temperature results in browning is a phenomena known as caramelization) together with the production of a unique flavor (Kocadağlı and Gökmen, 2018). When sugar combines with amino acids, another reaction phenomena starts, which is called as Maillard reaction. Maillard reaction produces various by-products which result in color changes, intensive flavor and aroma production (Martins et al., 2000). Both caramelization and Maillard reaction are initiated at the temperature above 150 °C. Starch is a complex carbohydrate, which gelatinizes when mixed with water during heating process. During gelatinization, each starch granule absorbs water and swells, which causes the liquid to thicken. Different starches gelatinize at different temperatures (Gerschenson et al., 2017).

Heating has significant effect on solubility and structural properties of proteins as it mostly denatures or causes unfolding by thermal processing (Malmgren et al., 2017). These conformational changes are associated with the intensity or severity of heating treatment. Sometimes these changes (denaturation or agglomeration) are desirable as in the case of meat and eggs (Tornberg, 2005).

Fats and oils impart flavor and silky mouthfeel to the end product and enhance the nutritional composition (Drake et al., 2010). Fats usually melt during heating at around 37–40 °C (Bhardwaj et al., 2016). However, melting point of fats varies from product to product according to their chemical structure. Fats are composed of fatty acids and vary in number of double bond, number of fatty acid and type of fatty acids. After melting, further heating can cause degradation of fats resulting in the formation of free fatty acids. Heating at elevated temperatures (e.g. in frying) can lead to the smoke point. Hence, oxidization is the end point, which may coincide with smoke point. Although, smoke point of fats is far above normal cooking temperature, in some cooking methods like deep frying, fat is heated to such elevated temperatures (Brühl, 2014).

## Cereal Products

Bread, pasta, cookies, flakes and cakes are the most common cereal products and mainly comprise of starch, protein and minute quantity of fats. These are consumed all over the world in raw form as well as in processed form (Caldwell et al., 2016).

Bread is the most eaten cereal product having diverse types depending upon the mode of processing and ingredients. The first observable effect in bread after the dough enters in oven is the formation of thin elastic outer film that prevents the dough to collapse and helps to retain gas formed due to yeast activity. This film becomes strong as the temperature of dough rises (Mann et al., 2014). As the internal temperature increase gradually the volume of the dough tends to rise to  $\frac{1}{3}$  of its original volume called as oven rise (gas expansion). This is due to the decrease in solubility of gas by increase in internal temperature hence the pressure increases that leads to rise in volume. This process continues till internal temperature reaches 50 °C. As internal temperature of the dough increases up to 50–60 °C, starch gelatinization begins, and starch granules swell by absorbing water (Yamada et al., 2015). Yeast activity increases by increase in temperature up to a certain limit and dough tends to rise more as more gas is produced. When temperature reaches at 60 °C, thermal death of yeast occurs, and gas generation stops.

As the internal dough temperature reaches at around 75 °C, gluten starts to coagulate. Moisture is removed from gluten molecules which is taken up by starch granules and aids in starch gelatinization and retrogradation. Activity of enzyme ( $\alpha$ -amylase &  $\beta$ -amylase) is greatly affected by the temperature and with every 10 °C rise in temperature, it becomes double. Above certain specific temperature, enzymes disrupt and stop their activity (Zhang et al., 2017).

Caramelization in bread starts at around 170 °C and produces colored substances known as caramels. This process is only confined to crust because internal dough temperature does not reach as high as needed for caramelization to take place (Purlis and Salvadori, 2009). Similarly, Maillard reaction also starts at around 170 °C and produces colored substances called melanoidins. These components also impart color and flavor to the final product (Helou et al., 2016) in Table 1.

## Dairy Products

Thermal treatments in dairy industry is of paramount importance because it has various benefits that are needed to ensure the safety of consumers, to maintain specific characteristics of product and to increase the stability of product. Along with all its benefits, it imparts various desirable as well as undesirable changes in nutritional, chemical, and organoleptic properties of final product.

Quality of milk fats is affected due to the formation of ketones and lactones through hydrolyzation and interesterification (Kim et al., 2017). Milk proteins are affected in a way that most of the enzymes become inactivated due to unfolding and casein micelles are aggregated that leads to coagulation (Rynne et al., 2004). Denaturation of some serum proteins occurs and becomes insoluble hence decrease the consistency of milk.  $\kappa$ -casein forms a complex with  $\beta$ -lactoglobulin. Denaturation of whey proteins (immunoglobulins and agglutinins) starts at 72 °C that eventually affects creaming properties as well as antimicrobial nature of milk (Schong and Famelart, 2017). Some of the enzymes such as alkaline proteinase, plasmin and plasminogen are heat resistant (Kelly et al., 2012; Sutariya et al., 2017). Decrease in redox potential happens due to formation of free sulfhydryl groups liberated during ultra-high temperature UHT (Hoffmann and van Mil, 1997).

**Table 1** Compositional changes in meat during heating

Meat components	Temp. (°C)	References
Fat melting, protein unfolding	30–40 °C	Yu et al. (2017), Liu and Lanier (2016)
Carbohydrates gelatinization	40–45 °C	Bombrun et al. (2015)
Water losses starts	46 °C	Bombrun et al. (2015)
Sarcoplasmic protein, Myosin and actinin denaturation	40–50 °C	Tornberg (2005), Yu et al. (2017), Liu et al. (2016)
Collagen and myoglobin denaturation, fat liquefaction	50–60 °C	Christensen et al. (2012), Shabbir et al. (2015)
Myofibrillar protein aggregation, connective tissue proteins shrinkage	65 °C	Li et al. (2010), Tornberg (2005), Christensen et al. (2011)
Titin denaturation	60–75 °C	Pospiech et al. (2002)
Actin denaturation, Connective tissue proteins gelatinization	70–80 °C	Scussat et al. (2017)
Tropomyosin and troponin denaturation, Perimysial and endomysial gelatinization	80–85 °C	Shabbir et al., 2015
Myofibrillar shrinkage	50–90 °C	Han et al. (2014)
Sarcoplasmic protein aggregation	90 °C	Yu et al. (2017)

Gases are important especially O<sub>2</sub> due to its role in oxidation reaction and it must be eliminated or decreased up to the safe limit. During heating, O<sub>2</sub> along with CO<sub>2</sub> are removed hence the risk of oxidation as well as the growth of bacteria becomes very low. Partial degradation of lactose occurs and is converted into organic acids and lactulose through Maillard reaction (Stapelfeldt et al., 1997). Maillard reaction decreases the availability of lysine hence decreasing the nutritional value of milk (Meltretter et al., 2007). Heat treatment results in an increase in the amount of inorganic phosphate due to hydrolyzation of phosphoric esters and phospholipids. There is also a decrease in pH observed due to creation of organic acid by lactose degradation and colloidal phosphates hence the titratable acidity increases (Lajnaf et al., 2018; Ma and Barbano, 2003).

Raw milk has a yellowish creamy white color that is a blend of individual effect of its constituents. Any change in these constituents may result in change in color (Chugh et al., 2014). Carotenes, caseinates and fat globules imparts yellow color and play a role in scattering light. Mild heat treatment increase whiteness due to increase in colloidal phosphates and decrease in Ca ions. But high heat treatment imparts brown color due to production of Maillard products (Kelly et al., 2012). Moreover, flavor of milk is due to lactose, minerals and fat and decrease in the amount of these contents results in flavor changes during heat processing. Sometimes, UHT produces cooked or heated flavor due to lactoglobulin denaturation and the liberation of volatile sulfur compounds (Al-Attabi et al., 2014). Viscosity also decrease by mild heat treatment but high heat treatment results in evaporation, hence increases solids and viscosity (Sutariya et al., 2017).

## Meat Products

Meat and meat products are of foremost importance as it nutritionally contains essential functional ingredients as well as valuable components such as iron, zinc, calcium, vitamins, proteins, carbohydrates, fat in conjugation with other bioactive compounds. There are different heat processing techniques or cooking methods that can be adopted to achieve desired product quality. These techniques include dry heat cooking (roasting, barbecuing, frying, broiling, and grilling) using electric or gas ovens (Suryanto and Armunanto, 2015), moist heat cooking (boiling, steaming, simmering, and poaching), their combinations (stewing and braising) and some other treatments like microwave heating, and sous vide. Heat stability of meat components need to be measured before commercially declaring safe, wholesome and nutritious meat and meat product (Pearson and Tauber, 1984).

During heat processing or cooking of meat the temperature of meat surface can rise as high as 300 °C compared to interior (around 80 °C). Major changes in meat structure start at the temperature of 30–40 °C which include softening and melting of meat fats and protein unfolding. At the temperature of 45–50 °C, gelatinization starts while actin and myosin (sarcoplasmic proteins) begin to denature with shrinkage of myofibrils. Myosin and actin denaturation enhances the toughness of meat structure (Yu et al., 2017). Changes in water contents start at 46 °C where it decreases in myofibrils and increases in intermyofibrillar space producing gel like structure (Tornberg, 2005). At the temperature of 50–60 °C denaturation of collagen and myoglobin starts and sarcomere length decreases (Scussat et al., 2017). At this point, the meat fats start liquefaction called rendering. Optimum physicochemical characteristics like tenderness, juiciness, flavor etc. can be achieved at this temperature. Afterwards collagens start to collapse, which squeezes out pink colored juice into muscle fibers and meat turns drier at 60 °C. However, at 66 °C, another meat protein called actin starts to contract and coagulate, which toughens the meat (Christensen et al., 2011). Above 70 °C moisture begins to evaporate, and inactivation of microorganism occurs. At 80–90 °C tough collagen starts to gelatinize, actomyosin and myosin undergo transitional changes, dehydrated muscle fibers start to detach from bones making the meat more tender and easy to shred (Bombrun et al., 2015). On the other hand, Maillard reactions render the meat surface crunchy and brown (Yu et al., 2017).

Raw meat has bright pink color which gradually converts into brown color as temperature increases. Changes in meat color depend upon denaturation or oxidation of muscle proteins (myoglobin) during heating at around 60–67 °C (Christensen et al.,

2012). At that point, myoglobin pigment starts shrinking or precipitating (Shabbir et al., 2015). During oven heating process, some gases like carbon monoxide or nitrogen can turn meat into pink color by reacting with myoglobin. When protein is denatured, it can convert the translucent meat into opaque appearance. This phenomenon is the result of change in protein configuration by coagulation process which blocks the passage of light through meat. Dry heating methods produce browning surface of the meat as compared to moist heating methods.

Heating induces odor and flavoring components in meat due to major alteration of fat, amino acids and carbohydrates as well as lipid degradation components. Millard reactions plays a significant role in the production of meat flavor. The dry heating process (frying and roasting) can increase the level of Millard reactions and produces the quality flavor as compared to moist heat methods e.g. boiling (Shabbir et al., 2015). On the other hand, juiciness of the meat is greatly affected by heating method. Elevated temperature decreases the juiciness regardless of the connective tissues level. More temperature drives more water removal resulting crusty and drier meat surface (less juiciness) (Boles, 2010). The overall summary about the effect of heating on meat is given in Table 1.

## Miscellaneous

Traditionally, legumes and beans are cooked through common heating and boiling techniques until they turn soft. During heating starch gelatinization and proteins denaturation produces brown color in addition to softening of tissues (Clark et al., 2014). However, research demonstrated that heating can also reduce the anti-nutritional components and toxic factors in legume seeds such as tannins and phytic acid (Rehman and Shah, 2005). Additionally, it increases the protein and starch digestibility, dietary fiber while reduces the stachyose, ash, potassium, magnesium and raffinose (Wang et al., 2010).

In fruits and vegetables heating process converts the chlorophyll into pheophytin, which is a green or brown color pigment while carotenoids are heat stable (Sumonsiri and Barringer, 2014). Other changes include textural or rheological changes (softening of tissues), and some nutritional quality changes. Heat treatments can inactivate some enzymes such as pectin methyl esterase, polygalacturonase lipxygenase, and polyphenol oxidase in fruits and vegetables (Ahmed and Shivhare, 2005).

## Conclusion

Thermal treatment produces several physical and chemical changes in foods. These changes result in both beneficial and harmful effects on nutritional, functional and organoleptic properties of foods and their components. Currently, a number of thermal techniques are being employed for food processing. Optimization of thermal processing techniques with respect to the type of foods is essential to ensure the availability of foods with better nutritional and sensory quality.

## Introduction

Browning of foods occurs by enzymatic and non-enzymatic mechanisms. It is difficult to distinguish between the two mechanisms unless, for example, enzymes are inactivated by heat. Non-enzymatic browning occurs during heating and is subdivided into three reaction categories. The first is a Maillard reaction, which occurs between amino compounds (e.g. in proteins, peptides, amino acids) and carbonyl groups of reducing sugars (e.g. glucose, lactose, fructose). The second reaction is caramelization, where sugars react with each other under more drastic conditions. The third reaction category is ascorbic acid oxidation, which is the nearest to enzymatic browning involving ascorbic acid oxidase. Depending on the process used during food preparation, a wide variety of modifications may occur in a food matrix facilitating browning by one or more of the above mechanisms. Some researchers investigated the use of some emerging technologies (e.g. pulsed electric fields, high-pressure processing, etc.) in order to reduce food browning during transformation, transportation, and/or storage. In this chapter, the positive and negative effects of emerging technologies on Maillard reactions will be highlighted with the aim of gaining insights on the suitability of these technologies to be effectively used in sensitive food products.

## Maillard Reaction in Foods

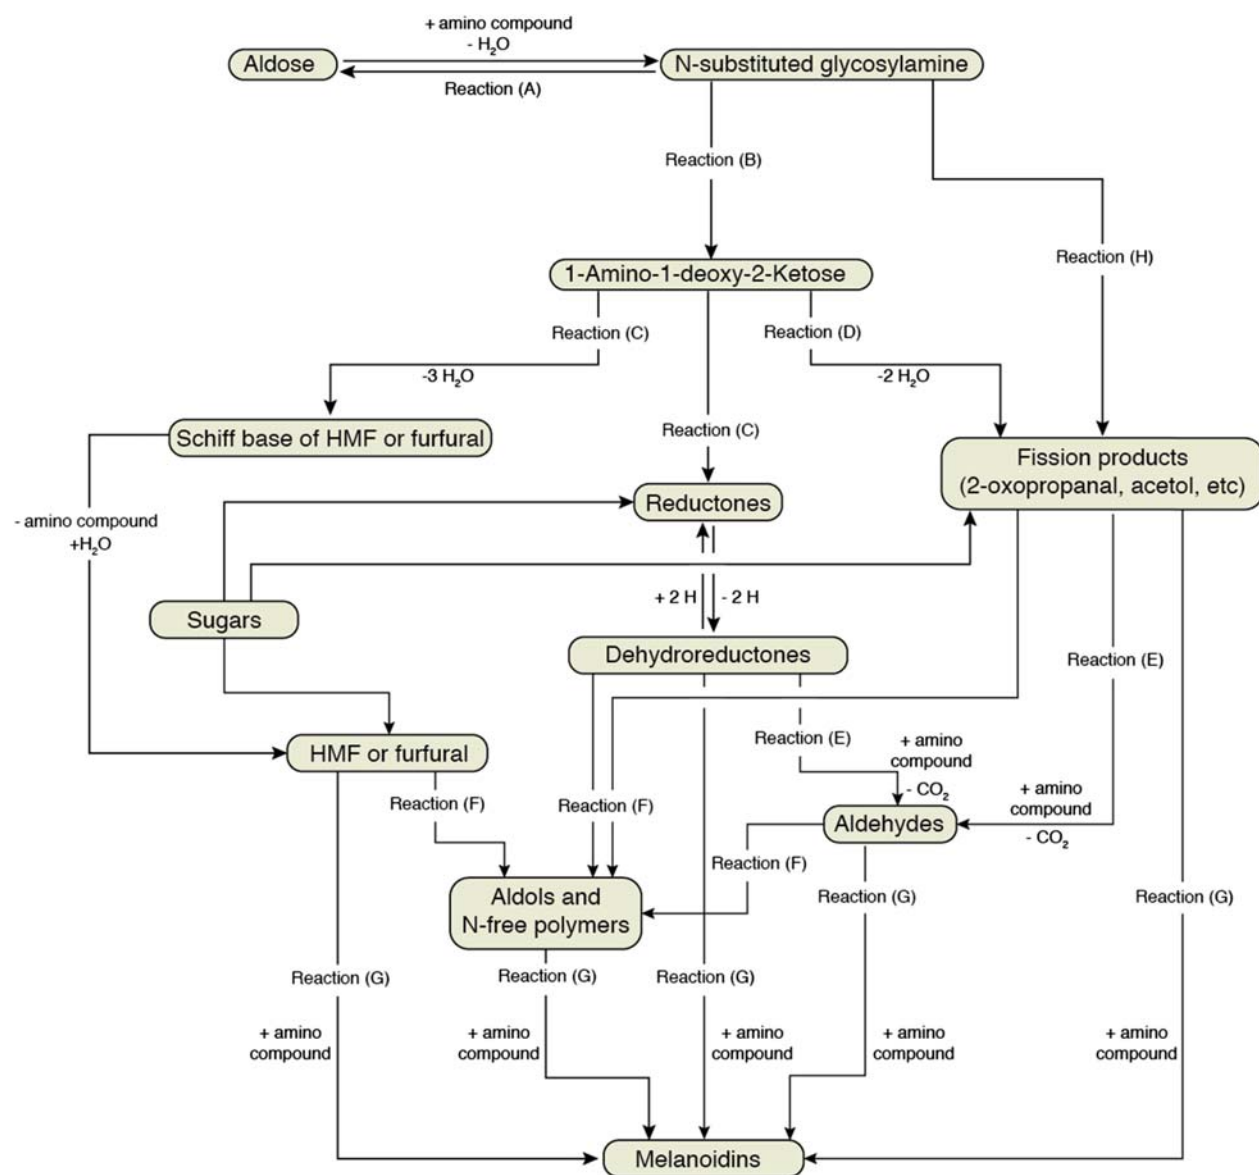

Maillard reactions were first described in 1912 by Louis-Camille Maillard (1878–1936); a French scientist qualified in medicine from the University of Nancy in 1903 (Feather and Waller, 1983; Nursten, 2005). Maillard reactions are very complex. For instance, as detected by HPLC and TLC, a condensation reaction between glucose and ammonia could lead to the formation of more than 15 compounds. The reaction between glucose and glycine gives more than 24 compounds, and the reaction between xylose and glycine gives about 100 compounds (O'Reilly, 1982). Typically, Maillard reactions result in the formation of a Schiff base followed by rearrangement to Amadori or Heyns products (Hodge, 1953; Hellwig and Henle, 2014). Several reviews have been published in the literature detailing Maillard reactions (Thorpe and Baynes, 2003; Peng et al., 2011; Hellwig and Henle, 2014; Lund and Ray, 2017). Hodge (1953) subdivided Maillard reaction into three stages as follows:

1. *Initial stage*: the product remains without any color and without ultraviolet (UV) absorption. Two reactions occur at this stage: sugar-amine condensation (reaction A) and Amadori rearrangement (reaction B).
2. *Intermediate stage*: the product's color may change to yellow with UV absorption. This stage will involve sugar degradation (reaction C) and fragmentation (reaction D), as well as degradation of amino acids (reaction E).
3. *Final stage*: the product becomes highly colored, and reactions such as condensation of aldols (reaction F), condensation of aldehyde-amine and formation of heterocyclic nitrogen compounds (reaction G) will occur.

The different reactions above-mentioned (reaction A–G) are described in Fig. 1. These three stages are known in literature as Early, Advanced, and Final Maillard reactions, respectively (Mauron, 1981). Melanoidins are the final products of non-enzymatic browning and should be distinguished from melanins, which are the final products of enzymatic browning. The dark-brown products formed in foods by enzymatic and non-enzymatic reactions are very complex to differentiate and their chemical analysis is difficult since they are relatively intractable.

Maillard reactions occur particularly when food products are processed at high temperatures (for example roasting, baking, extruding, etc.), when the processed products are stored for long periods at ambient temperature, or during transportation overseas where the temperature may increase up to 70 °C in the transportation containers (Meltretter et al., 2013, 2014). Depending on the time–temperature profile applied during food processing, as well as on the matrix, distinguished aromas could be formed (Ames, 1990). Many food industries are concerned by the occurrence of Maillard reactions especially when the product flavor is very important such as chocolate and coffee. Some of the changes found in non-enzymatic reactions are summarized in Table 1.

It should be noted that while Maillard reactions generate desired changes (i.e., especially flavors) in some food products such as coffee, bread, roasted meat, and dark beer (Vanderhaegen et al., 2006), these changes are perceived as off-flavors in other food products such as ultra-high-temperature (UHT) processed milk (Jansson et al., 2014a, 2014b). Thus their contribution to the quality of the product is product-dependent. Consequently, controlling Maillard reactions during food processing and storage is of paramount importance in order to maintain high-quality product. For instance, protein hydrolysis may occur in several food products, either naturally or during food processing (e.g., pasteurization, cooking, drying, tenderization ...) contributing to the release of free amino acids thus increasing the availability of amino groups for reactions. Another example is the

**Figure 1** Non-enzymatic browning. Adapted from Hodge (1953).

**Table 1** Changes in foods after non-enzymatic browning

Modification	Initial stage	Intermediate stage	Final stage
Color change or discoloration	—	+	+++
Flavor change or off-flavor	—	+	++
Water production	+	+	+
CO <sub>2</sub> production	Unknown	+	Unknown
pH decrease	Unknown	Unknown	Unknown
Increasing antioxidant activity	+	+	+
Solubility decrease	—	—	+
Loss of activity for vitamin C	+	—	—
Loss of proteins' value	+	+	+
Metals chelation	—	Unknown	+
Toxicity development	—	Unknown	Unknown
Fluorescence emission	—	+	+

production of lactose-free UHT milk where lactose is hydrolyzed into glucose and galactose, which causes 10 and 20 times faster reaction rates with amines than lactose, respectively, and thus increases the vulnerability of the product to Maillard reactions (Naranjo et al., 2013).

The functionality of proteins (e.g. properties of emulsifying, foaming, gelation, solubility, texturing, etc.) can also be impacted by Maillard reactions. Other changes in protein properties such as surface charge, hydrophobicity, and tertiary structure, can occur due to Maillard reactions, which allow manipulation of certain functionalities.

### Effect of Emerging Processing Technologies on Maillard Reaction

Some emerging technologies such as pulsed electric fields, ohmic heating, and high-pressure processing have shown their efficiency to be used as alternatives to conventional heating treatments, especially for the inactivation of microorganisms (Misra et al., 2017; Barba et al., 2017). Different results have been reported concerning their impact on Maillard reactions during food processing, and their mechanism of action seems to be complex and not well understood.

#### Pulsed Electric Fields

Many food industries have implemented pulsed electric field (PEF) systems in their processing chains and the technology was successfully tested for various applications. Extracting valuable compounds from plant and microbial matrices, inactivation of microorganisms, enhancing fermentation conditions, and accelerating unit operations of drying and freezing are among the multiple applications of PEF technology (Koubaa et al., 2016a; Lebovka et al., 2007; Roohinejad et al., 2014a, 2014b; Mota et al., 2018; Parniakov et al., 2016). The principle of PEF treatment consists of applying high voltage (usually < 50 kV/cm) pulses for short periods of time ( $\mu$ s to ms) to foodstuff placed between 2 electrodes (high voltage and grounded electrodes) (Koubaa et al., 2016a; Puértolas et al., 2016; Roohinejad et al., 2017). Generally, PEF equipment consists of an electrical generator producing square or exponential decay pulses, and either a batch or continuous treatment chamber (Huang and Wang, 2009). A schematic of a typical PEF treatment installation in the food industry as well as pulse shapes produced by PEF generators are presented Fig. 2.

PEF, as a non-thermal technology, does not increase the temperature of the processed food product and thus reduces the formation of undesired heat-derived or chemical changes. It has been demonstrated that applying PEF treatment, as compared to conventional heating, inhibited the formation of hydroxymethylfurfural (HMF) in some fruit juices (Aguiló-Aguayo et al., 2009). Lower levels of HMF were found in orange juice following PEF treatment compared to conventional pasteurization, along with reduced browning during the 6 week storage period (Cortés et al., 2008). Recently, it has been stated that removing one or more reactive compounds of the Maillard reactions could be the most promising use of PEF (Lund and Ray, 2017). For instance, treating potatoes by PEF increased glucose diffusion, which resulted in lowering the level of one of the components of Maillard reactions (Janositz et al., 2011a). Similarly, the impact of PEF treatment on the quality parameters of white asparagus (*Asparagus officinalis* L.) was investigated (Janositz et al., 2011b). Results from this study showed that PEF-treated samples had lower Maillard reaction substrate (glucose) compared to non-treated control samples.

It should be noted that applying PEF treatment at high intensities might promote the formation of Maillard reaction products, as demonstrated in an asparagine-glucose model system (Guan et al., 2010). The authors applied a PEF intensity of 40 kV/cm for 7.35 ms and noticed that asparagine and glucose levels were reduced by 14% and 66% (used for Maillard reactions), respectively. A similar observation was reported in a study of a glycine-glucose model system (Wang et al., 2011). The authors observed a consumption of 13.09% glycine and 50.76% glucose during the Maillard reaction and concluded that PEF treatment, especially with higher intensity over 30 kV/cm, can significantly promote Maillard reactions. These studies demonstrated that although PEF treatment has numerous advantages over conventional heating for food processing, its application should be controlled in order to achieve the required impact through Maillard reactions.

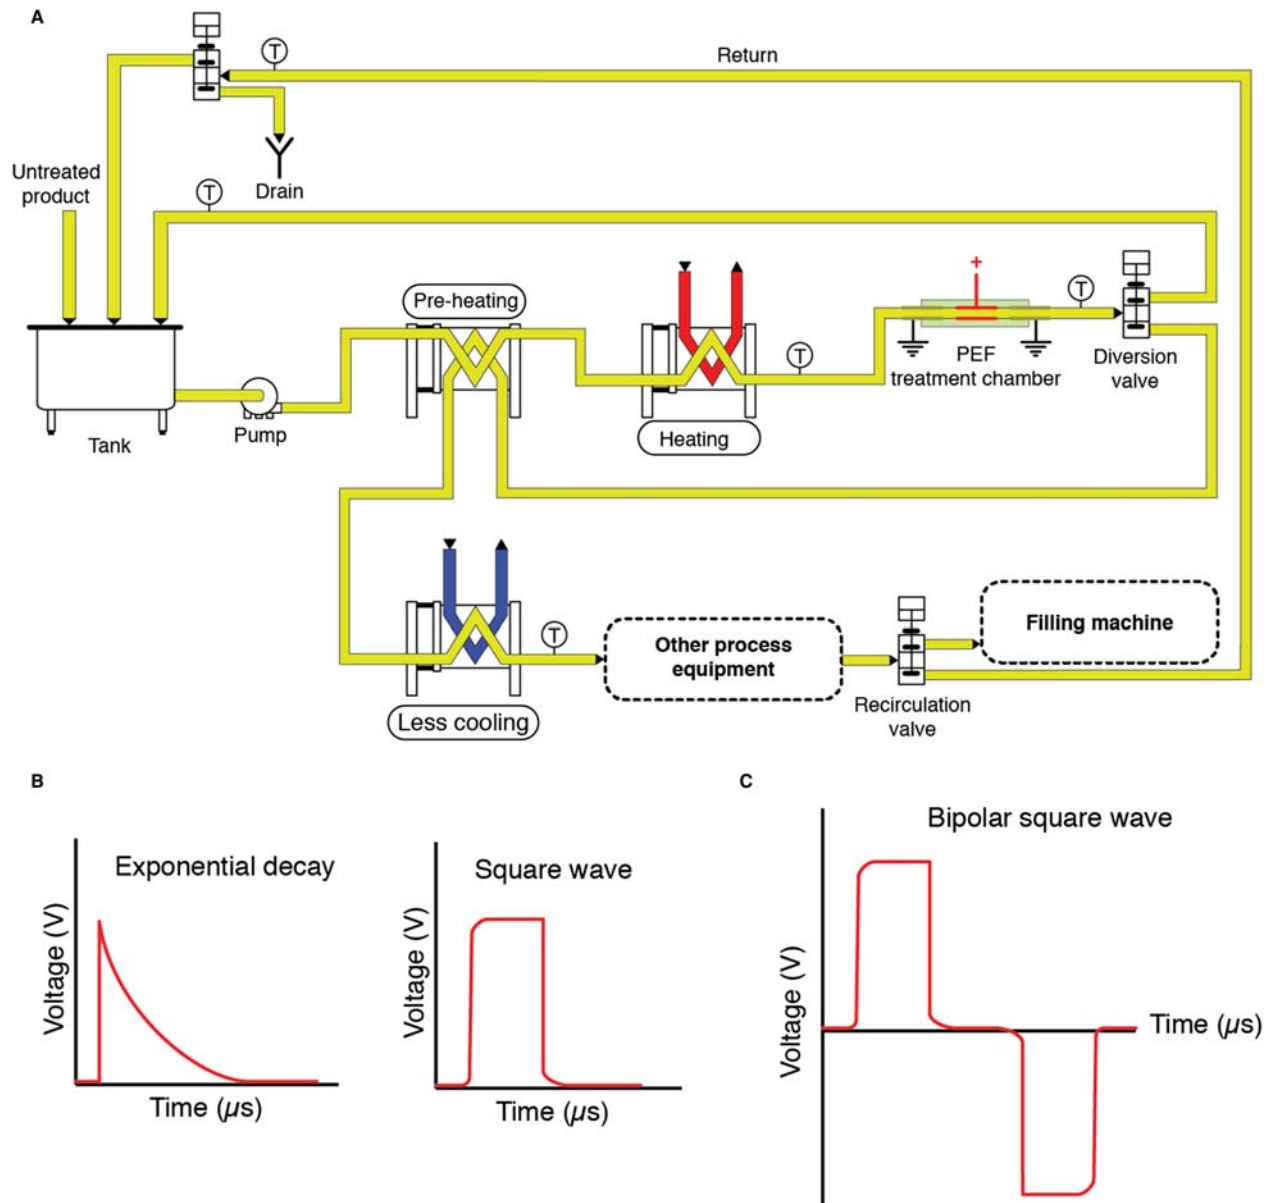

#### Ohmic Heating

Ohmic heating is a process used to heat materials when an electric current passes through them (Fig. 3) (Koubaa et al., 2016b; Hashemi et al., 2017). In ohmic heating, the food sample is not in direct contact with hot surfaces, and the process allows short-time and high-temperature thermal processing, which has the potential to control or minimize Maillard reactions (Lund and Ray, 2017). It has a low maintenance cost and high-energy conversion efficiency (Pereira and Vicente, 2010).

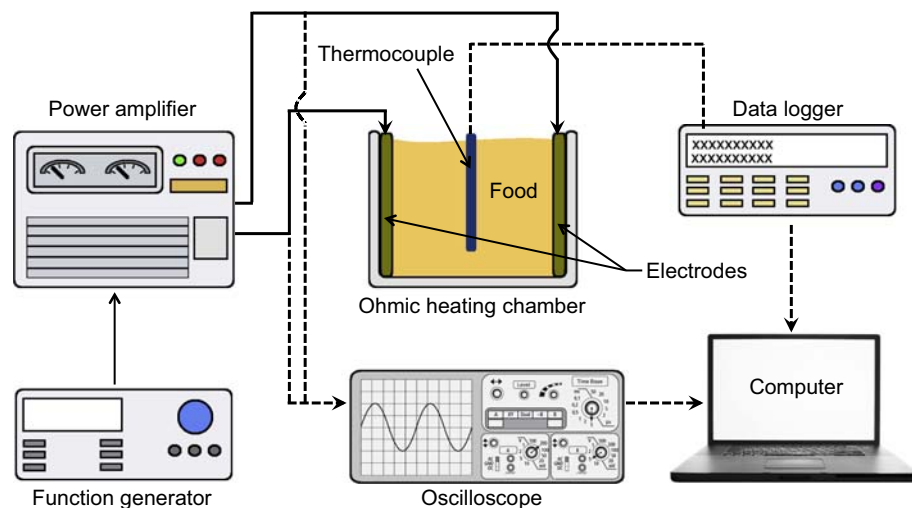

Due to its numerous advantages over conventional heating, ohmic heating is currently used in many applications such as blanching, evaporation, dehydration, fermentation, extraction, sterilization and pasteurization. The absence of heat exchanger surfaces leads to a better control of the thermo-chemical changes in the processed food. For instance, protein deposition on the walls of the plate exchanger during UHT milk processing leads to overheating and therefore chemical modifications, which could be avoided when using ohmic heating (Fillaudeau et al., 2006). This technology also showed its efficiency in limiting non-enzymatic browning by the inactivation of pea peroxidase after short treatment time, compared to sterilization with hot water (Icier et al., 2006).

In a recent study, the impact of ohmic heating in reducing the formation of furan in sterilized vegetable and vegetable/meat baby foods was investigated (Hradecky et al., 2017). The authors reported a reduction of 70%–90% of furan content in ohmic heated samples, compared to conventional sterilization. They suggest that this result is due to the faster heating time in ohmic heating,

**Figure 2** (A) Schematic diagram of industrial installation using PEF technology for the inactivation of microorganisms in food products. (B) Exponential and square waves used in PEF treatments. (C) Bipolar square wave. Reprinted with permission from Barba et al. (2017).

**Figure 3** Schematic representation of Ohmic heating equipment used for food applications. Reprinted with permission from Koubaa et al. (2016b).

which leads to reduce the degradation of furan precursor. In addition, analysis of compounds formed during Maillard reactions and fatty acid oxidation were significantly higher in conventionally sterilized samples compared to those treated by ohmic heating. These studies show that ohmic heating can lead to reduced Maillard reactions in processed foods.

### High Hydrostatic Pressure

Products treated with high hydrostatic pressure (HHP) were first commercialized in the Japanese market in 1990. Currently, various HHP-treated foods are commercialized and equipment is sold in many countries and used at industrial scale. This success is related to the efficiency of this technology in inactivating spoilage and pathogenic microorganisms, which offers a similar level of safety as afforded by heat sterilization. The principle of high pressure treatment consists of applying pressure to the food product in the range of 400–600 MPa from few seconds to several minutes (Oey et al., 2016). Nonetheless, HHP efficiency was demonstrated in the range of 100–1000 MPa (Oey et al., 2008). This efficiency was further enhanced when investigating the inactivation of bacterial spores by applying high pressure and high temperature ( $\approx 90$ – $120$  °C) (Martínez-Monteagudo et al., 2014; Mathys et al., 2009; Rajan et al., 2006). The process is thus called pressure-assisted thermal sterilization (PATS) or high-pressure sterilization (HPS) and was first developed for the treatment of mashed potato (Sizer et al., 2002) and green beans (Leadley et al., 2008) in order to extend their shelf life. The advantage over heat treatment is obtaining processed food that preserves most of the organoleptic, sensory, and nutritional properties compared to the fresh product (Barba et al., 2012, 2015). A schematic representation of HHP equipment used at laboratory scale is given in Fig. 4.

Recent works investigating the effects of HHP on Maillard reactions show that the related downstream reactions are complex and it would be wrong to affirm that HHP, as a non-thermal technology, provides minimal chemical changes to food products (Martínez-Monteagudo and Saldaña, 2014). Investigation in this field showed that the effect of HHP on Maillard reactions depends on the processing temperature, and it is more pronounced when combining high pressure and high temperature. To understand the mechanisms of action, model systems were used. For instance, Maillard browning was investigated in lysine/arginine-sugar model systems under HHP (Ma et al., 2017). Results from this study demonstrated that high pressure has different effects on lysine-sugar and arginine-sugar models. Intermediate and final stages were retarded in the lysine-sugar model, whereas degradation rate of Amadori compounds was decreased in the lysine-glucose model and increased in the arginine-sugar model. The influence of temperature was also studied. The author showed that Maillard reactions were accelerated along with the emission of fluorescent compounds.

The effects of HHP on oenological characteristics, amino acids and volatile profiles of Hongqu rice wines during pottery storage was investigated (Tian et al., 2016). The authors demonstrated that after 18 months of storage, a faster decrease in total sugars, lower free amino acid content, and higher ketone content were observed in HHP-treated wines. They suggested that these changes could be attributed to the occurrence of Maillard and oxidation reactions. In a similar study, accelerated changes in the volatile composition of sulphur dioxide-free HHP-treated wine was observed during storage (Santos et al., 2015). The authors reported that after 9 months storage, the pressurized wines (500 MPa and 425 MPa for 5 min) contained higher contents of furans, aldehydes, ketones, and acetals compared to untreated samples (wines with 40 ppm of SO<sub>2</sub> and without preservation treatment). They concluded that

**Figure 4** Schematic representation of a high hydrostatic pressure equipment used at laboratory scale. Reprinted with permission from Barba et al. (2016).

this behavior could be related to accelerated Maillard reactions in HHP-treated wines, thus giving similar composition of volatiles when compared to faster aged and/or thermally treated wines. The same research team also previously reported evidence of Maillard reaction acceleration in wine (Santos et al., 2013).

Investigations on reconstituted skim milk treated either with high-pressure thermal processing (HPTP) or conventional thermal processing showed color change and proteolysis in both samples (Devi et al., 2015). Maillard reactions were evidenced by the increased consumption of free amino acids proportionally to the increase in temperature, which indicates higher Maillard reaction rates rather than proteolysis.

## Conclusion

This chapter discussed the impact of emerging technologies (pulsed electric fields, ohmic heating, high hydrostatic pressure) on Maillard reactions in foods. Reported results from different studies showed that using these technologies do not completely inhibit Maillard reactions. However, applications of pulsed electric fields and ohmic heating treatments have shown the potential to control or minimize Maillard reactions in the processed foods, especially due to the mild processing temperature and low treatment time, respectively. Finally, positive and negative impacts of high hydrostatic pressure on Maillard reactions were reported during processing at low and high temperatures, respectively. In order to further explain the mechanisms of action of emerging technologies on Maillard reactions, further investigations should be conducted.

### Glossary

**Bioactive** Producing an effect in living tissue or in a living organism.

**Hyperbaric storage** Of fruit and vegetables, storage above atmospheric pressure.

**Hypobaric storage** Of fruit and vegetables, storage below atmospheric pressure to enhance loss of CO<sub>2</sub> and ethylene, so slowing ripening.

**Phytochemicals** Any naturally occurring plant substance, some of which have been shown in research to protect against disease.

### Introduction

Fruit is a rich source of valuable components like vitamins, minerals, and antioxidants. It is used to enhance/promote healthy living. However, most fruit are perishable commodities and normally available on a seasonal basis. Therefore, fruit is stored to increase its availability throughout the year. Various strategies have been developed to increase the shelf life and to ensure fruit availability throughout the year. However, consumers demand fresh and best quality fruit with all its nutritional and functionally bioactive components. Fruit quality deteriorates rapidly after harvesting due to increased rates of respiration and dehydration. Subsequently, deterioration results in weight loss, color changes, softening, surface pitting, browning, loss of acidity, and microbial spoilage. Therefore, the principle of storage technology is based on reduction of respiratory and enzymatic activities (Thompson, 2011). Other goals are described in Fig. 1. For this purpose, in the 19th century low-temperature storage or refrigeration storage technology was introduced, whereas controlled atmosphere storage and modified atmosphere packaging grabbed attention in the 20th century.

Evaluation of different storage technologies for improving organoleptic characteristics, reducing unnecessary losses, and preserving nutritional quality has become the center of attention now. Traditional fruit storage technologies include postharvest heat treatments, chemical treatments, and pressure-regulating storage. Some advanced storage practices are hypobaric or hyperbaric storage, ionizing or ultraviolet radiation treatment storage, high-pressure electrostatic field storage, ozone storage, magnetic field sterilization, ultrasonic processing technology, plasma treatment, and super low temperature ice technology or ice film storage (Ji et al., 2012). However, these technologies do not provide ideal condition to maintain quality, freshness, and other attributes. These technologies affect potential bioactive components of fruit, which are the focus of this chapter.

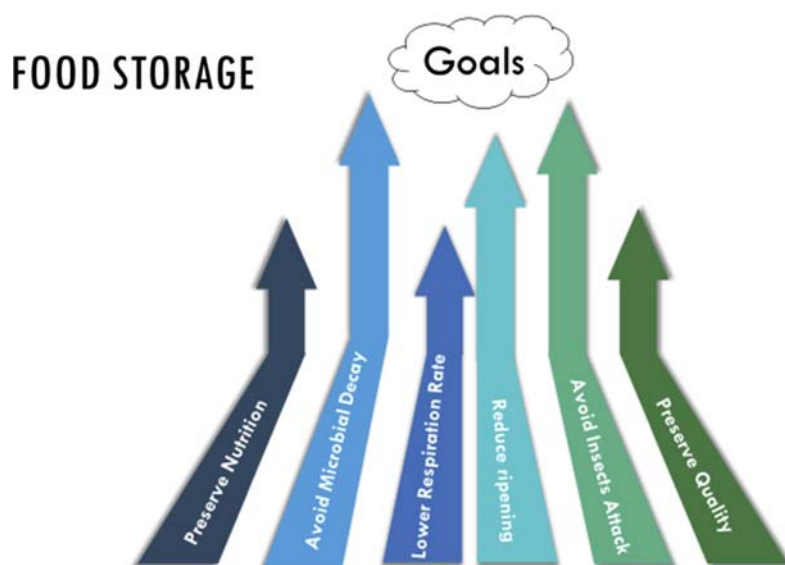

Figure 1 Food storage goals.

## Phytochemicals or Health-Promoting Compounds in Fruit

Fruit as nutritional commodities have an imperial role in human diet because of their countless functions in the prevention of diseases and improving health in conjunction with delightful sensory characteristics. Besides, fruit have various valuable components known as bioactive compounds including terpenoids, phenolic and polyphenolic compounds, alkaloids, sulfur-containing compounds, glucosinolates, carotenoids, anthocyanins, and lycopene. Among these compounds, polyphenols are secondary metabolites of plants and major antioxidants found in fruit. They have exhibited medicinal advantages such as lowering blood pressure and reducing cardiovascular diseases (CVDs), strokes (Russo et al., 2017; Williamson, 2017), and anticarcinogenic potential (Ferreira et al., 2017). They are subdivided into flavonoids (flavones, isoflavones, flavonols, flavanols, flavanones, anthocyanidins, anthocyanins, flavonones, and chalcones), tannins (hydrolyzed and condensed), lignans (sesamol, sesamin, sesamolol, and sesamololol), phenolic acids (hydroxybenzoic and hydroxycinnamic acids), and coumarins (Tokusoglu and Hall, 2011).

Flavonoids are further divided into subcategories including flavanones (hesperetin, hesperidin, naringenin, naringin, narirutin, didymin, eriocitrin, eriodictyol, neoriositrin, neohesperidin, isosakuranetin, pinocembrin, ponsirin, prunin), flavonols (quercetin, kaempferol, myricetin, quercitrin, isoquercitrin, rhamnetin, isorhamnetin, kaempferide, rutin, astragalin, hiperoside), anthocyanidins (cyanidin, malvinidin, delphinidin, pelargonidin, petunidin, peonidin), flavons (luteolin, baicalein, kryptin, diosmin, genkwanin, isorhoifolin, rhoifolin, tectokirisin), anthocyanins (grape extract), flavononols (dihydroflavonols), isoflavones (daidzin, genistein biokenin A, formononetin, glisitein, daidzin, genistin, glisitin) and chalcones (Tokusoglu and Hall, 2011). Flavonoids have clinical importance as antioxidants (Skrovankova et al., 2015) that are effective against many disorders including type 2 diabetes, CVDs and cancer (Martinez-Perez et al., 2014; van Dam et al., 2013). Other numerous advantages of flavonoids include antineoplastic effects, antiproliferative, anti-inflammatory, enzyme detoxification, activation of the immune system, prevention of cell proliferation, and reducing oxidative stress (Asha et al., 2017; Semaan et al., 2017; Zhang et al., 2017).

Other bioactive components of fruit include terpenoids (hemiterpenes, monoterpenes, sesquiterpenes, diterpenes, triterpenes, and tetraterpenes). Carotenoids (tetraterpenes) are fat-soluble compounds recognized as natural coloring components in fruit such as orange, red, yellow, and violet colors. These compounds are associated with much bioactive functionality such as preventing chronic diseases like CVDs (Meléndez-Martínez et al., 2014). They are classified into four main groups: carotenoid hydrocarbons (carotenes), carotenoid alcohols (xanthophylls), carotenoid ketones, and carotenoid acids.  $\beta$ -carotenes are precursors of vitamin A production within the body as well as have potential antioxidant ability. Xanthophyll absorbs light energy, so it is a factor in keeping human eyes healthy and functioning properly (Thomas and Harrison, 2016). Other bioactive functions of carotenoids include preventing atherosclerosis (Amengual et al., 2017), anticarcinogenic by scavenging of peroxy radicals, inhibiting cell proliferation, and antiinflammatory and immunity-boosting properties. Color is the key quality parameter, which can indicate the freshness of fruit. In fruit, carotenoids can be used as quality parameters because of their color-imparting characteristic. In tomatoes, lycopene (carotene) is a major pigmented component, which is nutritionally valuable as an antioxidant, particularly in reducing the risk of CVDs (Cheng et al., 2017; Müller et al., 2016). Table 1 shows a summary of bioactive components of different fruit.

**Table 1** Bioactive components of fruit

Bioactive components	Fruit	References
Anthocyanidins including cyanidin and delphinidin	Bananas	Padam et al. (2014) and Singh et al. (2016)

Xanthophyll	orange and yellow fruit	Al-Yafeai et al. (2017)
Flavones including luteolin	Red grape, oranges	Kozłowska and Szostak-Wegierek (2014)
Naringenin	Grapefruit, oranges	Seyedrezazadeh et al. (2015)
Flavan-3-ols (catechin)	Peaches, berries, red grape, bananas	Ageorges et al. (2014)
Gallocatechin	Berries, plums, pomegranate, persimmons	Zanotti et al. (2015)
Cyanidin	Berries, plums	Hubert et al. (2014)
Delphinidin, malvidin, peonidin	Berries, red grapes	Veberic et al. (2015)
Lycopene (carotene)	Tomatoes	Cheng et al. (2017) and Müller et al. (2016)
Carotenoids	Pumpkins, mango and papaya	Meléndez-Martínez et al. (2014)

## Effect of Different Storage Conditions on Fruit

During storage, fruit respire reducing its quality, and can possibly affect the quality of bioactive components in fruit. It may reduce health-promoting components, their concentrations, and antioxidative abilities. However, small changes in the antioxidant contents of the fruit have been reported during storage conditions because of alterations in ripening patterns (Kim et al., 2009; Park et al., 2006). On the other hand, significant increase in total phenolics (Gonçalves et al., 2004) and ascorbic acid concentrations (Khan et al., 2009) have been observed during storage. These advantages of premium quality can be enhanced by applying proper postharvest storage practices. Table 2 shows the effect of different bioactive compounds in different fruit.

### Cold Storage

Fruit deterioration starts with harvest and is enhanced at room temperature. However, use of low temperature may reduce the respiration and prevent microbial spoilage (Lamikanra, 2002). Therefore, it is necessary to cool down fruit as soon as possible to get premium quality fruit for the consumer. Fruit storage at low temperature has been the main postharvest technology to maintain fruit quality (Kader, 2002). Other important benefits of cold storage are reduction of ethylene production, delay in the adverse changes in parameters (color, acidity, and texture) related to fruit ripening and quality.

However, sometimes fruit exhibiting tissue injury or chilling injury show various physiological disorders (metabolic imbalance leading to undesirable chemical substance production in the tissues and eventual cell death) related to the lower temperature limits, which vary according to the type of fruit. Each commodity, kept in a specific storage temperature range (according to their metabolism), carefully monitored environment, and maintained uniformity in storage conditions, assures the retention of quality. Otherwise, storage conditions may affect the bioactive components leading to faster metabolism or cell death. Several types of cooling systems have been used worldwide such as room cooling, cryogenic cooling, hydro cooling, contact icing, forced air cooling, and vacuum cooling (Valero and Serrano, 2010). Among bioactive components present in fruit, phenolics and carotenoids are

**Table 2** Effects of postharvest storage on bioactive components of fruit

Storage	Fruit	Key findings	References
Cold storage	Tomato	Lycopene decrease at 5 °C	Javanmardi and Kubota (2006)
	Apple	Increases in TP, TA decreased at 0 °C after 120 days Nonsignificant flavonoids and TA losses, TP decrease after 3 months at 0°C	Leja et al. (2003) Ju et al. (1996)
	Pomegranate	TAA increases at 5°C, significant increase in AA Decrease in TP at 2°C Increases in TP, decline in TP after 4 months, TAA increase, significant decrease in AA after 3 months TP decrease at 5°C, TAA declined gradually	Miguel et al. (2004) Sayyari et al. (2011) Arendse et al. (2014)

Hyperbaric storage	Strawberry juice	TP and monomeric TA remained stable at 7th day. A significant decrease after 10 days	Bermejo-Prada and Otero (2016)
	Watermelon juice	Decrease TP	Fidalgo et al. (2014)
	Tomato	Retention of TAA, significant increase in lycopene, nonsignificant effect on TP and AA	Liplap et al. (2013)
		Lycopene increase	Inestroza-Lizardo et al. (2018)
Hypobaric storage	Peach	Retention of AA	Wang et al. (2015)
		Retention of AA	Chen et al. (2010)
	Pear	Retention of TP	Li et al. (2017)
	Chinese bayberry fruit	Higher TP	Chen et al. (2013)

AA, Ascorbic acid; TA, Total anthocyanin; TAA, Total antioxidant activity; TP, Total phenols; TPC, Total phenolic content.

generally stable, whereas ascorbic acid decreases during cold storage (Jaganath et al., 2008). Similarly,  $\beta$ -carotene, total carotenoids, pro-vitamin A, and total phenolics of fruit remain unaffected by storage. However, reduction of lutein contents has been reported during cold storage (Ayala-Zavala et al., 2004; Kidmose et al., 2004; Koca and Karadeniz, 2008). Decrease in anthocyanin contents of strawberry has been observed at 0 and 5°C, whereas it gradually increases at 10°C (Ayala-Zavala et al., 2004).

### Controlled Atmosphere Storage

For extending a fruit's shelf life and maintaining its quality characteristics, controlled atmosphere (CA) is a good choice to adopt. Normally, CA is adopted for gaining some advantages such as reducing enzymatic reactions, chilling injuries, respiration rates, substrate oxidation, breakdown of chlorophyll, ripening, rate of production of ethylene, degradation rate of soluble pectin and ultimately maximizing the storage period of fruit. CA storage rooms have been advanced from bricks or concrete-insulated refrigerated storage to metal-faced insulated panels in modern days. In this process, developed equipment are used to regulate and maintain the higher level of CO<sub>2</sub> and lower level of O<sub>2</sub>. Good temperature and humidity maintenance, airtight fitness, appropriate construction and insulation to prevent leakage are important points to be considered before constructing CA storage room (Fig. 2).

Although CA is a valuable tool for establishing a controlled setup for improving shelf life of fruit, sometimes it is associated with the onset of several physiochemical disorders because of mismanagement or long-term storage period, which affects the overall quality of the fruit. Generally, CA reduces the metabolism of the product, which indirectly affects its eating quality or flavor because of the production of some chemical byproducts (alcohols and aldehydes) during anaerobic conditions. Too-low levels of O<sub>2</sub> and anaerobic fermentation can damage fruit skin or textural properties (darker color, sharp edges). On the other hand, high levels of CO<sub>2</sub> can cause surface-scald browning and pitting without skin softening in addition to increase in acidity of fruit. Various studies on bioactive components of different fruit demonstrated that the total phenolic contents have been increased during CA storage (Leja et al., 2003; Zheng et al., 2003). Besides, a nonsignificant effect of storage was reported on phenolic contents (MacLean et al., 2006; Schotsmans et al., 2007). Other changes may include the synthesis of terpenoid components, synthesis of the carotenoids lycopene, xanthophyll (Goodenough and Thomas, 1981), and chlorogenic acid (MacLean et al., 2006), as well as decrease in anthocyanins (Leja et al., 2003; Romero et al., 2008) and lycopene (Jeffery et al., 1984), and chlorophyll degradation (Ben-Arie et al., 1992; Goodenough and Thomas, 1981). However, vitamin C and total flavonoid contents remained unchanged in CA storage (Martínez-Sánchez et al., 2006).

### Modified Atmosphere Packaging

The main purpose of this technology is to lessen respiration rate of the fruit, which ultimately reduces the metabolism or senescence process. Modified atmosphere packaging (MAP) was studied in the 19th century for the first time on the shelf life of horticultural products, and results demonstrated that anaerobic conditions strongly influenced the ripening process of fruit as unavailability of O<sub>2</sub> will block ripening. Therefore, in MAP fruit is generally packed in a modified environment, which has higher concentrations of CO<sub>2</sub> and lower concentrations of O<sub>2</sub>. This fixed gas composition (different from air) creates an anaerobic environment, which

**Figure 2** Controlled atmosphere storage. <http://www.agroripe.com/controlled-atmosphere-storage/>.

**Figure 3** Summary of MAP passive atmosphere modification phenomenon. Modified from Belay et al., (2016). <https://doi.org/10.1016/j.fpsl.2016.08.001>.

affects the respiration rate of products and enhances shelf life by lowering the rate of respiration. Other crucial factors that greatly influence composite gases are temperature, relative humidity, packaging material, and respiration rate of the product. One disadvantage of this system is that alteration of gas composition by microbial growth or packaged-film permeability can seriously affect the quality of fruit packed in hermetically sealed semipermeable containers. Theoretical considerations indicate that if the container is impermeable, then internal atmosphere can be altered because of the respiration process of the commodity; it will eventually deplete  $O_2$  level (from 21 to 0%) while increasing  $CO_2$  (from 0.03 to 20%) concentrations. On the other hand, semipermeable packaging has the same effect because of the passive atmosphere modification phenomenon (Al-Ati and Hotchkiss, 2002) (Fig. 3).

MAP gas concentration balance is a crucial factor, because an aerobic environment can enhance metabolic activity, sugar or starch consumption associated with flavor alteration, undesirable textural modifications, and production of water vapors, which degrade the other measures of the package selected for MAP. An anaerobic environment with depleted  $O_2$  level is also dangerous for fruit tissues as it reoxidizes reduced metabolites [pyridine nucleotides, nicotinamide adenine dinucleotide (NADH) and nicotinamide adenine dinucleotide plus hydrogen (NADPH)], produces  $CO_2$ , ethanol, and offensive odors. Maintained  $CO_2$  and  $O_2$  levels are required for generating the proper anaerobic environment to slow down respiration rate and the fruit's enzymatic activities. Inappropriate gas composition drastically degrades the physiochemical and sensory quality of the fruit and promote spoilage by pathogenic microorganisms, which ultimately produce undesirable changes in color, texture, aroma, or flavor (Artés-Hernández et al., 2006). Some recent developments of MAP have been introduced such as high-oxygen MAP, controlled MAP, and intelligent MAP (Zhang et al., 2015). MAP storage has advantage over bioactive components of fruit by retention of phenolics, antioxidants, anthocyanins, and ascorbic acid (maintain vitamin C concentration by limiting ascorbic acid oxidation) (Rojas-Graü et al., 2009), and lowering the postharvest ripening process (Jones, 2007). Furthermore, it enhances the sensory quality of the fruit, i.e., overall appearance, color, texture, aroma, etc (Akbudak and Eris, 2004; Martínez-Romero et al., 2003).

### Hypobaric Storage

Hypobaric or low-pressure storage, also known as subatmospheric pressure storage, consists of a ventilated chamber, which establishes a reduced  $O_2$  controlled environment (less than atmospheric pressure) that lowers the respiration rate of the produce and increases its shelf life. Proper monitoring of  $O_2$  level and low pressure are very important factors needed in well-maintained hypobaric storage (Thompson, 2011).

The positive effects of hypobaric storage on fruit have been reviewed by (Burg, 2014; Davenport et al., 2006; Li et al., 2008). Fruit stored in hypobaric conditions continuously respire and produce  $O_2$ , various volatile byproducts, and ethylene, which are constantly removed by vacuum pump, thus risk of ethylene-related disorders is reduced. Other advantages of hypobaric atmosphere storage conditions include inhibition of growth and sporulation of pathogenic microorganisms (fungi; Burg, 2004; Romanazzi et al., 2001) and control of insect infestation in fruit or disinfection [created hypoxic conditions, which reduce adenosine triphosphate (ATP) production and increase membrane phospholipid hydrolysis (Burg, 2010; Davenport et al., 2006; Jiao et al., 2013)]. In addition, advantages include enhanced antioxidant ability and reduced membrane damage of fruit (Wang et al., 2015), removal of scald-related volatile substances of apples (Wang and Dilley, 2000), delayed softening (Dilley et al., 1982), and reduction in the susceptibility to chilling injury (Chen et al., 2013; Zhao et al., 2006).

The major disadvantage of hypobaric is weight loss (higher desiccation) because lower pressure can increase the transpiration rate, which excludes water from the commodity (Burg, 2004). This problem of insufficient relative humidity can be resolved by spraying water and humidity control for maintaining the quality of fruit within hypobaric storage (Laurin et al., 2006).

### Hyperbaric Storage

Hyperbaric storage, the opposite of hypobaric storage, is storage in which high-pressure exposure is adopted for a short time as an alternative to chemical treatment for preserving food quality (Vigneault et al., 2012). Hyperbaric chambers are equipped with CO<sub>2</sub> removal and automatic O<sub>2</sub> replenishment systems and pressurized from 1 to 7 atm, with an automatically monitored gas concentration system, flow meter, CO<sub>2</sub> gas analyzer, and computer-controlled valves.

Advantages include lowering respiration rate and ripening processes (Goyette et al., 2012), reduction of microorganisms (irreversible damage to cell structure; Hite et al., 1914; Yordanov and Angelova, 2010), unchanged flavoring and nutritional components while retaining vitamin C (Day et al., 1998; Hill, 1997), controlling insect/pest infestation (UTZ et al., 2004). Other advantages include saving significant energy (Fernandes et al., 2015), preserving fruit color (López-Malo et al., 1998), improving texture and visual appearance (Luscher et al., 2005), reduced weight loss, improved lycopene retention, reduced chilling injury (Baba and Ikeda, 2002), enhancing antioxidative enzyme activity, oxygen radical absorbance capacity, and phenolic levels (Zheng et al., 2008). Still more advantages include structural rearrangements in enzymes (activation or inactivation; Ludikhuyze et al., 2001), inhibition of undesirable fermentation reactions, delay in enzymic browning (Day, 1996), and reduced peel spotting or browning by decreasing dopamine level (Maneenuam et al., 2007). Extreme high pressure (above 100 MPa) or increased O<sub>2</sub> concentrations may result in irreversible tissue damage, thus causing substantial injuries (Goyette et al., 2007, 2012), higher levels of free radicals (Fridovich, 1986), mealy flesh, browning of skin (Kidd and West, 1934), and peel injury (Solomos et al., 1997).

### Other Fruit Quality Defects During Storage

After picking or harvesting of fruit, deteriorative reactions have been observed, which include physiochemical defects due to environmental stresses as well as microbial infections due to mishandling or improper postharvesting treatments. Quality changes vary according to the nature of plants or trees from where fruit are collected. Fruit are divided into two main categories (climacteric and nonclimacteric) according to their ripening stage. Climacteric and nonclimacteric fruit have different ripening rates (ethylene, sugar, or acid concentration) and are therefore preserved by different storage conditions. Two such chemical alterations, lipid oxidation and nonenzymatic browning, are major factors of deteriorating the quality of fruit in regard to their color and flavor. Common physiochemical defects including weight loss (Galindo et al., 2004), alteration of color (chlorophyll losses; Wrolstad et al., 2005), texture (softening; Bennett and Labavitch, 2008), aroma (volatile profile changes), flavor, and taste (sugar or acid contents) have been observed (Crisosto et al., 2003; Hernández-Muñoz et al., 2006).

### Quality Management During Storage and Distribution

Fruit are perishable and need extensive care and quality control during storage. Superior quality products are the consumer's first demand, whether processed or not, which means the product must meet all quality parameters like taste, aroma, color, and freshness even after storage. There are some quality management strategies that may be adopted to ensure excellent quality during storage. Some of them are First in First out (FIFO), statistical prediction depending upon the effect of a specific parameter on quality loss, and installment of quality indicators that depend on a time-temperature relationship. Additionally, hygiene and cleanliness of storage area have significant effect on improving shelf stability of fruit during storage. Conclusively, quality management strategy depends on type of product to be stored as each food product needs specific strategy. In FIFO system, food must be stored in such a way that new stock should be stored after the older stock, so the older stock will dispatch prior to new stock, hence product will not deteriorate. Statistical prediction enables us to investigate the effect of specific parameters such as temperature, humidity, and other environmental conditions on the final product's quality, so we can calculate estimated shelf life in case of any change in environmental conditions. This system is very helpful during transportation of fruit, because temperature fluctuations occur that ultimately affect the quality. Hence, change in quality parameters may be predicted that helps in estimating final product quality.

### Conclusions

Fruit has been an important part of human diet since ancient times, but its importance is increasing day by day due to increased understanding about bioactive components present in them that are known to improve human health and help in combating diseases. Keeping its importance in mind, preservation of fruit and vegetables is a big concern due to drastic increase in human population and demand for quality food products. Various techniques of preservation have been employed by humans since the start of civilization. These techniques involve control over temperature and gaseous compositions, and their effect on preservation of fruit has been checked thoroughly. The use of hypobaric and hyperbaric environments in storage areas is still under study and has not yet been commercialized.

# Enzymatic Production of Antioxidants and Their Applications

Taiwo O Akanbi and Colin J Barrow, Deakin University, Geelong, VIC, Australia

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Antioxidants are compounds that can slow or prevent oxidation processes. They are required in low concentration for inhibiting the oxidation of oxidisable substrates such as lipids and lipid-soluble compounds. Antioxidants may be present in foods as endogenous factors or may be added to prevent their lipid components from quality deterioration (Shahidi, 2000). The major antioxidants used in foods are butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), tert-butylhydroquinone (TBHQ) and propyl gallate (PG) (Fig. 1). These are chemically synthesized and there are growing health concerns over their use as food antioxidants. For instance BHA and BHT have been suspected of being responsible for liver damage and cancer (Williams et al., 1999). In 1982, BHA was banned in Japan and in 1997 BHT was removed from the “GRAS” (generally recognized as safe) list of the FDA (Food and Drug Administration) in the United States (Hao et al., 2007). Europe and Japan are yet to approve TBHQ as a food antioxidant (Pinho et al., 2000). In Australia, New Zealand, China, USA, Philippines and Brazil, no more than 200 mg/kg of TBHQ is allowed in food (Perrin and Meyer, 2002).

Concerns about the safety of chemically synthesised antioxidants have motivated the food industry to seek natural alternatives. Natural antioxidants are generally derived from plants. The major ones are polyphenols, ascorbic acid (vitamin C) and tocopherols (vitamin E). Ascorbic acid and some polyphenols are water-soluble and are mostly effective in hydrophilic or water-containing food materials, while tocopherols are fat-soluble antioxidants and are effective in fatty or oily food materials. The effectiveness of natural antioxidants depends on the nature of the food materials, including the level of lipid present.

Natural antioxidants can be modified to improve their oxidative stability, solubility properties and bioavailability. For instance, attaching fatty acids to ascorbic acid and some water-soluble polyphenols can make them oil-soluble. Also, specific polyphenols can be attached to tocopherol to improve its antioxidant property. These modifications can be achieved by using chemicals or enzymes. The use of enzymes is preferred because reactions involving enzymes are carried out under mild conditions, with less side reactions compared to chemical methods. Lipases are widely used for these type of reactions. They are the most important enzymes for the formation or transfer of ester bonds, particularly for lipids including triacylglycerols.

Therefore, in this article, lipase-catalysed modification of three major natural antioxidants, vitamin C (ascorbic acid), vitamin E ( $\alpha$ -tocopherol) and polyphenols will be discussed. Specific applications of the modified antioxidants will also be discussed.

## Lipases

Lipases are a highly versatile group of biocatalysts that play an important role in biotechnological and industrial processes, including food, oleochemical and pharmaceutical applications. They are produced from various sources including animals, plants and microorganisms (Olusesan et al., 2009). However, microbial lipases are generally more stable and are cheaper to produce.

Lipases catalyse the hydrolysis of fats into fatty acids and glycerol in aqueous media (Olusesan et al., 2011; Xia et al., 2017). Because of their compatibility with a broad range of solvents, lipases can be used to synthesize or transfer ester bonds in non-aqueous media (Akanbi and Barrow, 2015; Pande and Akoh, 2016). These are known as esterification and transesterification reactions. The high cost of lipases has been recognised as the main constraint to their use industrially. From an economic point of view, these enzymes should be recoverable and reusable for continuous operations. To achieve these, lipases have to be

**Figure 1** Chemical structures of some of the major synthetic antioxidants used in foods.

immobilized so that they can be used in solid form (Akanbi and Barrow, 2017). Immobilized lipases are preferred to free lipases since the immobilized forms tend to be more robust and are more readily recovered and reused at manufacturing scale (Akanbi and Barrow, 2018; Mathesh et al., 2016). *Candida antarctica* lipase B, marketed in an immobilized form as Novozym 435, is a widely used immobilized lipase since it has been shown to catalyse a broad range of reactions.

### Lipase-Produced Antioxidants From Ascorbic Acid

Ascorbic acid is a natural antioxidant, but because it is highly hydrophilic, its use in fats and oils is restricted. This can be overcome by attaching fatty acid to it, thus making it fat soluble. Ascorbyl palmitate is the major fat soluble vitamin C ester available commercially today and it is manufactured through industrial-scale chemical reactions (Humeau et al., 1995). These reactions involve the use of strong acids that can lead to side reactions thus lowering the yield of esters. The use of lipase for producing fatty acid esters of vitamin C is preferred because of the moderate reaction conditions and also because it is considered a natural process. Acyl donors include triacylglycerols, alkyl esters, vinyl esters, fatty alcohols or free fatty acids. Fatty acids can be saturated or unsaturated. Saturated fatty acids are those with only single bonds while unsaturated fatty acids are those with double bonds. The major saturated fatty acids used for the synthesis of vitamin C esters include caprylic (C8:0), decanoic (C10:0), lauric (C12:0), myristic (C14:0), palmitic (C16:0) and stearic (C18:0) acids. Unsaturated fatty acids include oleic (C18:1), linoleic (C18:2), linolenic (C18:3), eicosapentaenoic (C20:5) and docosahexaenoic (C22:6) acids. Since esterification reaction involves the use of solvent, several non-toxic solvents have been identified for the lipase-catalysed production of fatty acid esters of vitamin C. These include 2-methyl-2-propanol (*tert*-butanol), 2-methyl-2-butanol, 1-octanol, acetone and dimethyl sulfoxide (DMSO) (Karmee, 2011; Stamatis et al., 1999). Column chromatography is the principal purification technique for most of these novel compounds. Column chromatography can be used for gram-to kilogram-scale purifications. Different analytical techniques such as capillary chromatography, gas chromatography (GC), nuclear magnetic resonance (NMR), high performance liquid chromatography (HPLC), and liquid chromatography-mass spectrometry (LC-MS) can be used to characterise these esters.

An example of a lipase-produced ascorbyl ester is shown in Scheme 1 where ascorbic acid and palmitic acid, a free fatty acid, are esterified to produce ascorbyl palmitate. As shown, the primary alcohol group from the ascorbic acid is esterified.

### Applications

The antioxidant activities of lipase-produced fatty acid esters of vitamin C acid have been previously reported. Rapeseed oil was stabilized using ascorbyl palmitate and oleate produced using Novozym 435 as biocatalyst (Viklund et al., 2003). These authors found that ascorbyl oleate was more effective than ascorbyl palmitate as it could protect rapeseed oil for up to nine weeks when stored at 30 °C. Ascorbyl palmitate was only able to preserve the oil for one week under the same storage conditions. Another study found that both ascorbyl palmitate and oleate produced by *Thermomyces lanuginosus* lipase showed similar antioxidant activity in soybean oil (Reyes-Duarte et al., 2011). Both esters slowed down the formation of peroxides in soybean oil. A study found that ascorbyl linoleate produced using Novozym 435 showed the same antioxidant activity as BHT in soybean oil at a concentration of 200 mg/kg oil (Liu et al., 2011). Ascorbyl decanoate, laurate, myristate, palmitate and stearate were produced using Novozym 435 under ultrasonic irradiation (Jiang et al., 2016). They prolonged the stability of lard in a similar manner as TBHQ. These authors found that these esters were better than TBHQ in stabilizing soybean oil (Jiang et al., 2016).

### Lipase-Produced Antioxidants From Polyphenols

Polyphenolic compounds are the most abundant and widely studied antioxidants from natural sources. They exist in the forms of phenolic acids, stilbenes, flavonoids, lignans, coumarins and tannins (Holland et al., 2017). The chemical structures of some polyphenolic compounds are presented in Fig. 2. All phenolic compounds contain a benzene ring and at least one or more hydroxyl groups, making most of them water-soluble (hydrophilic). The hydrophilic property of these compounds limits their dispersion in fats and oils, thereby reducing their effectiveness in protecting lipids against oxidation (Akanbi and Barrow, 2018). Again, an effective way of making them oil-soluble and with improved antioxidant properties is by attaching fatty acids to them using lipases. Lipases have been used to produce fatty esters of polyphenols, most of which have maintained or showed higher antioxidant activity than their parent polyphenols.

**Scheme 1** Lipase-catalysed synthesis of ascorbyl palmitate.

**Figure 2** Chemical structures of some polyphenolic compounds.

**Scheme 2** Lipase-catalysed synthesis of hydroxytyrosyl palmitate.

**Scheme 2** shows that hydroxytyrosol, an olive oil polyphenol and palmitic acid can be esterified using lipase as catalyst to produce hydroxytyrosyl palmitate.

## Applications

Fatty acid esters of polyphenols have been synthesised using lipases (**Table 1**). Some of these phenolic esters have been used to stabilize fats and oils against oxidation. In our group, we have recently modified the structure of hydroxytyrosol, a major polyphenol in olives, through esterification with a broad range of free fatty acids using Novozym 435. The abilities of these esters to stabilize anchovy oil were investigated (**Akanbi and Barrow, 2018**). We found that hydroxytyrosyl palmitate and eicosapentaenoate effectively stabilized bulk fish oil, fish-oil-in-water emulsions and microencapsulated fish oil, with antioxidant levels higher than those of BHT and  $\alpha$ -tocopherol. These novel antioxidants were also stable for one year when stored at  $-20^{\circ}\text{C}$ . In another study, where lipase was used to synthesize fatty acid esters of tyrosol, the authors found that tyrosyl oleate was the most

**Table 1** Examples of polyphenols and acyl donors reported in the literature

Polyphenols	Acyl donor	Lipase used	References

Resveratrol	Vinyl ester	Novozym 435	<a href="#">Torres et al., 2009</a>

efficient antioxidant for stabilizing an oil-in-water emulsion (Pande and Akoh, 2016). Also, a lipase-produced decanoic acid ester of rutin was found to be a more effective antioxidant than rutin in sardine oil during 20 days of storage (Vaisali et al., 2017). Since lipid oxidation may cause deterioration of other food components such as protein, many of these lipase-produced fatty acid esters of polyphenols can also be used for stabilizing lipid-containing protein rich foods.

### Lipase-Produced Antioxidants From Tocopherols

There are four types of tocopherols (alpha,  $\alpha$ ; beta,  $\beta$ ; gamma,  $\gamma$ ; and delta,  $\delta$ ), but the most abundant in nature is  $\alpha$ -tocopherol. Although  $\alpha$ -tocopherol is a natural antioxidant, it is unstable and is readily oxidised in the presence of oxygen, heat and other oxidising agents. Interestingly, esters of  $\alpha$ -tocopherol have been found to be relatively stable to atmospheric oxygen at room temperature. Different microbial lipases have been used to produce vitamin E esters, such as vitamin E acetate, vitamin E succinate and vitamin E ferulate (Ferreira-Dias et al., 2013; Hu et al., 2013). Scheme 3 shows the lipase-catalysed production of vitamin E succinate, where succinic anhydride and  $\alpha$ -tocopherol (vitamin E) are esterified using immobilized lipase from *Candida rugosa* (Hu et al., 2013).

### Applications

Enzymatic conjugation of two natural antioxidants,  $\alpha$ -tocopherol and ferulic acid, produces a potent natural antioxidant, tocopheryl ferulate or vitamin E ferulate. This lipase-produced ester can be used in fats and oils because it is a lipid-soluble antioxidant (Xin et al., 2011). Since ferulic acid is a polyphenol, several polyphenolic esters of vitamin E can be synthesised enzymatically and used as antioxidants in oil and fat-based foods and formulations. Lipases have been used to synthesize other vitamin E esters, such as vitamin E succinate and vitamin E acetate. These esters are more stable in the presence of light and oxygen than their parent vitamin E (Ferreira-Dias et al., 2013). However, the presence of the succinic or acetic groups on the tocopherol block their antioxidant activity, so they cannot be used as antioxidants in fats and oils. However, they have been added to foods to increase their vitamin E content, so that when they are consumed, digestive enzymes like esterase can break the ester bond and release the active tocopherol that then acts as antioxidant *in vivo*. Vitamin E acetate is the most common form of vitamin E used in the human and animal nutrition market (Torres et al., 2008; Ferreira-Dias et al., 2013).

### Conclusion

Enzymes, particularly lipases, are used to modify the oxidative stability and solubility of natural antioxidants, thereby expanding the range of nutritional applications where they can be utilised. The antioxidant activity of some of these lipase-produced esters of natural antioxidants are similar and in some cases better than food-grade chemically synthesised antioxidants such as BHT, BHA and TBHQ. Importantly, the lipase produced antioxidants are considered natural in many regulatory jurisdictions if the starting antioxidant is sourced naturally. In addition, some of these antioxidants, such as vitamin E and vitamin C and their derivatives have positive health benefits in addition to their antioxidant properties, and so can offer a dual benefit in nutritional products such as nutritional supplements and functional foods.

# Factors Influencing Red Wine Color From the Grape to the Glass

Jacqui M McRae, Bo Teng, and Keren Bindon, The Australian Wine Research Institute, Glen Osmond, SA, Australia

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Flavan-3-ol (syn. flavanols, condensed tannins, catechin derivatives, proanthocyanins)** Phenolic compounds consisting of a 15-carbon skeleton with two hydroxylated phenyl rings and a pyran ring with hydroxyl group at C-3 position.

**Interflavan bonds** Covalent bonds formed between flavan-3-ol subunits.

**Nucleophile** Molecule or ion with a free pair of electrons that can be donated to an electrophile to form a covalent bond.

**Oenotannin** A commercially-available tannin-rich product produced by extracting tannins from grapes or oak.

**Tannin (syn. condensed tannin polymer, pigmented polymer)** By definition, tannins are polymeric molecules that bind to protein. In grapes and wine, tannin refers to polymers that consist largely of flavan-3-ol subunits and can incorporate anthocyanins. These tannins also contribute to wine astringency by interacting with salivary proteins. Oak tannins are referred to as hydrolysable tannins and consist largely of gallic acid subunits.

**Veraison** Refers to the onset of grape ripening where sugars begin to accumulate in the berry.

## Nomenclature

BSA Bovine serum albumin

EC Epicatechin

EG Epigallocatechin

ECG Epicatechin gallate

M3G Malvidin-3-glucoside

MCP Methyl cellulose polymer

mDp Mean degree of polymerisation

## Introduction

Red wine color is closely related to perceived quality and is influenced by many viticultural and winemaking factors. Wine is a chemically-dynamic system that is acidic (pH 2.8–3.8) and contains high concentrations of oxidizing compounds, particularly phenolics. These factors induce changes to grape and wine pigments from the moment the grapes are crushed to end-product in the glass. Key pigments are extracted from grapes during winemaking and undergo multiple reactions to form purple wine pigments. As wines age, further reactions change the color to a red-brown hue. Such chemical diversity and reactivity makes red wine a fascinating topic of study. This article aims to summarise some of the main influencing factors of red wine color as well as the methods used to measure wine color chemistry.

## Molecules and Mechanisms Responsible for Red Wine Color

Red wine color is developed from interactions between tannins and anthocyanins extracted from grapes during winemaking. In the principal *Vitis vinifera* varieties used for red winemaking around the world, grape anthocyanins comprise monoglucoside derivatives of several structures with malvidin 3-*O*-glucoside being the most abundant. Other anthocyanins include delphinidin, cyanidin, petunidin, peonidin, and, to a lesser extent, pelargonidin (Fig. 1). Acylation of the glucose moiety at the C-6'' position is also common for grape-derived anthocyanins (Fig. 1), and include acetyl, coumaroyl and cafferoyl moieties (Monagas et al., 2005). The presence and composition of the acylated anthocyanins in grapes varies with variety, for example these types of anthocyanins are not present in Pinot Noir grapes (Cortell et al., 2007a).

The color of anthocyanins depends on the pH of the solution (Fig. 2). In acidic solutions (pH < 2), the anthocyanins exist as red flavylium cations and in higher pH solutions (pH 4.5–6) the blue quinoidal base dominates. Anthocyanins can also undergo hydration reactions which produce a colorless hemiketal form (Cheynier et al., 2006). At pH 3.5, such as in wine, anthocyanins are present in a mixture of colored and colorless forms, with the colorless forms dominating (Monagas et al., 2005). This indicates that while the concentration of free anthocyanins in young red wines might reach levels greater than 1 g/L (Bindon et al., 2014a; McRae et al., 2012), less than half of that concentration contributes to wine color (Monagas et al., 2005). Anthocyanins are

Anthocyanin	R <sub>1</sub>	R <sub>2</sub>
Pelargonidin 3-glucoside	H	H
Cyanidin 3-glucoside	OH	H
Delphinidin 3-glucoside	OH	OH
Peonidin 3-glucoside	OCH <sub>3</sub>	H
Petunidin 3-glucoside	OCH <sub>3</sub>	OH
Malvidin 3-glucoside	OCH <sub>3</sub>	OCH <sub>3</sub>

**Figure 1** Structures of grape anthocyanins. Monagas, M., Bartolome, B., Gomez-Cordoves, C., 2005. Updated knowledge about the presence of phenolic compounds in wine. *Crit. Rev. Food Sci. Nutr.* 45 (2), 85–118.

**Figure 2** Anthocyanin forms. Cheynier, V., Duenas-Paton, M., Salas, E., Maury, C., Souquet, J.M., Sarni-Manchado, P., Fulcrand, H., 2006. Structure and properties of wine pigments and tannins. *Am. J. Enol. Vitic.* 57 (3), 298–305.

also considered unstable and their concentration in red wine reduces rapidly after winemaking. Substantial reductions in the concentrations of free anthocyanins have been noted within two years after winemaking (Bindon et al., 2014d; McRae et al., 2013). With aging, the concentration of anthocyanins decreases and that of pigmented polymers increases. It is therefore the presence of other compounds, particularly anthocyanin derivatives, that provide the depth of color so strongly associated with quality wine (Somers and Evans, 1974).

The decrease in anthocyanin concentration as wines age relates to the formation of comparatively stable wine pigments derived from anthocyanins such as pyranoanthocyanins and pigmented polymers. These reactions will change the overall wine color from purple to red-brown (Cheynier et al., 2006). Pyranoanthocyanins are formed from the addition of yeast metabolites, such as acetaldehyde and pyruvic acid, to the C-4 position of the anthocyanin aglycone and subsequent reactions lead to the formation of a fourth ring structure (Håkansson et al., 2003; Quaglieri et al., 2017). Pyranoanthocyanins include orange vitisins and blue portisins (Cheynier et al., 2006). Vitisins, including vitisin A and vitisin B (Fig. 3), are the most common group of pyranoanthocyanins in wine and yet concentrations reach only around 5 mg/L in non-Port red wines. This concentration further declines with wine aging (Quaglieri et al., 2017) as free pyranoanthocyanins react with non-colored flavan-3-ols in wine to produce pigmented polymers (Fig. 3).

Flavan-3-ols are among the most reactive phenolics in red wine and readily form pigmented polymers via covalent interactions with anthocyanins (Garrido and Borges, 2013; Monagas et al., 2005; Somers, 1971). These pigmented polymers can persist in wines for decades and maintain the color density of red wines (McRae et al., 2012). The predominant flavan-3-ols in wine include catechin, epicatechin (EC), epicatechin gallate (ECG), and epigallocatechin (EG) (Fig. 4) which can be present as monomers, dimers, oligomers and as polymers (known as ‘tannins’) (Monagas et al., 2005). Flavan-3-ols generally form covalent bonds through the C-4 and C-8 positions, although linkages may also form between the C-4 and C-6 positions (Dallas et al., 1996; Wollmann and Hofmann, 2013). These are referred to as B-type linkages (Fig. 5) (Sun and Miller, 2003). Less commonly in grapes

**Figure 4** Grape flavan-3-ol structures. Monagas, M., Bartolome, B., Gomez-Cordoves, C., 2005. Updated knowledge about the presence of phenolic compounds in wine. *Crit. Rev. Food Sci. Nutr.* 45 (2), 85–118.

**Figure 5** Examples of A-type and B-type flavan-3-ol dimers. Monagas, M., Bartolome, B., Gomez-Cordoves, C., 2005. Updated knowledge about the presence of phenolic compounds in wine. *Crit. Rev. Food Sci. Nutr.* 45 (2), 85–118.

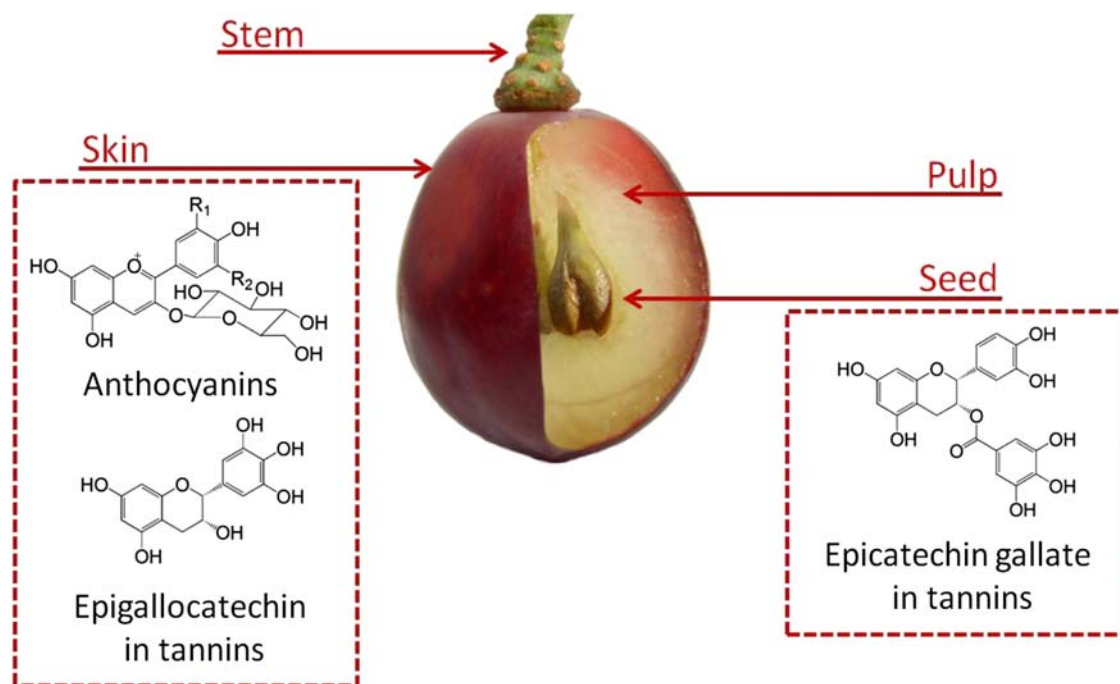

and wine, the C-4 and C-2 positions of one flavanol may interact with the C-6 and C-8 positions of the second flavanol forming A-type linkages (Fig. 5) (Aron and Kennedy, 2007).

Covalent interactions between monomeric flavan-3-ols and anthocyanins form flavanol-anthocyanin (F-A) adducts through either direct or indirect condensation reactions (Cheynier et al., 2006; Monagas et al., 2005). Direct condensation reactions involve the formation of quinones due to oxidation and subsequent polymerisation via B-type linkages producing a red F-A dimer. Indirect condensation reactions involve an ethyl-bridge linkage formed between monomers by interactions with acetaldehyde. This produces a purple F-ethyl-A dimer (Cheynier et al., 2006; Monagas et al., 2005). Both F-A and F-ethyl-A adducts further polymerise over time to produce longer pigmented polymers (Sun et al., 2008). Polymerisation reactions occur more readily between anthocyanins and flavan-3-ol oligomers (3–5 subunits) than with flavan-3-ol monomers, dimers or polymers (25 subunits) (Bindon et al., 2014b; Dallas et al., 1996). Anthocyanin self-association can occur via ethyl- or vinyl-linkages to produce highly colored dimeric or trimeric pigments. These pigments contribute to the color of aged wines and yet are not resistant to bisulfite bleaching (Bindon et al., 2014b; Kilmister et al., 2014). The formation of stable pigmented polymers therefore requires adequate concentrations of both tannins and anthocyanins and in the correct ratios (Bindon et al., 2014b; Kilmister et al., 2014).

Non-covalent interactions between anthocyanins and non-colored phenolic compounds may also influence red wine color via copigmentation. The planar surfaces of anthocyanins interact with the planar surfaces of phenolic moieties via  $\pi$ - $\pi$  interactions to form molecular stacks (Andersen and Jordheim, 2010; Cheynier et al., 2006). Such structures can form from intramolecular interactions between the anthocyanin aglycone and a phenolic acyl group or from intermolecular interactions between anthocyanins and flavan-3-ol oligomers (Escribano-Bailón and Santos-Buelga, 2012). Copigmentation potentially increases color intensity (hyperchromic effect) and purple color (bathochromic shift) (Cheynier et al., 2006; Heras-Roger et al., 2016) although anthocyanin self-association is likely to have a greater contribution to the color of young red wines (Herderich et al., 2006; Lambert et al., 2011).

### Viticultural Factors Influencing Red Wine Color

Many factors influence red wine color before the winemaking begins. The concentration and composition of color-related compounds in red wine depends on the composition of phenolic compounds in grapes and these are influenced by many viticultural factors. Anthocyanin concentrations begin to increase in grape skins after veraison (Pirie and Mullins, 1977) whereas flavan-3-ol monomers in both grape skins and seeds appear to increase prior to veraison and then decline significantly after veraison (Kennedy et al., 2000, 2002). This decrease in flavan-3-ol concentration with ripening does not necessarily relate to tannin formation as tannin concentrations can either increase, decrease or remain unchanged after veraison (Bindon et al., 2014c). Tannin extraction during winemaking depends on anthocyanin concentration (Bindon et al., 2014a; Kilmister et al., 2014) and therefore the concentrations of both species in grapes are linked to wine color.

**Figure 6** Grape structure with significant tannin subunits for skin and seed.

Anthocyanins are generally specific to grape skins while derivatives of flavan-3-ols are distributed throughout the grape including the seeds and pulp (Fig. 6). Tannins in grape skins are longer polymers with an average number of flavan-3-ol subunits (mean degrees of polymerisation, mDp) of around 32 subunits (Kennedy et al., 2001). Epicatechin (EC) subunits dominate grape tannin polymers. In grape skins, the tannins also contain around 20%–50% EG subunits and 5% ECG subunits (Kennedy et al., 2001). Grape seed tannins are much shorter than skin tannins, with mDp around 5 subunits, contain no EG subunits and a higher proportion of ECG subunits (around 24%) (Fournand et al., 2006; Kennedy et al., 2001, 2002).

The concentrations and compositions of grape anthocyanins and tannins in grapes and wines vary greatly and are influenced by genetic origin, grape ripeness, sunlight or UV exposure, plant water status and pathogens. Cabernet Sauvignon, for example contains significantly greater concentrations of tannin than Pinot Noir (Harbertson et al., 2008, 2002). Delaying harvest and increasing grape ripeness can also potentially increase wine color. This may be due to increases in extractable tannin and anthocyanin concentrations as the grape matures, which result in greater pigmented polymer formation, although ripening-related berry shrivel can also underpin this effect (Bindon et al., 2013; Schelezi et al., 2017). Increasing sunlight exposure of grapes, such as by removing leaves in the grapevine canopy, may lead to significantly higher concentrations of both anthocyanins and tannins in grapes (Edwards et al., 2015; Ristic et al., 2010) and shading grapes can reduce the color density of wine (Ristic et al., 2007). This is also related to variations in the concentration of pigmented polymers formed in the wines.

Grapes that receive less water are generally smaller than irrigated grapes which may result in an overall increase in grape skin phenolics, including anthocyanins and tannins, relative to berry volume (Ojeda et al., 2002). Early season water deficit may also enhance the biosynthesis of grape anthocyanins but does not directly impact tannin synthesis (Castellarin et al., 2007). Wine color can be increased by water deficit when both grape anthocyanin and tannin concentrations are enhanced, which in turn results in production of pigmented polymers (Bindon et al., 2014d; Kennedy et al., 2002). The application of elicitors, such as methyl jasmonate or benzothiadiazole, mimic pathogen attack and increase the synthesis of anthocyanins and skin tannins in grapes. This leads to increased grape skin tannin and color, resulting in greater color density of the wine (Ruiz-Garcia et al., 2012). Other viticultural factors can also influence anthocyanin and tannin concentrations in grapes and wine including temperature, nutrient status, crop load, canopy size, grapevine vigor, soil type and elevation (Bergqvist et al., 2001; Cohen and Kennedy, 2010; Cortell et al., 2005, 2007b; Downey et al., 2006; Kennedy et al., 2002).

## Winemaking Factors Influencing Red Wine Color

Reactions of color-related grape compounds begin once grapes are harvested and continue until the wine is consumed. Fermentation of grapes to wine induces the greatest changes in chemical composition. The key factors influencing red wine color during fermentation include oxygen exposure, extent of grape skin contact, variety of yeast for primary fermentation and fermentation additions. Wine pH and oxygen ingress through barrels or bottle closures will also influence color properties during wine aging.

### Oxygen Exposure

Reactions between phenols and oxygen begins when grapes are crushed. Polyphenol oxidase (PPO) enzymes from grapes catalyze the oxidation of caftaric (caffeoyltartaric) acid and cutaric (*p*-coumaroyl-tartaric) acid to highly reactive *o*-quinones. The formation of quinones triggers either oxidation–reduction reactions with anthocyanins or condensation reactions. Anthocyanins with hydroxyl groups on the B-ring, such as cyanidin-, delphinidin-, and petunidin-3-glycosides, undergo oxidation–reduction reactions via coupled oxidation with *o*-quinones of caftaric and cutaric acid to form anthocyanin quinones. Condensation reactions involve nucleophilic attack by *o*-quinones of the C-8 or C-6 position of anthocyanins, particularly malvidin- and peonidin-3-glucoside when in the hemiketal form. This produces colorless adducts that then equilibrate to flavylum forms (Monagas et al., 2005).

Chemical oxidation reactions also occur due to the presence of phenolate ions (Monagas et al., 2005). Such reactions may be catalyzed by iron or copper activation of dissolved oxygen (Quaglieri et al., 2017) and forms products similar to those of enzymatic oxidation (Monagas et al., 2005). The presence of other chemicals as a consequence of oxidation, such as acetaldehyde from ethanol, also promote condensation reactions and the formation of pigmented polymers (Drinkine et al., 2007) and pyranoanthocyanins (Quaglieri et al., 2017).

Oxygen is introduced to wine throughout its lifecycle from grape crushing to bottle aging. Most oxygen is introduced during fermentation due to the practice of pumping wine to break up the grape material, particularly grape skins, that collect at the top of the ferment. Greater oxygen exposure during fermentation can lead to lower concentrations of tannins but an increase in the proportion of more stable pigments (McRae et al., 2015). Oxygen can also be added post-fermentation using micro-oxygenation (MOX) techniques (Schmidtke et al., 2011). Introducing small amounts of oxygen, such as 45 mg/L over three months, can increase the production of stable pigmented polymers and pyranoanthocyanins (Kontoudakis et al., 2011; Quaglieri et al., 2017). The efficacy of MOX is greater in wines of lower pH (Kontoudakis et al., 2011). Further oxygen exposure occurs through barrels during barrel-aging (Quaglieri et al., 2017) and from slow oxygen ingress through bottle closures during long-term storage (Gambuti et al., 2013; Han et al., 2015; Ugliano, 2013). The effect of the long-term oxygen exposure is also greater at lower wine pH (McRae et al., 2013).

## Maceration

The time during which wines are fermented in the presence of grape material, including skins, pulp and seeds, is known as maceration. This process is crucial for the extraction of color-related pigments from grapes. Anthocyanins and grape skin tannins are extracted earlier in the fermentation process due to greater permeability of grape skins (Smith et al., 2015). Seed tannins are extracted later in the ferment as grape seeds are less permeable and require greater hydration for tannin extraction (Casassa et al., 2013; Hernandez-Jimenez et al., 2012; Peyrot des Gachons and Kennedy, 2003). Extending maceration may result in greater color density and higher concentrations of phenolic compounds including grape seed tannins (Aron and Kennedy, 2007; Gomez-Plaza et al., 2001). Addition of enzymes during maceration can lead to higher concentrations of tannins in wine due to the hydrolysis of cell wall pectins which limits the back-binding of extracted tannin, but does not necessarily lead to greater anthocyanin extraction or the improvement of wine color (Bautista-Ortín et al., 2013; Zietsman et al., 2015). More effective maceration techniques for wine color enhancement include thermal treatments such as elevated fermentation temperature, thermovinification, and microwave (Carew et al., 2013b; Sacchi et al., 2005). Thermal treatment can increase the extraction of anthocyanins, tannins and potentially other phenolics, leading to increased polymeric pigment formation and enhanced wine color.

## Yeast Selection

*Saccharomyces cerevisiae* yeast is used to ferment grapes to wine and the selected strain can influence red wine color properties. *S. cerevisiae* AWRI 1631 and RC212 strains can increase tannin extraction from grape skins (Carew et al., 2013a; Holt et al., 2013). *Saccharomyces bayanus* AWRI 1176 and 1375 consistently produced wines with lower tannin concentrations and wine color density (Carew et al., 2013a; Hayasaka et al., 2007; Holt et al., 2013). The higher production of acetaldehyde in these strains can also potentially influence the color development of red wines. Yeast cells can also adsorb anthocyanins, particularly acylated derivatives. The adsorbed anthocyanins settle with yeast at the end of fermentation, reducing their concentration in wine (Morata et al., 2003).

## Fermentation Additions

Many additions are made to wine during fermentation to influence the efficacy of the process as well as the properties of the wine. Some of these additives are known to influence the color parameters of red wines. The most critical of these color-influencing additives is potassium- or sodium-metabisulfite, which is added at the end of fermentation to prevent wine spoilage. Reactions between free anthocyanins and sulphites can reduce the charge state of the anthocyanin forming colorless bisulfite adducts (Fig. 7). Pyranoanthocyanins and pigmented polymers are resistant to this bleaching (Cheynier et al., 2006).

Fining agents, such as with animal-based proteins including casein and gelatin, are sometimes added to wine to remove tannins and lower wine astringency (Maury et al., 2001). This can also potentially reduce anthocyanin concentration and color density (Ghanem et al., 2017; Guerrero et al., 2013).

The addition of copigments prior to fermentation can potentially improve the color properties of wine. Caffeic acid addition, for example, can increase red color produced in wine (Darias-Martín et al., 2002). The addition of enotannins from oak or grape seed can also potentially stabilise color although the efficacy of enotannin addition in improving wine color for many wines may be limited (Li et al., 2017; Versari et al., 2013).

Phenolics extraction from grapes during winemaking is also increased by prefermentation juice runoff or saignée. Removing a portion of juice prior to fermentation increases the ratio of grape solids to juice and thereby improves the efficacy of phenolics extraction. In some cases this can increase the concentration of anthocyanins and tannins in wine (Harbertson et al., 2009; Sacchi et al., 2005) although efficacy of the treatment can vary with vintage and source of fruit (Gawel et al., 2001). The many different winemaking techniques available to winemakers can significantly impact the concentrations of anthocyanins, tannins and copigments in red wines, even in those wines produced from the same package of grapes.

## Analytical Methods for Measuring Red Wine Color

Understanding wine color involves analysis of the diverse range of pigments and copigments in wines as well as the total color metrics. Measuring red wine color therefore uses many different methods to obtain the required information. The color properties of red wines are measured using spectroscopic techniques to give overall wine color properties and concentration estimates for free anthocyanins and pigmented polymers. The concentration and composition of free anthocyanins can be more accurately measured using high performance liquid chromatography (HPLC) analysis with UV detection at 520 nm (Mercurio et al., 2007). Determining the structures of pigmented polymers is best achieved after isolation and depolymerisation reactions combined with HPLC analysis or LC-mass spectrometry (LC-MS) techniques.

Spectroscopic techniques use different wavelengths, wine additions or polymer precipitation to gain information about the overall wine color as well as the type of pigments present. Several techniques are commonly used and each vary in the information provided. CEILAB parameters measure the lightness ( $L^*$ ), angular hue ( $H^*$ ), red-green contribution ( $a^*$ ), yellow-blue ( $b^*$ ), Chroma ( $C^*$ ), and saturation ( $s^*$ ) (Esparza et al., 2009; OIV, 2014). Glories parameters measure absorbance at 420, 520 and 620 nm color intensity (CI), hue (H), brightness (B), and the percent contributions of yellow, red and blue (Glories, 1984). Somers color parameters measure absorbance at 280, 420 and 520 nm before and after treatment with either excess metabisulfite to induce excess  $SO_2$  production, acetaldehyde, or hydrochloric acid. These measurements provide estimations of anthocyanin concentrations, pigmented polymers, hue and wine color density (Mercurio et al., 2007).

Precipitation assays involve interactions between wine pigmented polymers and an added binding polymer such as methyl cellulose polymer (MCP) (Mercurio et al., 2007) or bovine serum albumin (BSA) (Harbertson et al., 2015, 2003). The change in measured absorbance before and after BSA addition and with and without the addition of metabisulfite can also be used to measure pigmented polymers separately from smaller pigments (Harbertson et al., 2003). Changes in the absorbance at 280 nm before and after MCP addition can be used to measure tannin concentration including pigmented polymers. Absorbance is compared to a standard curve of either EC at 280 nm to give tannin concentration as mg/L EC equivalents or malvidin 3-O-glucoside (M3G) at 520 nm to give pigmented polymer concentration as mg/L M3G equivalents.

Anthocyanin monomers are separated and measured using HPLC, monitoring absorbance at 520 nm and/or by MS. Separation is best achieved with a reversed phase C-18 column with a gradient solvent system from aqueous to acidified acetonitrile (Mercurio et al., 2007). Isolating larger quantities of anthocyanins is useful for accurate characterization of structures. This is effectively achieved with multilayer countercurrent chromatography (MLCCC) using quaternary solvent systems such as acetonitrile, water, butanol and butyl methyl ether mixtures (Kneknopoulous et al., 2011). Pigmented polymers and tannins are more effectively isolated from red wines using solid-phase extraction media including Toyopearl (McRae et al., 2010), Sephadex LH-20 (Bindon et al., 2010) or Oasis HLB cartridges (Waters, Australia) (Jeffery et al., 2008).

Compositional analysis of isolated tannins and pigmented polymers is achieved with depolymerisation techniques that enable the determination of the mDp and subunit identification (Cheynier et al., 1997; Kennedy and Jones, 2001). Interflavan bonds are cleaved at elevated temperatures and in acidic solutions to release free monomeric subunits. The addition of nucleophiles will then stabilise the released monomers against further polymerisation. Nucleophiles include toluene-thiol or benzyl-thiol for thiolytic reactions (Cheynier et al., 1997; Poncet-Legrand et al., 2010; Prieur et al., 1994) or phloroglucinol for phloroglucinolysis reactions (Kennedy and Jones, 2001). Polymer extension units and terminal units can be differentiated by the ratio of monomers with and without a nucleophile adduct, respectively, giving the average number of subunits per polymer (mDp). Subunit composition is then achieved with HPLC separation and analysis (Koerner et al., 2009). This method can provide information about the composition of flavan-3-ol subunits in the pigmented polymer, however anthocyanins cannot be detected (McRae et al., 2013) and bonds created as a result of tannin oxidation cannot be cleaved (Poncet-Legrand et al., 2010). Thus the amount of tannin converted in the reaction (mass conversion or % yield) must also be considered for accurate interpretation of results (Poncet-Legrand et al., 2010).

## Conclusions

Research into wine pigments and factors influencing wine color is ongoing. This article highlights some of the key research outcomes in this fascinating area of study and there are likely to be more developments emerging in coming years. These will continue to improve our understanding of wine color and enable the effective production of quality red wines.

## Introduction

Fermentation, by far, is the oldest, most valued and economical food processing and preservation method practised by mankind dated back to old civilizations of more than 4000 years (Steinkraus, 2004). Thus, fermented foods and beverages are amongst the first types of processed foods produced and consumed by human beings worldwide (El Sheikh and Montet, 2016). Diverse types of fermented foods and beverages are available due to differences in fermentation substrates and microorganisms, fermentation conditions, environmental conditions, ethnic and social preferences, religion, and cultural practices (Tamang, 2010). Based on the substrates used, fermented foods can be classified as grains, vegetables, fruits, meat, and milk-based fermented foods. Fermented grain is the major type of fermented foods and is not only considered as staple food in developing countries but it also considered as healthy food in the developed world. Fermentation of grains is done through both traditional and modern techniques leading to the production of numerous fermented grain products that are distributed, traded and consumed by humans worldwide. Traditionally, the main goal of grains fermentation was to preserve them for a long time and prevent deterioration by spoilage microorganism. However, recently the fermentation of grains had expanded beyond preservation to the enhancement of nutritional, sensorial, and health-promoting potential of grains. This monograph will give an overview of the fermentation of grains, the major fermented grain products, the types of microorganisms involved in the fermentation of grains, and the impact of fermentation on quality of the final products.

## Fermentation of Grains

Grains used for food could be classified as cereals (such as wheat, rice, maize, sorghum, millet, barely, rye, oat, teff, and triticale), pseudocereals (such as amaranth, buckwheat, and quinoa), legumes (such as coffee beans, cocoa beans, soybeans, broad beans, lima beans, kidney beans, mung beans, chickpea, pigeon pea, grass pea, field pea, cowpea, green gram, black gram, lupines, and lentil) and oil seeds (peanuts, canola, cottonseeds, sunflower, safflower, linseeds, rapeseeds, sesame seeds, and mustard) (Graybosch, 2016). In addition to protein and energy, whole grains are rich source of bioactive compounds such as phenolics, flavonoids, sterols, dietary fibre, essential fatty and amino acids, vitamins, macro- and micro-minerals,  $\beta$ -glucans, carotenoids, probiotics, and prebiotics and they are thus considered as important functional foods (Bultosa, 2016). However, whole food grains may contain several antinutritional factors such as phytic acids, tannins, non-starch polysaccharides, cyanogenic glycosides, saponins, and protease and amylase inhibitors that strongly reduce the bioavailability, digestibility, and metabolisms of essential nutrients in these grains (Madsen and Brinch-Pedersen, 2016). Several processes such as fermentation, dehulling, milling, soaking, germination, cooking, and irradiation had been used to overcome such limitations of food grains. Fermentation of grains is exceptionally the most effective method for the reduction of antinutritional factors and toxic compounds of these products (Wood, 2016). In addition, this process is also believed to improve grains storability, safety, digestibility, palatability, availability of essential minerals, enrichment of the fermented products with vitamins and bioactive compounds, as well as improving the health-enhancing potential of grain products (Nout et al., 2007; Wood, 2016). Fermentation increases the diversity of food products and consequently, huge numbers of fermented grains products are now produced and consumed worldwide. Many types of fermentations (alkaline, acetic acid, lactic acid, and alcoholic or a combination thereof) and methods (natural, backslopping, starter cultures, solid state, and submerged fermentations) are used in the production of fermented grain products. In addition, diverse groups of bacteria, yeasts, and moulds are used for fermentation and they are responsible for the production and diversity of the fermented grain products. Fermented grain foods are classified based on the grains classification itself as; cereal and pseudocereals, legumes and oilseeds, and cereal-legumes fermented foods. Some fermented grain foods and beverages are presented in Table 1, and the major types of these products are discussed in the following sections.

## Fermentation of Cereals and Pseudocereal Grains

Cereals are extensively grown world-wide where they considered as important part of diet by peoples all over the world. Although they are not popular like cereals, pseudocereals received great attention in recent years as raw materials for preparation of gluten-free foods. Cereals and pseudocereals contain a high starch proportion and they thus often milled to flours and used for the production of bread and bakery products (Fletcher, 2016). Prior to consumption, a large volume of cereals and pseudocereals grains are processed through fermentation and consequently diverse numbers of fermented foods and beverages are produced from these grains. The fermentation of cereals has a long history of more than 7000 years when Chinese prepared alcoholic beverages from Chu, a mould fermented rice or wheat products, and around 3500 years latter bread and beer making was also developed by Egyptians (Steinkraus, 2004). Since then, thousands of cereal- and pseudocereal-based fermented foods and beverages have

**Table 1** Cereal, legumes, and cereal-legumes based fermented foods and beverages (Adebo et al., 2017; Blandino et al., 2003; Coda et al., 2017; Kohajdová, 2015; Nagai and Tamang, 2010; Nout, 2009; Nout et al., 2007; Tamang, 2010; Taylor, 2016; Vogelman et al., 2009)

Grains group and names	Fermented foods (regions)	Nature of uses	Functional microorganisms in the fermentation
<b>Cereals and pseudocereals</b>			
Wheat ( <i>Triticum aestivum</i> & <i>T. turgidum</i> subsp. <i>Durum</i> )	Babroo (India)	Fried discs used in festivals	Unknown
	Bahtura (India)	Bread	LAB, Yeasts
	Bhatooru (India)	Baked bread, staple foods	LAB
	Bouza (Egypt)	Thick and acidic alcoholic beverage	Unknown
	Boza (Albania, Turkey)	Thick, sweet and slightly sour alcoholic beverage	LAB
	Chilra (India)	Thin, crisp pancake	LAB, Yeasts
	Craft beer (Italy)	Un-filtered beer	Yeasts
	Gulgule (India)	Deep fried sweets used in festivals	Unknown
	Jalebies (India)	Pretzel-like syrup confection	Yeasts, LAB
	Kishk (Egypt)	Dried balls dispersed in water for beverage preparation	LAB, Yeasts
	Kurdi (India)	Solid, fried crisp, salty noodles	Unknown
	Mantou (China)	Steamed cake	Yeasts
	Marchu (India)	Bread	Unknown
	Minchin (China)	Condiment	Moulds
	Nan (India, Pakistan)	Leavened bread	LAB, Yeasts
	Seera (India, Pakistan)	Sweet dish	
	Shamsy bread (Egypt)	Spongy bread	Yeasts
	Siddu (India)	Steamed oval-shaped bread	Unknown
	Sourdough (Worldwide)	Mildly acidic leavened bread	LAB, Yeasts
	Taotjo (East Indies)	Condiment	Yeasts
	Takju (Korea)	Alcoholic turbid drink	LAB, Yeasts
	Tarhana (Turkey)	Dried powder seasoning for soups	LAB
	Aliha (Ghana, Togo, Benin)	Mild acidic non-alcoholic drink	LAB
	Aceeda (Sudan)	Porridge	LAB
	Bogobe (Botswana)	Soft porridge	Unknown
	Burukutu (Nigeria, benin, Ghana)	Creamy liquid alcoholic drink	LAB, Yeasts
	Hulu-mur (Sudan)	Sour and sweet taste non-alcoholic drink	LAB
	Hussuwa (Sudan)	Cooked dough	LAB, Yeasts
	Jiu (China)	Alcoholic beverage	Fungi, Bacteria, Yeasts
	Kisra (Sudan)	Thin pancake bread	LAB, Yeasts
	Merissa (Sudan)	Alcoholic drink	Yeasts
	Nasha (Sudan)	Thick non-alcoholic drink	LAB, Yeasts
	Ogi (Nigeria, West Africa)	Mildly acidic porridge	LAB, Yeasts
	Otika (Nigeria)	Alcoholic beverage	Unknown
	Pito (Nigeria, Ghana)	Dark brown alcoholic beverage	LAB, Yeasts
	Sorghum beer (South Africa)	Acidic and weakly alcoholic drink	LAB, Yeasts
	Talla (Ethiopia)	Alcoholic beverage	Unknown
	Ting (South Africa)	Sour porridge	LAB
	Uji (Kenya, Uganda, Tanzania)	Acid and sour porridge	LAB
Sorghum ( <i>Sorghum bicolor</i> )			

Maize ( <i>Zea mays</i> L.)	Atole (Mexico)	Porridge	LAB
	Banku (Ghana)	Solid maize dough	LAB, Yeasts
	Busaa (Nigeria and Ghana)	Alcoholic beverage	LAB, Yeasts, fungi
	Chicha (Peru)	Spongy solid	Yeast, Bacteria, Fungi
	Chikokivana (Zimbabwe)	Alcoholic beverage	Yeasts
	Ilambazi lokubilisa (Zimbabwe)	Porridge	LAB, Yeasts, Moulds
	Jamin-bang (Brazil)	Cake-like bread	Yeast, bacteria
	Kaanga-kopuwai (New Zealand)	Soft slimy bread	Yeast, bacteria
	Kachasu (Zimbabwe)	Alcoholic beverage	Yeasts
	Kaffir beer (South Africa)	Alcoholic beverage	LAB, Yeasts
	Kenkey (Ghana)	Acidic, solid and steamed dumpling	LAB, Yeasts
	Koko (Ghana)	Porridge	LAB, Acetic acid bacteria, Yeasts
	Maheu (South Africa)	Sour non-alcoholic beverage	LAB
	Mahewu (South Africa)	Sour non-alcoholic beverage	LAB
	Mawe (Benin, Togo)	Sour non-alcoholic beverages and porridges	LAB, Yeasts
	Munkoyo (Africa)	Liquid drink	Unknown
	Mutwiwa (Zimbabwe)	Porridge	LAB, Yeasts, Moulds
	Ogi (Nigeria)	Mildly acidic porridge	LAB, Yeasts, Fungi
	Poto poto (Congo)	Slurry for gruel making	LAB, Yeasts
	Pozol (Mexico)	Mildly acidic porridge	Yeast, Bacteria, moulds
	Rabdi (India)	Semisolid mash	LAB, Fungi, Bacilli
	Seketeh (Nigeria)	Alcoholic beverage	LAB, Yeasts, Fungi
	Tesguino (Mexico)	Alcoholic beverage	Bacteria, Yeasts, Moulds
	Tobwa (Zimbabwe)	Non-alcoholic beverage	LAB
	Uji (Kenya, Uganda, Tanzania)	Acid and sour porridge	LAB
	Ambali (India)	Acidic pancake	LAB
	Bagni (Caucasus)	Liquid drink	Unknown
	Ben-Saalga (Burkina Faso)	Gruel, weaning food	LAB, Yeasts
	Braga (Romania)	Liquid drink	Unknown
	Busa (Syria, Egypt, Turkistan)	Liquid drink	LAB, Yeasts
	Dalaki (Nigeria)	Thick porridge	Unknown
	Darassum (Mangolia)	Liquid drink	Unknown
	Doro (Zimbabwe)	Thick alcoholic drink	Bacteria, Yeast
	Jaanr (India)	Alcoholic paste	Fungi
	Jnard (India, Nepal)	Alcoholic beverage (opaque beer)	Fungi, LAB, Yeasts
	Kwunu-Zaki (Nigeria)	Paste used for breakfast	LAB, Yeasts
	Mangisi (Zimbabwe)	Sweet and sour non-alcoholic beverage	Unknown
	Sura (India)	fermented drink	Unknown
	Tumba (India)	Liquid drink	<i>Endomycopsis fibuligera</i>
Millet ( <i>Pennisetum americanum</i> & <i>Eleusine coracana</i> )

Grains group and names	Fermented foods (regions)	Nature of uses	Functional microorganisms in the fermentation
Rice ( <i>Oryza sativa</i> )	Anarshe (India)	Sweetened snack foods	LAB
	Ang-kak (China)	Colorant of dry red powder	Moulds
	Aska (India)	Fermented flour	Unknown
	Bhattejnaar (India)	Sweet-sour alcoholic paste	Yeast, Moulds
	Brem (Indonesia)	Cake	Moulds
	Brembali (Indonesia)	Dark brown alcoholic beer	Yeast, Moulds
	Chongju (Korea)	Clear alcoholic wine	Yeast
	Khanomjeen (Thailand)	Noodle	LAB
	Khaomak (Thailand)	Semisolid, sweet alcoholic beverage	Yeasts, Moulds
	Kichudok (Korea)	Steamed cake	Yeasts
	Lao-Chao (China)	Soft, juicy paste	Yeasts, Moulds
	Me (Vietnam)	Acidic sour condiment	LAB
	Mifen (China)	Fermented noodles for breakfast	LAB
	Mirin (Japan)	Clear liquid seasoning	Moulds
	Puto (Philippines)	Steamed cake	LAB, Yeasts
	Sake (Japan)	Clear alcoholic wine	Yeast
	Shaosinghjiu (China)	Clear alcoholic wine	Yeast
	Sierra rice (Ecuador)	Brown yellow dry rice	Yeasts, Moulds, and Bacilli
	Takju (Korea)	Turbid alcoholic beer	LAB, Yeast
	Tapai pulut (Malaysia)	Semisolid, sweet alcoholic beverage	Moulds, Yeasts
	Tape ketan (Indonesia)	Sweet-sour alcoholic paste	Moulds, Yeasts
	Tapuy (Philippines)	Sour-sweet paste and liquid	LAB, Moulds, Yeasts
	Torani (India)	Seasoning liquid	Yeasts
Barley ( <i>Hordeum vulgare</i> )	Beer (Worldwide)	Alcoholic drink	Bacteria, Yeasts, Fungi
	Chhang/Lugri (India)	Beverage	Unknown
	Pinni/Bagpinni (India)	Solid uncooked dough	Unknown
	Rabadi (India)	Fermented barley dough	LAB, Moulds, <i>Bacillus</i> spp.
	Sourdough (Worldwide)	Leavened dough for bread making	Yeast, LAB
	Thuktal (India)	Steamed food	Unknown
Oat ( <i>Avena sativa</i> )	Beer (Germany)	A berry flavored beer	Yeasts, LAB
	Baijiu (China)	Alcoholic drink	Yeasts, LAB
	Functional beverage (Bulgaria)	Probiotic drink	LAB
	Yosa	Snack	LAB and Bifidobacteria
Rye ( <i>Secale cereale</i> )	Bread (Denmark)	Sandwich bread	LAB
	Kvass (Lithuania)	Non-alcoholic or mild alcoholic beverage	Yeasts, LAB
	Perkarnaya (Russia)	Acidic and aerated bread	Yeasts, LAB
	Pumpernickel (Switzerland and Germany)	Acidic and aerated bread	Yeasts, LAB
	San Francisco bread (USA)	Mildly acidic leavened bread	Yeasts, LAB
	Sourdough (America, Europe, Australia)	Mildly acidic leavened bread	Yeasts, LAB

Teff ( <i>Eragrostis tef</i> )	Bread (Africa) Injera (Ethiopia) katikalla (Ethiopia) Sourdough (Europe) Tela (Ethiopia)	Sourdough and non-sourdough bread Acidic sour, leavened pancake-like flat bread Alcoholic beverages Dough for making bread Alcoholic beverages	Yeasts, LAB LAB, Yeast Unknown LAB, Yeasts Unknown
Buckwheat ( <i>Fagopyrum esculentum</i> )	Aktori (India) Beer (Slovenia) Bread and sourdough (Europe) Mangjangkori (India)	A cake or pancake –like fermented food Gluten free fermented beverage Leavened bread from fermented dough Thick, brown color pancake-like food	Unknown Yeasts LAB, Yeasts Unknown
Amaranth ( <i>Amaranthus caudatus</i> )	Chicha (Peru) Ogi (Africa) Sourdough and bread (Germany)	Traditional beer Porridge Gluten free sourdough bread	LAB, Yeast, Moulds LAB, Yeast, Moulds LAB and Yeasts
Quinoa ( <i>Chenopodium quinoa</i> )	Beer (Europe) Chichi (Latin America) Sourdough and bread (Europe, Latin America)	Gluten free sourdough bread Traditional drink of the Andes Gluten free sourdough bread	Yeast Unknown Yeasts, LAB
<b>Legumes and oil seeds</b>			
Soybean ( <i>Glycine max</i> )	Aakhone (India) Bekang (India) Chee-fan (China) Chiang (China) Chinese yeast Chungkukjang (Korea) Dauchi (China, Taiwan) Doenjang (Korea) Furu or Sufu (China) Hawaijar (India) Ketjap (Indonesia) Kinema (India, Nepal) Meitauza (china) Meju (Korea) Natto (Japan) Pepok (Myanmar) Perayaan (India) Sieng (Cambodia, Laos) Shoyu (Japan) Tempe (Indonesia) Tofu si (China, Japan) Tua nao (Thailand) Tungrymbai (India)	Alkaline and sticky paste used as side dish Alkaline and sticky paste used as side dish Cheese-like food Alkaline paste used as soup Solid and eaten as fresh Alkaline and sticky used as condiment and soup Alkaline paste used as condiment and soup Alkaline paste used as soup Mildly acidic and used as savory Alkaline and sticky paste used as side dish Seasoning syrup Sticky alkaline curry soup Liquid drink Sticky and alkaline paste used as seasoning agent Alkaline and sticky, ammonia odor, side dish Alkaline and sticky, side dish Alkaline and sticky used as side dish Alkaline and sticky used as side dish Alkaline, liquid used as seasoning Alkaline and fried cake Alkaline, liquid used as seasoning Alkaline and dry paste used for soup and curry Alkaline and sticky paste used for soup Cooked fermented beans with ghee and yogurt Flat, glossy, and brown colour product Salty paste Sourdough	<i>Bacillus</i> spp. <i>Bacillus</i> spp. Moulds Moulds Moulds, Yeasts <i>Bacillus</i> spp. <i>Bacillus</i> spp., Moulds Moulds Moulds <i>Bacillus</i> spp. Moulds LAB, <i>Bacillus</i> spp. Mould Mould <i>Bacillus natto</i> <i>Bacillus</i> spp. <i>Bacillus</i> spp. <i>Bacillus</i> spp. Moulds Moulds <i>Bacillus</i> spp. <i>Bacillus</i> spp. <i>Bacillus</i> spp. Unknown Bacilli, LAB Unknown LAB, Yeast Moulds Mould

**Table 1** Cereal, legumes, and cereal-legumes based fermented foods and beverages (Adebo et al., 2017; Blandino et al., 2003; Coda et al., 2017; Kohajdová, 2015; Nagai and Tamang, 2010; Nout, 2009; Nout et al., 2007; Tamang, 2010; Taylor, 2016; Vogelmann et al., 2009)—cont'd

Grains group and names	Fermented foods (regions)	Nature of uses	Functional microorganisms in the fermentation
Cotton seeds ( <i>Gossypium hirsutum</i> )	Beverage (Brazil)	Non-alcoholic beverage	LAB, Bacilli
Black gram ( <i>Vigna mungo</i> )	Owoh (Nigeria), Amriti (India)	Condiments, soup	Bacilli, LAB
		Snacks	Unknown
	Bedvin roti (India)	Snacks used for breakfast	Unknown
	Bhallae (India)	Fried patties snack	LAB, Bacilli, Yeast
	Borhe (India)	Fried disc having hole in the centre	Unknown
	Dosa (India)	Snacks used for breakfast	LAB, Bacilli, Yeast
	Maseura (India)	Brittle and friable ball or cone-shaped mixture	Bacilli, LAB
	Mashbari (India)	Staple food	LAB, Bacilli, Yeast
	Masyaura (India)	Side dish	LAB, Moulds, Yeast
	Papadam (India)	Breakfast or snack food	Yeast
	Sepubari (India)	Marriage festival special dish	LAB, Bacilli, Yeast
	Teliye mah (India)	Semi-solid foods	Unknown
	Vadai (India)	Paste used as side dish	LAB
	Wadi (India)	Condiment	LAB
	Wari (India)	Dried, hollow, brittle, spicy, and friable balls, snack, side dish	LAB, Bacilli, Yeast
Locust bean ( <i>Ceratonia siliqua</i> )	Dawadawa (Africa)	Alkaline, sticky Condiment, soup	Bacilli
	Iru (Nigeria)	Alkaline, sticky Condiment, soup	Bacilli
	Kinda (Sierra Leone)	Alkaline, sticky Condiment, soup	Bacilli
	Soumbala (Borkina Faso)	Alkaline, sticky Condiment, soup	Bacilli
	Uri (West Africa)	Alkaline, sticky Condiment, soup	Bacilli
Chickpea/Bengal gram ( <i>Cicer arietinum</i> )	Dhokla (India)	Steamed, soft cake, snack	LAB, Bacilli, Yeast
	Gergoush (Sudan)	Snack used with morning tea	Unknown
	Khaman (India)	Snack	LAB, Bacilli
	Papad (India)	Thin, usually circular, wafer-like product	Yeast
African yam beans ( <i>Sphenostylis stenocarpa</i> )	Oturu	Greyish brown, a strong ammonia-like odour product	LAB, Bacilli, Yeast
Cereals-legumes based	Hamanatto (Japan)	Soft flavoring agent	Moulds
	Idli (India),	Steamed, soft cake, snack	LAB, Yeast
	Kecap (Indonesia)	Liquid flavoring agent	LAB, Moulds, Yeast
	Koji (Japan)	Used to make soya sauce	Mould
	Miso (Japan)	Alkaline paste used as soup	Moulds
	Soybean sauce (Worldwide)	Alkaline, liquid used as seasoning	Moulds
	Tauco (Indonesia)	Alkaline paste used as soup	Moulds

been produced and consumed worldwide. Given the enormous diversity, it is hard to discuss all fermented foods and beverages made from cereals and pseudocereals within this report. However, the general groups and popular fermented product are discussed.

### **Alcoholic and Non-alcoholic Beverages**

Preparation of alcoholic beverages from cereals and pseudocereals has been practised for thousands of years. Historical evidences suggested wine was produced in Caucasus and Mesopotamia as early as 6000 BC (Tamang, 2010). Depending on the raw material, production methods, type and composition of fermenting microorganisms culture, and fermentation techniques and conditions; a vast diversity of traditional and commercial alcoholic drinks are now produced and consumed all over the world (Blandino et al., 2003; Tamang, 2010). These drinks are used for various purposes such as relieving thirst, refreshment, entertainment, social and religious celebrations and ceremonies, and to improve health and wellbeing (Tamang, 2010). The production of alcoholic and non-alcoholic drinks differ from region to another based on tradition, scale (artisanal or industrial), and the level of technology employed in the process. Beer, by far, is the most produced alcoholic beverage, which was initially prepared from barley, but nowadays all types of cereals and pseudocereals are used as raw materials for its production using both modern and traditional technologies (Blandino et al., 2003; Tamang, 2010). Other alcoholic drinks prepared from one or more of cereals or pseudocereals are traditionally produced and consumed in many countries. Among those, Bhaati jaanr, Brem, Chhang, Huangjiu, Judima, Krachae, Lao-chao, Poko, Sake, Satoh, Takju, Tapé, Tapai pulut, Tapuy, and Yakju, which are rice-based alcoholic drinks prepared mainly in Asian countries (Emerald et al., 2016; Tamang, 2010). Ajon, Amgba, Bouza, Burukutu, Darassun, Dolo, Jiu (Chinese Liquor), Inard, Katata, Kweete, Malwa, Merissa, Omuramba, Pito, and Tchoukoutou are alcoholic drinks prepared from sorghum, millet, and maize or mixtures thereof in African and Asian countries (Emerald et al., 2016; Nout, 2009; Tamang, 2010). Several non-alcoholic drinks are also produced from cereals and pseudocereals in some parts of the world. For example, Abreh, Hulu-mur and Nasha, are traditional Sudanese drinks prepared from sorghum and sorghum malt that are consumed to relieve thirst during the month of Ramadan and they believed to enhance the health and promote milk production in lactating women. Agua-agria, Aliha, Kunun-zaki, Mahewu, Mageu, Masvusvu, Mawe, Motoho oa mabela, Munkoyo, Oshikundu, Togwa or Tobwa, and Uji are some of the non-fermented alcoholic beverages prepared from sorghum, maize, and millet (Blandino et al., 2003; Nout, 2009; Tamang, 2010; Taylor, 2016). Boza is also non-alcoholic refreshing drinks that prepared from wheat, barley, millet, oat, and rye (Blandino et al., 2003; Taylor, 2016) and Kvass is non-alcoholic or very mild alcohol drink beverage traditionally produced from rye and barley malt in eastern European countries (Kohajdová, 2015). Both spontaneous and starter culture fermentation processes occur during fermentation of cereals and pseudocereal-based fermented drinks. During traditional fermentation, starch is initially hydrolyzed by amylolytic yeasts and moulds, followed by alcoholic forming yeast, and finally by the flavour-enhancing lactic acid bacteria (LAB) (Tamang, 2010). Generally, wide arrays of microorganisms are involved in the fermentation of cereals and pseudocereals for production of alcoholic and non-alcoholic beverages. Yeasts, moulds, and LAB represent the main genera of microorganisms responsible for the production of these beverages. The major yeast genera involved in this fermentation are; *Saccharomyces*, *Saccharomycopsis*, *Schizosaccharomyces*, *Endomycopsis*, *Pichia*, *Hansenula*, *Candida*, *Kluyveromyces*, *Debaryomyces*, *Torulopsis*, and *Zygosaccharomyces*. Whereas, the major genera of the LAB are *Pediococcus*, *Lactobacillus*, *Enterococcus*, *Weissella*, and *Leuconostoc* and that of moulds are *Actinomucor*, *Amylomyces*, *Mucor*, and *Rhizopus* (Blandino et al., 2003; Nout, 2009; Tamang, 2010).

### **Sourdough and Bread**

As one of the oldest fermentation processes, sourdough fermentation was developed early in human history relaying on spontaneous fermentation of cereal flours by naturally occurring lactic acid bacteria (LAB) and yeast (Poutanen et al., 2009). During the fermentation of sourdough, yeast and LAB work in harmony to develop specific characteristics of leavening (releasing CO<sub>2</sub> by yeasts) and acidification (production of acids by the LAB) in the dough. Maintaining of the combined activities of yeast and lactic acid bacteria in sourdough are obtained and optimized through the use of fresh microorganisms or backslipping (use of small fermented material as a starter). This refreshment approach leads to the development of sourdough with a constant and reproducible acidification and leavening properties (Corsetti, 2013). Based on the processing technologies and microorganisms applied, sourdoughs are grouped as type I, type II, and type III sourdoughs (Corsetti, 2013; Emerald et al., 2016). Type I sourdough contain cultures of metabolically active microorganism(s) that enriched through three stages of fresh culture capable of producing large quantities of lactic and acetic acids, fermentation and leavening without the addition of commercial yeasts (Corsetti, 2013; Emerald et al., 2016). Type II sourdough is normally prepared by a single fermentation step at 30 °C for 15–20 h and is produced at industrial level using bioreactors and the adapted strains are used to start new fermentations. Type III sourdough is made at an industrial level as a dried form of type II sourdough, and it has constant quality (Corsetti, 2013; Emerald et al., 2016). The chemical composition of the materials used, the applied fermentation conditions, and composition and their interactions with the fermenting microbiota have significant effect on the yield and the quality of sourdough and bakery products (Emerald et al., 2016). Sourdough and breads have apparently been made from almost all cereals, pseudocereals, and mixtures thereof. Wheat and rye flour are the most used grains in the preparation of sourdoughs and leavened breads (such as wheat leavened bread, altamura bread, levain tout point, San Francisco bread, white pan bread, Naan, rye sourdough bread, straight rye bread, crispy flat rye bread) (Corsetti, 2013). Also, sourdough leavened bread have been prepared from amaranth, barley, buckwheat, teff, maize, millet, oat, quinoa, and rice (Vogelmann et al., 2009). Microorganisms involved in sourdough fermentation constitute a diverse species of LAB and yeast. The most dominant LAB isolated from cereal and pseudocereal sourdough includes: *Lactobacillus fermentum*, *L. fructivorans*, *L. pontis*, *L. plantarum*, *L. delbrueckii*, *L. sanfranciscensis*, *L. helveticus*, *L. paralimentarius*, *L. spicheri*, and others

(Corsetti, 2013; Emerald et al., 2016; Vogelmann et al., 2009). The dominant yeasts strains responsible for fermentation of sourdough are *Candida milleri*, *C. holmii*, *Saccharomyces cerevisiae* and *S. exiguus*, *Issatchenkia orientalis*, *Pichia anomala*, *P. saitoi*, *P. membranifaciens*, *Torulaspora delbrueckii*, *Debaryomyces hansenii* and others (Emerald et al., 2016; Vogelmann et al., 2009).

### **Gruel, Porridge, Cake, Dumpling, and Pancake**

Cereals and pseudocereals have been also used for the preparation of various types of fermented gruel, porridge, dumpling, cake, and pancake in many countries in the world (Nout, 2009; Taylor, 2016). Numerous types of staple cereal- and pseudocereal-based fermented foods are available worldwide that vary based on the raw materials and processing traditions and techniques used. Kisra is a fermented flatbread prepared from sorghum and is considered a staple food in Sudan (Blandino et al., 2003). Injera, a leavened pancake that considered as staple Ethiopian food, is prepared from fermented flours of teff, sorghum, millet and wheat (Nout, 2009; Taylor, 2016). Puto is a leavened steamed rice cake and Idli is also a spongy cake produced from a fermented mixed batter of parboiled rice (80%) and black gram (20%) (Blandino et al., 2003; Taylor, 2016). Maize-based fermented products, such as uncooked dough (Mawe) and cooked gruel or dumpling (Kenkey), fermented gruel (Ogi), cooked dough (Pozol), are considered a staple food in Benin, Ghana, Nigeria, and Mexico, respectively (Nout, 2009; Taylor, 2016). Aceeda and Ting are fermented porridges made from sorghum and millet and considered as commonly consumed foods in Sudan and South Africa, respectively (Taylor, 2016). Yosa is an oat bran-based fermented snack produced and consumed in Scandinavian countries (Blandino et al., 2003). Several potentially functional fermented foods and drinks have been produced from cereals and pseudocereals (Kohajdová, 2015). Due to the variation in the composition of raw materials and processing conditions of fermented gruel, porridge, dumpling, cake, and pancake, the diversity of fermenting microorganisms is very high. However, the most frequently isolated microorganisms from these products include, but not limited to, LAB such as *L. fermentum*, *Leuconostoc mesenteroides*, *L. brevis*, *L. plantarum*, *L. delbrueckii*, *L. lactis*, *L. confusus*, *L. reuteri*, *L. harbinensis*, *L. parabuchneri*, *Lactobacillus casei*, *L. coryniformis*, *Pediococcus cerevisiae*, *Pediococcus pentosaceus*, *Enterococcus faecalis* and several species of yeast of the genera *Saccharomyces*, *Geotrichum*, and *Torulopsis* and some *Bifidobacteria* (Blandino et al., 2003; Taylor, 2016).

### **Fermentation of Legumes Grains**

Grain legumes are considered as the main sources of protein in human diets in countries where animal proteins are unaffordable and religiously-prohibited. However, these grains contain several antinutritional factors and allergens that could negatively affect the health and reduce the overall benefits of legume-based foods. Fermentation of legumes is a vital approach to reduce the antinutritional factors and allergens and could thus enhance the nutritional, sensorial, functional, and health properties of these products. Although the fermentation of grain legumes is a traditional practice in Asia and Africa, currently fermented legumes products receive high global interest due to their great health-promoting and disease-preventing potentials (Adebo et al., 2017). Due to the high protein content of legumes and microorganism used, the type of fermentation of legumes mostly belong to alkaline fermentation, in which ammonia is released from proteins by the action of microbial or indigenous proteases at elevated pH. In Asian and African countries, legumes-based fermented products represent the major source of daily intake of good quality proteins, vitamins, minerals and bioactive compounds with great potential health promoting properties. Fermented legumes products are highly appreciated in these regions and are very diverse due to differences in the raw substrates, fermentation conditions, and consumer preferences. The major types of legumes-based fermented foods are discussed in the following paragraphs.

#### **Soybean-Based Fermented Foods**

The production and consumption of soybean-fermented foods is the highest among all legumes, especially in Asia. Natto is a traditional fermented soybean product produced exclusively in Japan, with other similarly processed products such as Chungkukjang (soup) in Korea and Thao noa (paste) in Thailand (O'Toole, 2016). Traditionally, the soybeans is soaked in water overnight, boiled, drained, the beans slightly dried, covered with rice straw, and stored at warm temperature (up 36 °C) for 1–2 days to permit the growth of the fermenting bacteria namely *Bacillus subtilis* (natto) and to form a product with viscous sticky slime, with high umami and slightly bitter and sweet tastes, and ammonia odour notes (Nout et al., 2007; O'Toole, 2016). In other types of Natto (e.g. Yukiwari natto and Hama natto), the soybeans are fermented using koji starter culture (*Aspergillus oryzae*) that is prepared by growing the moulds on steamed polished rice (Nout et al., 2007; O'Toole, 2016). Kinema is another soybean-based fermented food traditional produced in India, Nepal, and Bhutan. It is largely resembles Natto with exception that, in Kinema the soybeans are crushed to split the cotyledons. It is a naturally fermented product with the main fermenting microorganism is *Bacillus subtilis* in addition to enterococci, and yeasts (Nagai and Tamang, 2010; Nout et al., 2007). Others Bacilli fermented, sticky, and non-salty soybean products are produced and consumed by ethnic groups in many Asian countries such as Aakhone, Bekang, Hawaijar, Peruya, and Tungrymbai in India, Pepok in Myanmar, and Sieng in Cambodia and Laos (Nagai and Tamang, 2010). Tempeh or Tempe is a mould-fermented soybean product originated in Indonesia and due to its high nutrition, it is considered as a meat substitute. In traditional processing, soybeans are soaked in water or acidified water at room temperature to allow the indigenous LAB bacteria (*L. casei*, *Streptococcus faecium*, *Staphylococcus epidermidis*, and *Klebsiella pneumoniae*) to grow and ferment the beans, the beans are then dehulled, properly cooked, drained, covered with wheat flour, and inoculated with *usar* or *ragi* (Tempe starters) that composed of many *Rhizopus* species and mainly *R. oligosporus* (Nagai and Tamang, 2010; Nout et al., 2007; O'Toole, 2016). Douchi is a salt-fermented soybean product traditionally produced in China, and based on the type of microorganisms used in the fermentation four types of douche are available; *Mucor*-fermented, *Aspergillus*-fermented, *Rhizopus*-fermented, and

*Bacillus*-fermented are produced (Nagai and Tamang, 2010; Nout et al., 2007). Several products similar to *Aspergillus*-fermented douchi can be found in other countries, e.g. Hammanatto in Japan, Tao-si in the Philippines, and Tao-tio in India (O'Toole, 2016). Tofu (Japan) and Sufu or Furu (China) are fermented cheese-like products prepared from soymilk by coagulation and fermentation with moulds of the genera *Actinomucor*, *Mucor*, and *Rhizopus* or bacteria of genus *Micrococcus* and *Bacillus* (Nagai and Tamang, 2010). In addition, there are many other fermented soybean-based products prepared from soybeans and cereals such as Doenjang (Korea), Meitauza (China), Miso and Shoyu (Japan), Soy sauce (worldwide), and Tauco (Indonesia) among others, and the fermentation of these products was attained by various types of moulds, yeasts, and LAB (Nagai and Tamang, 2010; O'Toole, 2016).

### Non Soybean-Based Fermented Legumes

Although the majority of the legume-based fermented products are prepared from soybeans, many other fermented foods are traditionally prepared from various types of legumes by many ethnic groups in Central Asia and West Africa. For example, Maseura (hollow, brittle and friable ball or cone-shaped mixture), Wari (a dried, hollow, brittle, spicy, and friable ball), and Papad (a thin, usually circular, wafer-like product) are fermented products prepared from black gram alone or mixed with Bengal gram, lentil, red gram, or green gram in Central Asia (India, Nepal and Pakistan). Wide range of microorganisms is involved in the fermentation of these products including; bacteria (*L. fermentum*, *L. salivarius*, *Pediococcus pentosaceus*, *P. acidilactici*, *E. durans*, *B. subtilis*, *Bacillus mycoides*, *Bacillus pumilus*, and *Bacillus laterosporus*), yeasts (*Saccharomyces cerevisiae*, *Pichia burtonii*, *Candida castellii*, and *C. versatilis*), and moulds (*Cladosporium*, *Penicillium*, and *Aspergillus niger*) (Nagai and Tamang, 2010; Nout et al., 2007). Dawadawa in an ethnic fermented food condiment prepared from African locust bean (*Parkia biglobosa*) and widely consumed as protein-rich source in West Africa. The fermented product is known under different names such as Iru in Nigeria, Dawada in Ghana, Kinda in Sierra Leone, and Soumbala in Burkina Faso (Nagai and Tamang, 2010). The main microorganisms involved in the fermentation of these products are *Bacillus subtilis*, *Bacillus licheniformis*, *Bacillus amyloliquefaciens*, *B. pumilus*, *Bacillus megaterium*, *Staphylococcus xylosum*, *S. saprophyticus*, *S. hominis*, and *Micrococcus* spp (Nagai and Tamang, 2010; Nout et al., 2007). Ugba is a Nigerian flat, glossy, and brown colour fermented legume product prepared from African oil beans, in which the fermentation is carried out by strains belonging to the genera *Bacillus*, *Staphylococcus*, *Micrococcus*, *Corynebacterium*, *Alcaligenes*, and *Citrobacter* (Obeta, 1983). Otiru is a fermented food with greyish brown colour, and a strong ammonia-like odour and is prepared from the seeds of African yam beans in West Africa. A diverse range of bacteria and yeasts were involved in the fermentation of Otiru such as *Lactobacillus jensenii*, *Bacillus coagulans*, *Aerococcus viridans*, *P. pentosaceus*, *Saccharomyces cerevisiae*, and *Candida vini* (Jeff-Agboola, 2015). Oncom is a traditional Indonesian fermented food produced from peanut and peanut cake, in which the fermentation was mainly carried out by different moulds belonging to the genus *Neurospora* (merah or red oncom) and *Rhizopus* (hitam or black oncom) (Nout et al., 2007). Dhokla and Khaman are fermented spongy-textured products made from Bengal gram alone or mixed with rice and the main LAB strains were *L. mesenteroides* and *E. faecalis* (Nagai and Tamang, 2010).

### Impact of Fermentation on the Overall Quality of Grains-Based Products

Fermentation is an incredible process that significantly improves the diversity, storability, nutritional, sensorial, technological, safety, and health potentials of food grains and grain-based products. As the fermentation of grains is mostly done by ethnic groups in developing countries, it is considered as the source of income and employs many peoples in these countries. In addition, fermentation of grain is the easiest and cheapest methods for preservation of grain-based foods from spoilage microorganisms as fermenting microorganisms such as LAB are believed to produce metabolites such as acids, ethanol, hydrogen peroxide, carbon dioxide, and bacteriocins that inhibited the growth of pathogenic and spoilage microorganisms in foods. Fermentation could degrade and remove the toxic and allergic compounds from grains and thus improve the safety of these products. Fermentation also enhances the protein and starch functional properties of food grains and increases the gas, water and oil retention capacities of fermented foods and thus improves the sensory properties and overall acceptability of final products. For example, fermentation reduces the viscosity of porridges by the action of microbial amylases and consequently improves its palatability without effects on the amounts of nutrients and energy (Taylor, 2016). Nutritionally, fermentation of grains are believed to reduce antinutritional factors (tannin, phytate, and protease inhibitors) and complex carbohydrates, increase essential minerals, amino acids, fatty acids, and vitamin content and their bioavailability as a result of improving the protein and starch digestibility. In addition, fermentation improves the yield and profile of polyphenolic of fermented grains products by the action of microbial metabolic activities through phosphorylation, glycosylation, deglycosylation, methylation and glucuronidation and consequently leads to the formation of new metabolites with specific functional and pharmaceutical properties (Emerald et al., 2016). Therapeutic and health promotion potential of fermented grains are diverse and include, but not limited to, antioxidant, anticancer, antihypertension, anti-inflammation, anticholesterol, antidiabetics, and prevention of cardiovascular diseases, gastrointestinal disorders, hepatic disease, obesity, and allergic reactions (Emerald et al., 2016).

## Conclusions

Fermentation of grains was discovered earlier in the history and grain-based fermented foods and beverages became a major part in the diet of all nations and civilizations. Fermented grains indeed will have a great role to play as functional foods in the future. Large number of different grain-based fermented foods and beverages that ranging from indigenous to commercially produced products are prepared and consumed worldwide due to their beneficial roles in nutrition and health. Fermentation of grains provide many desirable outcome, such as reducing the antinutritional factors, removing toxic and allergic materials, improving the safety, shelf-life, digestibility, texture, taste, flavour, micronutrients, and phenolic profile, and add probiotic microorganisms to the products, and thus it contribute to food security. Despite of the great potential of grain-based fermented foods, the processing methods of most of these foods still largely dependent on the traditional acknowledge at home-level or small factories scales that might results in products with changeable quality, safety and low marketability. Thus, application of modern fermentation technologies, using microorganisms with known metabolic pathways, is needed to get the maximum benefits of grain-based fermented foods. In addition, omics approaches (genomics, transcriptomics, proteomics, and metabolomics) could offer opportunities for developing new grain-based fermented products, diversifying the processes, assuring the quality and safety of the products, and validating the health potentials of fermented foods.

## Glossary

Ethylene

Natural plant hormone

Functional food

Food that potentially offers health benefits beyond basic nutrition

Pigment

Plant compounds that are perceived by humans to have color

## Pigments in Climacteric and Non-climacteric Fruits

Plant pigments are important in controlling photosynthesis, growth and development of plants (Sudhakar et al., 2016). Pigments act as visible signals to attract insects, birds and animals for pollination and seed dispersal. Pigments also protect plants from damage caused by UV and visible light (Tanaka et al., 2008). Many pigment-rich fruits are consumed in the human diet. The pigment content of fruits has been studied for many decades not only because of the aesthetic appeal of ripe fruit colors, but also due to the wide variety of compounds that are present and are responsible for the characteristic green, yellow, orange, red, blue, and purple colors. Chlorophylls are the source of green in all fruits and function as the primary pigment to capture yellow and blue lights for photosynthesis to produce energy for plant development and growth. Unlike chlorophylls, carotenoids and anthocyanins are accessory pigments (generally with the absorbance spectrum complementary to chlorophylls) and also secondary metabolites that possess much more diverse structures and functions in plants and offer more potential nutritional and health benefits in the diet (Chen, 2015).

Ripening refers to the physiological and biochemical changes of a fruit to attain desirable color, flavor, aroma, sweetness, texture, and thus eating quality. The process of ripening usually does not occur until a fruit reaches its full maturity. When a fruit reaches its full maturity, its size and weight reach a maximum and its growth rate decreases. Ripening of a fruit may occur on the plant or after harvest, depending on the species (Li, 2012). Respiration is the fundamental process whereby living organisms carry out the production of energy. Based on respiration, fruits can be grouped as climacteric and non-climacteric (Lelièvre et al., 1997; McMurchie et al., 1972; Pech et al., 2012). Ripening in climacteric fruits manifests itself by a climacteric rise in respiration and autocatalytic ethylene production (Abeles et al., 1992; Biale and Young, 1981). The main specificity of climacteric fruits is their capacity to produce ethylene and ethylene stimulates its own biosynthesis (Burg and Burg, 1965; McMurchie et al., 1972). Fruits typically contain a mixture of pigments, including the green chlorophylls; yellow, orange, and red carotenoids; red, blue, and violet anthocyanins; and/or other pigments. Examples of climacteric fruits and their main pigments and typical colors are listed in Table 1.

In non-climacteric fruits respiration shows no change and ethylene production remains at a very low level during ripening (Burg and Burg, 1965; Giovannoni, 2001). Hence, the concept of two systems of ethylene production has emerged (Pech et al., 2012). One is characterized by low levels of ethylene production and is present throughout the ripening of non-climacteric fruit. These low levels of ethylene production occur in climacteric fruit during the period preceding the climacteric rise in respiration. Another system operates at the onset of climacteric rise in respiration and is responsible for auto-catalytic ethylene production (Pech

**Table 1** Climacteric and non-climacteric fruits and their main pigments and typical colors

Fruits	Pigment class	Examples	Typical colors
Climacteric	Chlorophyll	Avocado, guava, kiwifruit, apple	Green
	Carotenoid	Tomato, apricot, banana, breadfruit, mango, papaya, peach, passion fruit, durian, jackfruit	Orange, yellow, pink, red
Non-climacteric	Anthocyanin	Fig, plum	Purple, red
	Chlorophyll	Olive, honeydew	Green
	Carotenoid	Orange, grapefruit, lemon, pineapple, lime, carambola (star fruit)	Orange, yellow, pink, red
	Anthocyanin	Blueberry, grape, strawberry, cherry, cranberry, raspberry, pomegranate	Purple, blue, red

et al., 2012). The respiration rate of non-climacteric fruits responds primarily to temperature (Biale, 1960). Examples of non-climacteric fruits and their main pigments and typical colors are listed in Table 1.

### Chlorophyll Changes During Fruit Ripening

Chlorophylls are the most abundant pigments among biologically produced pigments (Lee and Schwartz, 2005). The green color in all higher plants including fruits is due to chlorophylls. Chlorophylls participate in photosynthesis which is one of the most important life processes by converting energy from light into chemical energy (Chen et al., 2010; Sudhakar et al., 2016). Chlorophylls can absorb visible light in the red region between 600 and 700 nm and the blue region between 400 and 500 nm (Lee and Schwartz, 2005). Chlorophylls are chemically classified within the porphyrin group with a tetrapyrrole macrocycle, linked by methylene bridges and coordinated with a  $Mg^{2+}$  ion. Chlorophyll also contains a modified propionic acid chain in the form of cyclic-ketoester (isocyclic ring) and, on C-17, a chain of propionic acid esterified with the diterpene alcohol phytol. In higher plants there are two types of chlorophyll, a and b. The difference between them is that chlorophyll a has a methyl group on carbon C-7, whereas chlorophyll b has an aldehyde group (Fig. 1) (Artes et al., 2002). Chlorophyll a (blue-green) and b (yellow-green) are present in green plants in the ratio of 3:1 (Lee and Schwartz, 2005).

Chlorophylls of higher plants are located in specialized plastids named chloroplasts. The biosynthesis of chlorophyll occurs in the chloroplast, and all the enzymes involved have already been identified (Beale, 2005; Brzezowski et al., 2015; Tanaka and Tanaka, 2007). In contrast to the biosynthetic pathway, the degradation pathway of chlorophylls is not completely deciphered (Roca et al., 2016). Chlorophyll a is degraded to pheophorbide a, losing the phytol chain and the central magnesium atom (Eskin and Hoehn, 2013; Hörtensteiner and Kräutler, 2011; Kräutler and Hörtensteiner, 2012). The order in which both reactions take place and the enzymes implied in that process are different in senescent leaves than in fruits, and new hydrolases are still to be identified (Kräutler and Hörtensteiner, 2012). An example of enzyme is chlorophyllase which removes the lipophilic phytol anchor of the chlorophyll molecules, which is crucial for binding of the green pigment to the chlorophyll binding proteins and for insertion of the chlorophyll-protein complexes into the thylakoid membranes of chloroplasts (Harpaz-Saad et al., 2007; Kräutler, 2003).

Chlorophyll degradation is central to the degreening process occurring during ripening of most fruits (Hörtensteiner, 2006; Hörtensteiner and Kräutler, 2011). Degradation of chlorophyll causes color change in fruits which in turn unmasks previously synthesized pigments. An example of this process occurs in the degreening of lemons. Degreening process is usually followed by the biosynthesis of other pigments such as carotenoids or anthocyanins (Tucker, 1993). Ethylene has been reported to promote the degradation of chlorophyll during fruit ripening (Burg and Burg, 1965; Hiwasa-Tanase and Ezura, 2014). In most fruits, chlorophyll content increases during green stages and diminishes through maturation, paralleling chloroplast disintegration. There

**Fig. 1** Chemical structures of chlorophyll a and b

are some exceptions of fruits retaining chlorophylls at the ripe stage. For examples, certain apple, pear, fig, plum, limes, avocado, melon, kiwi, and grape cultivars. These fruits are characterized by a low accumulation of pigments other than chlorophylls at the ripe stage (Rodrigo et al., 2012).

### Carotenoids Changes During Fruit Ripening

Carotenoids are lipid-soluble pigments widely found in nature. Carotenoids play an important role in the photosynthetic apparatus (Schieber and Weber, 2016) as they are essential components of the photosynthetic membranes in all photosynthetic organisms (Goodwin, 1986). Carotenoids are much more widespread and not confined to photosynthetic organisms, and structurally and functionally more diverse than chlorophylls (Scheer, 2013). Carotenoids are well known for their diverse yellow, orange, and red colors of most fruits, flowers, and vegetables, and for the characteristic colors of many birds, insects, fish, and crustaceans by intaking carotenoids through the diet (Britton, 1995).

Carotenoids are a large class of pigments of which more than 750 different chemical structures have been reported (Britton et al., 2004; Scheer, 2013). Carotenoids are produced via the general isoprenoid biosynthetic pathway (Da Silva Mendes et al., 2015; Delgado-Vargas et al., 2000; Rosas-Saavedra and Stange, 2016; Tanaka et al., 2008) and normally contain a hydrocarbon backbone of 40 carbon atoms, consisting of 8 isoprene units. The great diversity of carotenoids generally derives from an acyclic  $C_{40}H_{56}$  structure that has a long central light-absorbing conjugated polyene compound constituting the chromophoric system, which absorbs light at 400–500 nm (Alcaíno et al., 2016). Carotenoids are classified into two groups, carotenes and xanthophylls. The carotenes are structurally related to hydrocarbons while the xanthophylls include the corresponding oxidized derivatives (hydroxy, epoxy, and oxy compounds) and are frequently esterified (Eskin and Hoehn, 2013).

Carotenoids are located in the chloroplasts of plants and often masked by more dominant chlorophyll pigments. Thus, carotenoids are distributed in a wide range of fruits containing chlorophyll pigments with  $\beta$ -carotene being the most common carotenoid, which exhibits a yellow color. Tomatoes (lycopene), carrots ( $\alpha$ - and  $\beta$ -carotenes), pumpkin ( $\beta$ -carotenes), corn (lutein and zeaxanthin), and sweet potatoes ( $\beta$ -carotenes) are typical examples of plant containing carotenoids (Lee and Schwartz, 2005). Among plant organs, fruits display one of the most heterogeneous carotenoids patterns in terms of diversity and abundance (Lado et al., 2016). As in other plant organs, carotenoid content in fruit is directly influenced by the stage of developmental and their environmental conditions. At the green stage, carotenoid composition is the characteristic of chloroplastic tissues, lutein being the most representative, followed by  $\beta$ -carotene, violaxanthin and neoxanthin (Fig. 2), and other minor carotenoids as zeaxanthin and antheraxanthin (Bramley, 2013). Ethylene has been shown to influence the biosynthesis of carotenoids in plants (Marty et al., 2005).

Pigmentation changes during fruit ripening are accompanied by structural changes in the chloroplasts. The granal-integral network, in particular, becomes disorganized, resulting in the formation of chromoplasts (Eskin and Hoehn, 2013). The chromoplasts no longer contain chlorophyll or photosynthetic pigments but become the major site for carotenoid biosynthesis (Camara and Brangeon, 1981). A typical example is in the green-to-red transition of tomato fruit. Carotenoid formation during tomato fruit ripening has been studied extensively and has become the best model system for other chromoplast-containing tissues (Bramley, 2013). During ripening, the concentration of carotenoids in tomato increased between 10- and 14-fold due mainly to the accumulation of lycopene (Fraser et al., 1994). Ikemefuna and Adamson (1984) monitored changes in the chlorophyll and carotenoid pigments of ripening palm fruit and observed a similar degeneration of chloroplasts and formation of chromoplasts. These changes were accompanied by increase in carotenogenesis with the formation of  $\alpha$ - and  $\beta$ -carotenes as the major pigments in the ripe fruit. On the other hand, in fruits which accumulate pigments other than carotenoids, such as grapes, carotenoid content decreases during ripening. A decrease in carotenoid content was observed during ripening of grapes in which lutein content decreased until 66%, whereas  $\beta$ -carotene slowly decreased, having a constant level until the harvest date (Oliveira et al., 2004).

### Anthocyanins Changes During Fruit Ripening

Anthocyanins are water-soluble pigments belonging to the large group of flavonoids, a subclass of the polyphenol family. Anthocyanins give colors in fruits ranging from pink, red, purple to blue (Sudhakar et al., 2016). More than 700 different anthocyanins have been identified (Wallace and Giusti, 2014). Anthocyanins have structures consisting of two aromatic rings linked by three carbons in an oxygenated heterocycle. The basic chromophore of anthocyanins is the 7-hydroxyflavylium ion. Anthocyanin pigments consist of two or three chemical units: an aglycon base or flavylium ring (anthocyanidin), sugars, and acylating groups (Bueno et al., 2012). There are only six different anthocyanidins found in nature that occur frequently and are of dietary importance: cyanidin, delphinidin, petunidin, peonidin, pelargonidin, and malvidin (Fig. 3) (Bueno et al., 2012; Kammerer, 2016; Shrikhande and Francis, 1976). The distribution of these anthocyanidins in fruits and vegetables is cyanidin (50%), pelargonidin (12%), peonidin (12%), delphinidin (12%), petunidin (7%), and malvidin (7%) (Kong et al., 2003). Each aglycon may be glycosylated or acylated by different sugars and aromatic or aliphatic acids. The sugar moiety is typically attached at the 3-position on the C-ring or the 5-position on the A-ring (Bueno et al., 2012). The absorption maxima of anthocyanins in the visible range is between 465 and 550 nm, but they also absorb in the UV range between 270 and 280 nm (Glover and Martin, 2012).

Anthocyanins are mostly accumulated in outer plant parts such as in the vacuoles of epidermal cell layers. As a result, small-sized fruits characterized by a high surface-to-volume ratio are often particularly rich in anthocyanins. This high pigment concentration usually brings about enhanced pigment stability (Kammerer, 2016). In some species anthocyanins are bound to membrane of the

**Fig. 2** Chemical structures of carotenoids.

main cell-vacuole called anthocyanoplasts (Riaz et al., 2016a). Anthocyanins are derived from phenylalanine (phenylpropanoid metabolic pathway) (Riaz et al., 2016b) and synthesized in the cytosol and localized in vacuoles (Rodrigo et al., 2012). The biosynthetic pathway of anthocyanins has been well characterized (Delgado-Vargas et al., 2000; Grotewold, 2006; Schwinn and Davies, 2004; Tanaka et al., 2008). Regulation of the pathway is species-specific and different genes of encoding relevant enzymes of the biosynthetic pathway have been found to be responsible for color variations in different anthocyanin accumulating fruits (Rodrigo et al., 2012). Ethylene has been shown to influence the biosynthesis of light-induced anthocyanin formation in plants (Craker and Wetherbee, 1973).

Anthocyanins are often markers of ripening as many fruits accumulate anthocyanins only during the ripening phase (Macheix et al., 1990). These pigments are formed as the fruit matures and ripens. Examples are for strawberries (Fuleki, 1969), certain varieties of cranberries (Lees and Francis, 1971; Zapsalis and Francis, 1965), apples (Bishop and Klein, 1975; Proctor and Creasy, 1971), black grapes (Liao and Luh, 1970) and blueberries (Suomalainen and Keränen, 1961). Anthocyanins are synthesized at an increasing rate during maturation reaching a maximum in a fully ripe fruit (Rodrigo et al., 2012).

Anthocyanins do not always follow the general pattern of accumulation towards maturity. For example, fruits of some red pear attain their highest anthocyanin levels while immature and red color gradually fades towards harvest (Steyn et al., 2004). Many apple cultivars including varieties that are typically yellow or green at maturity display a peak in anthocyanin levels shortly after fruit set (Lancaster et al., 2000). Anthocyanin-accumulating fruits often display a range of intermediary colors progressing from green to white or pink, then red or blue and finally purple to black with increasing anthocyanin and decreasing chlorophyll levels (Wheelwright and Janson 1985; Willson and Thompson, 1982). Rapid direct color changes from green to black also occur (Willson and Thompson, 1982). In cherry the anthocyanin profile does not change during fruit development but changes in color is due to increasing anthocyanin concentrations. In blueberry a change in anthocyanin profile during fruit development resulting in change in fruit color from red immature fruits to blue and purple in ripe fruits (Macheix et al., 1990).

**Fig. 3** Chemical structures of anthocyanidins.

## Conclusions

Chlorophylls, carotenoids and anthocyanins are important pigments that are highly abundant in fruits. The changes of these pigments during ripening are important knowledge for the fruit industry. In addition, analyzing pigment composition of ripe fruit and fruit products can be used to determine their genuineness. The great biodiversity of plants has generated a concomitant variety of pigment structures from fruits and many to be discovered. Further analysis of different plant species will allow the discovery of novel structures and possibly new biosynthetic and metabolic pathways. Carotenoids and anthocyanins contribute in various ways to quality characteristics of ripe fruit and fruit products. The multiple health benefits of these pigments are of major interest and interest will continue to grow among researchers in the coming years. Further studies on these pigments will contribute to the improvement of agriculture, food, pharmaceutical, and chemical industries involving these pigments.

## Introduction

Enzymes have long been used in various industrial sectors. The heightened need and interest in recent years to utilize renewable materials for biorefinery have attracted further attention to industrial application of enzymes (Kudakasseril Kurian et al., 2013; Loman and Ju, 2016b, 2017). While cellulose and hemicellulose in biomass are often the focuses for biorefinery development, galacto-oligosaccharides and pectic polysaccharides are also abundant in plants, particularly in legumes and vegetables (Sengupta et al., 2015). When consumed as feed or food components, galacto-oligosaccharides and pectic polysaccharides are associated with indigestibility concerns (Kien, 2008).  $\alpha$ -Galactosidase ( $\alpha$ -D-galactoside galactohydrolase, EC 3.2.1.22) is a group of glycoside hydrolase enzymes that catalyze hydrolysis of the terminal  $\alpha$ -galactosyl moieties of both simple and complex oligosaccharides and polysaccharides.

## Classification

Classification of  $\alpha$ -galactosidase has been based on either substrate specificity or amino acid sequence similarity. By substrate specificity,  $\alpha$ -galactosidases can be divided into two groups (Garman, 2007): Group I act on oligosaccharides such as the raffinose family oligosaccharides (RFOs), and Group II act on polysaccharides such as galacto(gluco)mannans. According to the amino acid sequence similarity,  $\alpha$ -galactosidases have been classified into more than 100 glycoside hydrolase (GH) families, notably GH 4, 27, 36, 57, 97 and 110 in the CAZy database (<http://www.cazy.org/>). Most of the eukaryotic  $\alpha$ -galactosidases belong to the GH family 27. GH family 36 includes predominately bacterial  $\alpha$ -galactosidases. Some  $\alpha$ -galactosidases hydrolyze the substrate with retention of the stereochemistry at the substrate anomeric center; others induce its inversion.

## Substrate

Group I  $\alpha$ -galactosidase catalyzes the hydrolysis of  $\alpha$ -1,6 linkage in low molecular weight galacto-oligosaccharides and galactosides; Group II acts on branched polysaccharides such as galactomannan and galactoglucomannan. Galacto-oligosaccharides are found in legume seeds and different parts of plants. For example, in soybeans galacto-oligosaccharides are the most abundant soluble carbohydrates besides sucrose. In descending order of concentrations, these include stachyose, raffinose and verbascose composed of a terminal sucrose linked with 1 (raffinose), 2 (stachyose) or 3 (verbascose) galactose residues by  $\alpha$ -1,6 linkages. Stachyose is shown in Fig. 1 as an example. These galacto-oligosaccharides can be hydrolyzed to D-galactose and sucrose by  $\alpha$ -galactosidase. Sucrose can be hydrolyzed to glucose and fructose by other enzymes (sucrase, invertase).

## Optimal pH and Temperature

Optimal pH is an important property of enzymes. Generally, fungal (Shankar and Mulimani, 2007) and yeast (Viana et al., 2011)  $\alpha$ -galactosidases are most active and stable in the acidic pH 4.5–5.5. Bacterial  $\alpha$ -galactosidases from *Bacillus* sp. and *Bifidobacterium breve*, on the other hand, have optimal pH at or closer to the neutral range (Gote et al., 2004; Aguilera et al., 2012). The acidic pH optimum is desirable for functioning of the enzymes in the acidic gastric environment. Despite their acidic pH optima, a few fungal  $\alpha$ -galactosidases are stable over a wide range of pH 3–12 (Yanan et al., 2009; Similä et al., 2010; Katrolia et al., 2012). Some bacterial  $\alpha$ -galactosidases are also active in wide pH ranges (Gote et al., 2004). Being active and stable over a wide pH range is a favorable property for industrial applications. For processing of soybean milk, which has a pH of about 7.2, it is desirable to use an  $\alpha$ -galactosidase stable at pH 7–7.5. Cao et al. (2010) used a recombinant *Escherichia coli* with an  $\alpha$ -galactosidase gene from *Streptomyces* sp. S27 (ATCC 41168) to produce the enzyme optimal at pH 7.4 for soybean milk processing.

Most  $\alpha$ -galactosidases have optimal temperatures of 30–40 °C. Thermal stability is desirable for industrial uses, to allow higher reaction rates and process productivities at higher temperatures or to withstand the high temperatures used in, for example, pulp and paper industries.  $\alpha$ -Galactosidases with higher thermal stability have been found from different microorganisms. Most  $\alpha$ -galactosidases from mesophilic fungi and yeast are stable at up to about 50 °C (Simerská et al., 2007; Viana et al., 2010), while a few thermostable enzymes can withstand temperatures above 65 °C (Jin et al., 2001; Gote et al., 2004; Shankar et al., 2009). Some  $\alpha$ -galactosidases from extremophilic bacteria such as *Thermotoga* sp. (Duffaud et al., 1997) and archaeon *Sulfolobus solfataricus* (Brouns et al., 2006) are optimally active at 90 °C and above.

**Figure 1** Hydrolysis of stachyose to galactose and sucrose by  $\alpha$ -galactosidase. Modified from Loman, A. A., Ju, L.-K. 2017. Enzyme-based processing of soybean carbohydrate: Recent developments and future prospects. *Enzyme and Microbial Technology*, 106, pp. 35–47.

## Microbial Production

$\alpha$ -Galactosidase has been isolated from bacteria, fungi, plants and animals (Shankar and Mulimani, 2007). Acidic and alkaline  $\alpha$ -galactosidases differ in their optimal pH for activity. The acidic ones play important roles in seed development and germination.  $\alpha$ -Galactosidase is ubiquitous in legume seeds and vegetables. Filamentous fungi such as many *Aspergillus* (Liu et al., 2007), *Trichoderma* (Savel'ev et al., 1997) and *Penicillium* (Shibuya et al., 1995) species produce generally extracellular  $\alpha$ -galactosidases. Intracellular expression has also been observed such as with *Humicola* sp. (Kotwal et al., 1999).  $\alpha$ -Galactosidase is also widespread in bacteria. Marine proteobacteria and bacterioidetes are reported as good producers of  $\alpha$ -galactosidase that is stable at low temperature and useful for medical and food applications (Bakunina et al., 2014).

For industrial applications of  $\alpha$ -galactosidase, bacteria and fungi are potentially more economic producers (Jin et al., 2001). Plants and animals synthesize this enzyme in lower amounts, necessitating extensive purification for industrial production. Microbial production yield and cost can be more easily optimized with production conditions and use of cheaper substrates. Fungi are considered most suitable because of the extracellular localization of the enzymes produced and availability and stability in a wide range of environmental conditions (Katrolia et al., 2014). Extracellular enzymes are easier to collect and purify. Fungi also give generally higher production yields. Both submerged and solid-state fermentation processes have been used to produce  $\alpha$ -galactosidase (Shankar and Mulimani, 2007; Aleksieva et al., 2010). Agricultural residues have been used as substrate to reduce costs (Gao and Schaffer, 1999; Xiao et al., 2000). Statistical modeling tools like response surface methodology have been used to help optimize process conditions (Liu et al., 2007). Recombinant strains have also been used to increase production (Chen et al., 2000). Compared to fungal sources,  $\alpha$ -galactosidase from yeast has been less explored. For example, intra- and extracellular  $\alpha$ -galactosidases were produced by *Candida guilliermondii* H-404 and *Debaryomyces hansenii* UFFV-1 in media containing melibiose and galactose (Viana et al., 2010, 2011). Several bacteria have been screened for  $\alpha$ -galactosidase production and the culture conditions optimized for different carbon sources, e.g., *S. solfataricus* (Brouns et al., 2006) and *B. breve* (Xiao et al., 2000) on raffinose, and *Bacillus* species on agricultural residues such as wheat bran, rice bran, coconut cake, mustard cake, cotton seed

cake, chana bran and soybean meal (Gote et al., 2004, 2006). Cell immobilization of *Streptomyces griseolalbus* in calcium alginate gel was reported to double  $\alpha$ -galactosidase production yield over the free-cell fermentation (Anisha and Prema, 2008).

## Applications in Food Processing

### Soybean Processing

Soybean protein has a more comprehensive amino acid profile than other vegetable proteins. Soybean-based food has therefore long been considered as promising protein-rich food supplements. The galacto-oligosaccharides in soybeans, however, can cause indigestion problem in monogastric animals and human (Suarez et al., 1999).  $\alpha$ -Galactosidase has been used to reduce the oligosaccharide content in soybean meal, soy protein concentrate, soybean milk and other soybean-based food.

Opazo et al. (2012) produced an enzyme mixture including cellulase and  $\alpha$ -galactosidase by solid-state fermentation of mixed cellulolytic bacteria isolated from different environments. The bacterial mixture included those in the *Streptomyces*, *Cohnella* and *Cellulosimicrobium* genera. They used the enzyme to treat soybean meal and achieved reduction of 83% stachyose, 69% raffinose but only 24% insoluble polysaccharides. Presumably because it contained mainly cellulase and  $\alpha$ -galactosidase, this enzyme was less effective in breaking down pectin which is a major polysaccharide component in soybean meal. More recent studies used the enzymes produced by *Aspergillus niger* and *Trichoderma reesei* to examine the effects of multiple enzyme activities ( $\alpha$ -galactosidase, sucrase, pectinase, xylanase and cellulase) on hydrolysis of soybean meal carbohydrate (Loman and Ju, 2016a,c; Loman et al., 2016).  $\alpha$ -Galactosidase and pectinase were found to be two key enzymes generally insufficiently produced in fungal enzyme mixtures (Coffman et al., 2014; Li et al., 2017) when used for soybean meal processing to enrich protein content and/or remove oligosaccharides and polysaccharides. A new process with partial hydrolysate recycle was developed to retain a large portion of the limiting  $\alpha$ -galactosidase in fungal enzyme mixture so that the carbohydrate monomerization rate could be significantly improved (Loman et al., 2017). Using single-pass retention time of 6 h and recycle rate of 62.5%, the oligosaccharides and polysaccharides were essentially completely hydrolyzed to monosaccharides and the reducing sugar concentration in the harvested hydrolysate reached up to 120 g/L. The continuous-flow recycle process was also shown to potentially increase the volumetric productivity of reducing sugar and protein product by 57% and 300%, respectively, over the corresponding batch process.

Soybean milk is a low-cost substitute for dairy milk and a nutritional supplement for the lactose-intolerant population. It is used in a variety of proteinaceous food and beverage. There are several literature reports on the use of  $\alpha$ -galactosidase from plant, bacterial and fungal sources to remove the anti-nutritional oligosaccharides in soybean milk. For example, Gote et al. (2004) produced a thermostable  $\alpha$ -galactosidase using *Bacillus stearothermophilus* (NCIM 5146). When applying the enzyme at 1 Unit per mL soybean milk at 65 °C for 2 h, they could hydrolyze 100% stachyose and 94% raffinose. In another study, a thermophilic fungus *Humicola* sp. was used to produce an extracellular thermostable  $\alpha$ -galactosidase by solid state fermentation (Kotwal et al., 1999). At the same loading of 1 U per mL soybean milk, this enzyme completely hydrolyzed raffinose and stachyose in 2 h at 50 °C. Cao et al. (2010) used an  $\alpha$ -galactosidase from recombinant *E. coli* together with intestinal protease (trypsin) for degrading oligosaccharides in soybean milk and obtained 25%–30% higher galactose release compared to the use of  $\alpha$ -galactosidase alone.

$\alpha$ -Galactosidase is often immobilized for use in processing soybean products (Anisha and Prema, 2008). Immobilization can improve enzyme reusability and cost-effectiveness (DiCosimo et al., 2013). Natural and synthetic polymers such as calcium alginate, cellulose acetate, chitosan, polyurethane foam, gelatin, and polyacrylamide gel have been used for  $\alpha$ -galactosidase immobilization for soybean milk processing (Sripuan et al., 2003; Kulkarni et al., 2006; Filho et al., 2008; Ansari and Husain, 2010).  $\alpha$ -Galactosidase immobilized in polyacrylamide gel showed better thermal stability (Sripuan et al., 2003). This allows the use of higher process temperature to achieve faster oligosaccharide degradation and limit microbial contamination. Low molecular weight substrates like stachyose and raffinose could easily diffuse into the porous polyacrylamide gel without restricted accessibility to enzyme, which was sometimes a concern for use of immobilized  $\alpha$ -galactosidase. With this immobilized  $\alpha$ -galactosidase, 66% oligosaccharides in soybean milk were degraded in 12 h with retention of 90% enzyme activity and the enzyme could be repeatedly used for at least 4 times (Sripuan et al., 2003). However, polyacrylamide-based enzyme support is not suitable for food application.  $\kappa$ -Carrageenan, a linear, sulfated polysaccharide extracted from marine red algae, was also used successfully to immobilize  $\alpha$ -galactosidase (Girigowda and Mulimani, 2006). At loading of 0.75 U per mL soybean milk, the  $\kappa$ -carrageenan immobilized enzyme degraded more than 76% oligosaccharides in 8 h at 50 °C. However, free enzyme at the same loading hydrolyzed more than 80% of oligosaccharides in 2 h and 91% in 8 h. Despite the lower reaction rate, the immobilized enzyme could be reused; when evaluated in 4 repeated batches, the oligosaccharide reduction was 77%, 72%, 68% and 61% after each successive 4-h processing. The immobilized enzyme by  $\kappa$ -carrageenan was also used in a 150 mL fluidized bed reactor at the same enzyme loading to treat a continuous flow of soybean milk. At 50 °C, this fluidized-bed process reduced 92% oligosaccharides in the soybean milk fed at a 25 mL/h flowrate.

### Other Food Processing

$\alpha$ -Galactosidase has been used for processing other legume foods. Legumes make up an important part of the diet for many people across the world, providing proteins, fiber and other nutrients with lower fat contents. Like soybean, other legumes also contain indigestible galacto-oligosaccharides that can cause abdominal distress. The degradation of galacto-oligosaccharides in various legumes by  $\alpha$ -galactosidase has been demonstrated to be more effective than the traditional methods like soaking and cooking

(Pugalenthi et al., 2006; Katrolia et al., 2014). Pugalenthi et al. (2006) studied the effect of an  $\alpha$ -galactosidase extracted from guar weed *Cassia sericea* on jack bean (*Canavalia ensiformis*) and five types of sword bean (*Canavalia gladiata*). They found 71%–85% reduction of the combined content of raffinose, stachyose and verbascose. In another study, the  $\alpha$ -galactosidase gene (*RmGal36*) from *Rhizomucor miehei* was cloned and expressed in *E. coli* (Katrolia et al., 2012). The enzyme produced was used to hydrolyze the galacto-oligosaccharides in kidney bean flour. There are several other known food processing applications of  $\alpha$ -galactosidase, mainly in the sugar industry; for example, hydrolysis of raffinose in beet sugar syrup is used to improve the crystallization of sucrose.  $\alpha$ -Galactosidase can also be used to improve the gelling properties of galactomannans used as food thickeners (Aleksieva et al., 2010). The enzymes used in food industry are produced by food-grade microorganisms with the Generally Regarded as Safe (GRAS) status.

### Livestock Feed Supplementation

The diets of poultry and swine include high percentages of galacto-oligosaccharide-containing components such as soybean meal. Such diets can cause gastric problems to the non-ruminant animals lacking sufficient intestinal  $\alpha$ -galactosidase. The problems can increase the rate of feed passage in the intestines and reduce the feed utilization. Pre-treatment of animal feed with  $\alpha$ -galactosidase to remove galacto-oligosaccharides improves digestibility and nutritional uptake and reduces the viscosity of digesta. For example, studies have indicated the  $\alpha$ -galactosidase supplementation improves growth performance, nutrient uptake and ileal digestibility of soybean oligosaccharides in piglets and in poultry (Pan et al., 2002; Ghazi et al., 2003). The more advantageous  $\alpha$ -galactosidases for use as feed additives are those active at pH and temperature similar to those in the intestines of mammals and poultry and resistant to protease enzymes (Pan et al., 2002; Ghazi et al., 2003).

## Importance of Vitamins

Vitamins are organic compounds which cannot be synthesized in adequate quantities by humans and, therefore, must be supplied by our diet. Moreover, they have different regulatory functions that determine the development, physical efficiency, and health status of our body. To date, 15 vitamins have been recognized in human nutrition. Depending on their solubility, vitamins are either classified as water soluble or fat soluble vitamins (Katouzian and Jafari, 2016). As shown in Table 1, water soluble vitamins include vitamin C and the members of the vitamin B group, whereas fat soluble vitamins comprise vitamins A, D, E, and K; also included are the carotenoids that possess varying degrees of vitamin A activity (Pamela et al., 2005; Ball, 2005; Kim and Driskell, 2009).

## Impact of Food Processing Operations on Vitamins

Technological processing applied in the food industry often includes many thermal and non-thermal processes. These processes can have either negative or positive effects on the food materials. Food-processing operations are primarily focused on inactivation of enzymes, food-borne pathogens, prolongation of shelf-life, improved digestibility and bioavailability of nutrients, including augmented antioxidants. In contrast, these processing operations can also bring some unintentional and undesired consequences, such as loss of certain vitamins (Van Boekel et al., 2010; Nayak et al., 2015). Furthermore, the rate of this reduction in vitamin content is influenced by a number of factors: heat, moisture, oxygen, pH, light, oxidising and reducing agents, presence of metallic ions (e.g. iron, copper), and presence of other vitamins (Ottaway, 1993).

Considering the increasing demand of consumers for nutritious and functional foods, manufacturers in the food industry have to develop preservation technologies to ensure that the nutrients of the foods are lost to a minimum. Clearly, different food processing operations such as pasteurization, sterilization, blanching, cooking, frying, high pressure processing, etc. have undesirable effects on vitamins. In this chapter, we will consider these processes in two classes: conventional food processes; and modern processes particularly the non-thermal ones.

## Influence of Conventional Food Processing Operations on Vitamins

Vitamin degradation during heating is dependent on several factors such as the processing method, food type, oxygen, light, moisture, pH, the chemical matrix, type of vitamins, and active enzymes (Awuah et al., 2007; Leskova et al., 2006). A brief overview of studies considering the effect of conventional food processing on vitamins is discussed in this section. Although there are some investigations on the effects of food processing operations on the retention of vitamins, generally speaking, the literature in this field is scarce. More studies have been focused on vitamin C and vitamin B group. In fact, retention of vitamin C during various food processes is a model and control index which predicts the retentions of other vitamins too.

### Vitamin C

Various conventional food processes have been investigated for their effects on the vitamin C content of different fruits and vegetables as shown in Table 2; almost all these investigations have reported to result in some losses of vitamin C. For example, it has been revealed that conventional food processing operations bring about significant decreases of vitamin C content of various foods, such as pasteurization of tomato (Capanoglu et al., 2008), orange (Gil-Izquierdo et al., 2002), guava (Ordóñez-Santos and Vázquez-Riascos, 2010), and strawberry (Klopotek et al., 2005). Blanching as a mild thermal processing has been determined to reduce vitamin C levels in parsley leaves by 47%–51% (Lisiewska and Kmiecik, 1997), and in broccoli by 40% (Wu et al., 1992). Abushita et al. (2000) also reported that during hot-break pulping of tomato, about 38% of its original ascorbic acid was lost, and further processing to produce tomato paste by vacuum evaporation resulted in losses of more than 16% of the ascorbic acid content (Abushita et al., 2000). Moreover, Al-Duais et al. (2009) reported the losses of ascorbic acid, in *Cyphostemma Digitatum* plant, 59% after sun drying.

Vitamin C is very susceptible to chemical and enzymatic oxidation during the processing, storage, and cooking of foods (Ball, 2006). It is clear that raw tomato contains more vitamin C than processed tomato, and there is a higher loss of this vitamin during the production of tomato concentrates than in tomato juice or whole canned tomatoes (Riso and Porrini, 2001). Results from some other studies have also indicated that vitamin C is destroyed mainly due to oxidation reactions and the heat applied in the presence of air during processing (Leoni, 2002). In addition to the effect of oxygen, such high temperature applications themselves cause oxidative stresses. On the other hand, losses of vitamin C are minimal when vegetables are cooked without any water, whereas maximum losses are associated with cooking in a large amount of water (Leskova et al., 2006). For example, Ordóñez-Santos

**Table 1** Classification of the vitamins, their sources and associated anemias

<i>Solubility</i>	<i>Vitamins</i>	<i>Other names/forms</i>	<i>Food sources</i>	<i>Nutritional anemias</i>
Water-soluble	Vitamin C	Ascorbic acid	Tomatoes, strawberries, peppers, broccoli, citrus fruits	Scurvy
	Vitamin B <sub>1</sub>	Thiamine	Pork, beef, yeast, whole grains, legumes	Beriberi, Wernicke-Korsakoff syndrome
	Vitamin B <sub>2</sub>	Riboflavin	Meats, dairy products, enriched cereals, breads, green leafy vegetables	Dermatitis, Cheilosis, Glossitis
	Vitamin B <sub>3</sub>	Niacin Nicotinic acid Nicotinamide	Yeasts, meats, poultry, fish, nuts, and enriched products such as cereals and grains.	Pellagra, Neurological symptoms
	Vitamin B <sub>5</sub>	Pantothenic acid	Liver, yeast, meats, egg yolks, whole grains, potatoes, broccoli, mushrooms, and avocados	Burning foot syndrome
	Vitamin B <sub>6</sub>	Pyridoxine Pyridoxal Pyridoxol Pyridoxamine	Meats, whole-grain products, vegetables, some fruits (e.g. banana), nuts, fortified cereals	Weakness, Sleeplessness, Cheilosis, Glossitis, Stomatitis, Microcytic
	Vitamin B <sub>8</sub>	Biotin	Liver, egg yolks, soybeans, bakers and brewer's yeasts	Dermatitis, Glossitis, Loss of appetite, and nausea
	Vitamin B <sub>9</sub>	Folic acid Folate	Green leafy vegetables, orange juice, dried beans, peas	Macrocytic Megaloblastic Neural tube Defects in the fetus
	Vitamin B <sub>12</sub>	Cobalamin Cyanocobalamin Hydroxocobalamin	Meats, poultry, liver, whole milk, eggs, oysters, fresh shrimp, pork, chicken	Megaloblastic Pernicious Dementia Paranoia Depression
				Night blindness Xerophthalmia Anorexia, Immune deficiencies, Follicular hyperkeratosis
Fat-soluble	Vitamin A	Retinol, Retinal Retinoic acid (A <sub>2</sub> ) $\alpha$ -carotene $\beta$ -carotene $\gamma$ -carotene $\beta$ -cryptoxanthin Echinenon	Meats, egg yolks, fortified food products, dark green leafy vegetables, yellowish-orange fruits and vegetables.	
	Vitamin E	$\alpha$ -Tocopherols $\beta$ -Tocopherols $\gamma$ -Tocopherols $\delta$ -Tocopherols $\alpha$ -Tocotrienol $\beta$ -Tocotrienol $\gamma$ -Tocotrienol $\delta$ -Tocotrienol	Polyunsaturated plant oils, almonds, peanuts	Sensitivity of erythrocytes to peroxide, Abnormal cellular membranes
	Vitamin D	Ergocalciferol (D <sub>2</sub> ) Cholecalciferol (D <sub>3</sub> )	Self synthesis via sun light, fish and fish oils	Rickets Osteomalacia
	Vitamin K	Phylloquinone (K <sub>1</sub> ) Menaquinone (K <sub>2</sub> ) Menadione (K <sub>3</sub> )	Green leafy vegetables, plant oils	Hemorrhagic syndrome

(Adapted from Leskova et al., 2006; Harvey and Ferrier, 2011; Kim and Driskell, 2009)

and Vázquez-Riascos (2010) observed that the production of nectar and pulp from fresh guava decreased vitamin C (28.3%–37%). Consistent with these results, they indicated that the reduction of vitamin C is attributed primarily to the dilution effect generated by addition of water in the product. Another study showed that vitamin C losses during blanching were found to be 10% for sweetcorn, 20% for green beans and 30% for broccoli (Klein, 1997). It has been shown that harvest damage, cutting/slicing, particle size, and type of blancher (steam/water, rotary/cabin) are the main factors affecting the losses of vitamin C (Davey et al., 2000).

Babalola et al. (2010) showed that green leafy vegetables were affected by different processing methods. They reported that boiling (91.5%) and squeeze washing (94.9%) caused more loss than blanching (79.23%). Consequently, it is better to inactivate the oxidase enzyme that destroys vitamin C, blanching vegetables in hot water. Moreover, when comparing various cooking procedures for vegetables, Bureau et al. (2015) observed that boiling was the less suitable method, with a high loss of vitamin C, compared to steaming, microwaving or pressure cooking. Another study conducted by Dewanto et al. (2002) showed that after 2, 15, and 30 min of heating at 88 °C, the vitamin C content significantly decreased by 10.2%–29.4%. Similarly, baking at

2%		34.41% ↓	
4%		33.66% ↓	

↓: decrease, ↑: increase.

220 °C of tomato, the vitamin C content significantly dropped by 2%–62% (Gahler et al., 2003). In addition, certain pre-treatments such as thawing cause higher vitamin C loss. Therefore, frozen vegetables must not be thawed before cooking.

These investigations show that vitamin C is a heat unstable vitamin. The losses of vitamin C are primarily due to chemical degradation including oxidation of ascorbic acid to dehydroascorbic acid (DHAA), followed by hydrolysis of the latter to 2,3-diketogulonic acid. Afterwards, polymerization to form other nutritionally inactive products (Dewanto et al., 2002; Ordóñez-Santos and Vázquez-Riascos, 2010) occurs. In a more recent study, Jafari et al. (2017) investigated the effects of thermal processing by nanofluids on vitamin C retention of tomato juice. The results showed that increasing nanoparticle concentration from 0 to 2% and 4% could culminate in the slightly better retention of vitamin C due to shorter process times. On the other hand, Leong and Oey et al. (2012) reported 1.2–2.5 fold and 1.6–2.5 fold increases in vitamin C content of some fruits and vegetables following the heating and freezing, respectively. This study indicated that heating and freezing enhanced the stability of vitamin C, resulting in higher levels after processing compared to fresh. This was due to ascorbic acid oxidase inactivation during heating leading to L-AA protection towards enzymatic oxidation (Leong and Oey, 2012).

### Vitamin E

Some selected studies considering the influence of conventional food processing on the retention of vitamin E has been summarized in Table 3. Generally, vitamin E in foods is predominantly represented by  $\alpha$ -tocopherol. Capanoglu et al. (2008) compared values for the starting material in tomato paste and found that 22% of  $\alpha$ -tocopherol was increased during thermal processing while 69%  $\delta$ -tocopherol and 84%  $\gamma$ -tocopherol were also lost. Seybold et al. (2004) reported that homogenization and sterilization of tomatoes during tomato juice production resulted in significant losses in  $\alpha$ -tocopherol. Also, extrusion process variables could affect this vitamin content. For instance, extrusion cooking was determined to decrease vitamin E levels in cereals by 63%–94% (Zielinski et al., 2001), and in buckwheat by 63% (Zieliński et al., 2006). Moreover, Thammapat et al. (2016) observed that the parboiling process significantly decreased the concentrations of  $\alpha$ - and  $\gamma$ -tocopherols as compared to raw rice (18%–25%). Similarly, Stuetz et al. (2017) noted that concentrations of  $\alpha$ -tocopherol were decreased in hazelnuts, almonds and walnuts (20%–54%). The effects of processing on the content of vitamin E in foods have been the subject of limited investigations. In another study, Murcia et al. (1999) observed that boiling, omelette, and microwaving of egg yolk led to a 21.63%, 53.24%, and 43.12% reduction in vitamin E activity, respectively. The possible explanations could be the formation of peroxides as intermediate products in the autooxidation of the fatty acids, destroying the oxidation sensitive vitamins such as vitamin E since it would react with the peroxides (Murcia et al., 1999).

### Vitamin A

Similar to the observations for vitamin C, loss of  $\beta$ -carotene also varies depending on the type of vegetable (the matrix) as well as the processing method applied (Table 3). It has been reported that boiling and frying of Thai vegetables led to a 14% and 24% reduction in vitamin A activity, respectively (Speek et al., 1988). Moreover, according to Achidi et al. (2008), processing and cooking of cassava leaves caused minimal decrease in  $\beta$ -carotene content. Bolin and Stafford (1974) found that sun-drying (30%), shade-drying (10.1%), and dehydrating (9.2%) of apricot resulted in significant losses in  $\beta$ -carotene. Similarly, thermal processing of peppers resulted in a 25% decrease of total provitamin A activity (Howard et al., 1994).

On the other hand, Mosha et al. (1997) reported that the increase in vitamin A activities were in the range of 32.5%–63.1% for blanched vegetables, and 68.6%–228.6% for cooked vegetables. In another study conducted by Sánchez-Moreno et al. (2006), it was revealed no significant differences in vitamin A contents among low pasteurization, high pasteurization, freezing, high pasteurization plus freezing purée samples in comparison with the untreated sample. As seen in the examples, more researchers have studied the effect of different methods of cooking and processing on the levels of both vitamin A and their vitamers in foods. These results show that vitamin A is sensitive to destruction by heat, light and oxygen. Moreover, thermal food processing can result in remarkable losses of vitamin A activity.

**Table 3** The influence of conventional food processing operations on different vitamins (other than Vitamin C)

Processing	Product	Vitamin	Result	References
Pasteurization (93 °C)	Tomato	$\alpha$ -tocopherol	22% ↑	Capanoglu et al. (2008)
		$\beta$ -tocopherol	128% ↑	
		$\delta$ -tocopherol	69% ↓	
		$\gamma$ -tocopherol	84% ↓	
		$\beta$ -carotene	36% ↓

### Vitamin B Group

Athar et al. (2006) reported a significant decrease in vitamin B<sub>1</sub> (39%–77%), vitamin B<sub>2</sub> (14%–30%), vitamin B<sub>3</sub> (25%–40%), and vitamin B<sub>6</sub> (65%–82%) in extruded food products. Similarly, Anuonye et al. (2010) indicated a 6% decrease in riboflavin (vitamin B<sub>2</sub>) and 86.36% decrease in pyridoxine (vitamin B<sub>6</sub>) after extrusion of Acha/soy bean blend. In another study, it was revealed that high vacuum flame sterilization of tuna flake led to a 14% reduction in vitamin B<sub>3</sub> (Seet et al., 1983). Jiratanan and Liu (2004) observed that thermal treatments of beet caused a 23%–39% decreases in folic acid. Al-Khalifa and Dawood (1993) indicated that Thiamin (vitamin B<sub>1</sub>) was more sensitive to heat than was riboflavin. Moreover, the study reported that higher losses of thiamin occurred during roasting and deep-frying, while braising and microwave cooking resulted in lower losses. Bassett and Sammán (2010) investigated the retention of folate in foods after using different cooking processing. They reported that the folate retention was in the range 14%–99% according to both type of food and method of processing. Another study conducted by Achidi et al. (2008) concluded that thiamine losses from 35.14% to 38.95% occurred while processing cassava leaves. In a separate study, Kinyuru et al. (2010) observed that the toasting of frozen green vegetables, pyridoxine (B<sub>6</sub>), folic acid, niacin (B<sub>3</sub>), and riboflavin (B<sub>2</sub>) was found to result in approximately 4%, 37%, 21%, and 34% losses, respectively.

Kwok et al. (1998) investigated effect of thermal processing on thiamine and riboflavin content in soy milk. They reported that thiamine was found to be much more heat sensitive than riboflavin. In another study, Mahgoub et al. (1999) noted that fermentation of kisra increased riboflavin (16%) but decreased thiamine (35%), whereas fermentation of hulu-mur reduced the levels of both riboflavin (15%) and thiamine (10%). Moreover, the same researchers observed that riboflavin was not affected by baking of kisra but thiamine level was markedly decreased. Hulu-mur baking caused reduction of both thiamine and riboflavin. These high losses may be attributed to the both long baking times and high baking temperatures. Chapman et al. (1957) reported that pasteurization (except riboflavin), sterilization, ultra-high temperature processing, evaporation (except riboflavin), and spray drying led to a decrease in all B complex vitamins. Furthermore, 7.9%–11.9% loss of thiamine and 0.9%–2.7% loss of riboflavin was observed on heat processing of milk (Haddad and Loewenstein, 1983).

Raab et al. (1973) showed that steam blanching (83%–87%) of lima beans may have somewhat improved retention compared to water blanching (76%–81%). Kōmura et al. (1990) investigated the effects of different cooking methods, including boiling, steaming, parching, frying on thiamine recovery and noted that the loss of thiamine was largest in boiling (70%), followed by parching (35%) and frying (30%). In a separate study, Mosha et al. (1995) investigated that effect of blanching and cooking processing on the retention of riboflavin and thiamine. They found a decrease in thiamine content by blanching (67.7%–85.6%) and cooking (29.3%–88.6%) of vegetables. This is explained by the water-soluble nature of the vitamin being leached out into the water. Moreover, the losses of thiamine content may have resulted from severity of heat treatment. The rate of thiamine degradation is accelerated by increase in temperature and pH (Kinyuru et al., 2010). In contrast, it has been shown that blanching and cooking resulted in a significant increase in riboflavin content in some vegetables (cowpea, peanut and pumpkin greens (10%–91%)), whereas in amaranth and sweet potato leaves (19%–87%), a significant decrease was observed. These increases in riboflavin are supposed to result from an increased tissue breakdown and increased accessibility of the vitamin to the extracting solvent. Kwok et al. (1998) reported that riboflavin is more heat-stable than is thiamin, and its thermostability is independent of heating methods. Some other results have been briefly shown in Table 3.

### The Influence of Modern and Non-thermal Food Processing Operations on Vitamins

Traditional thermal processing led to remarkable losses in nutritional quality as mentioned in the previous section. Considering the increasing consumer fresh-like products demands, food industries have directed their studies to the search for alternative processing technologies including UV light, high intensity light pulses,  $\gamma$ -irradiation, pulsed electric fields, radiofrequency electric fields, Ohmic heating, microwave heating, ultrasonication, high hydrostatic pressure, supercritical carbon dioxide, ozonation, and flash vacuum (Jiménez-Sánchez et al., 2017). In general, it has been revealed that these technologies seem to be less detrimental than the thermal processing. In this section, the effects of modern and non-thermal food processing operations on retention of vitamins will be discussed and a brief overview of the relevant studies have been shown in Table 4.

#### Pulsed Electric Field Processing

Pulsed electric fields (PEF) have been developed during the last decades as an alternative to thermal pasteurization of liquid foods. A number of studies have shown high vitamin C retention after PEF processing compared to the thermal treatment (Table 4). For example, Odriozola-Serrano et al. (2008) reported that vitamin C retention just after treatment in heat treated tomato juice was 79.2%, whereas in PEF-processed juice, there was a 86.5% retention. Moreover, Elez-Martínez and Martín-Belloso (2007) reported that high intensity pulsed electric field (HIPEF) treated orange juice (87.5%–98.2%) and gazpacho (84.3%–97.1%) always showed a vitamin C retention higher than that of the heat-pasteurized products. Similarly, Elez-Martínez et al. (2006) showed that HIPEF-processing resulted in higher ascorbic acid content in orange juice (91.2%) than thermal pasteurization (82.8%).

In the study conducted by Salvia-Trujillo et al. (2011), they observed 99.5%–97.0% vitamin C retention after applying HIPEF treatment to the fruit juices. Sánchez-Vega et al. (2015) reported that HIPEF-treated broccoli juice exhibited greater relative content of  $\beta$ -carotene than the juice treated by heat. Similarly, Odriozola-Serrano et al. (2009) showed that  $\beta$ -carotene has been shown to substantially increase in PEF-processed tomato juices, whereas  $\gamma$ -carotene content is slightly depleted (3%–6%). Odriozola-Serrano et al. (2013) proposed that HIPEF processing could trigger the biosynthesis of carotenoids, resulting in an increment of some of them. On the other hand, Oms-Oliu et al. (2009) indicated that HIPEF processing of watermelon juice led to a 4%–60% reduction

**Table 4** The influence of non-thermal food processing operations on vitamins

Processing	Product	Vitamin	Result	References

High intensity pulsed electric field	Tomato juice	Vitamin C	13.5% ↓	Odriozola-Serrano et al. (2008)
High-intensity pulsed electric field	Orange-carrot juice	Vitamin A	6%–69% ↑	Torregrosa et al. (2005)
Ultrasound treatment	Tomato juice	Vitamin C	3.1%–39.3% ↓	Adekunte et al. (2010)

↓: decrease, ↑: increase, ↔: no changes.

in vitamin C. According to these researchers, electric field strength, pulse frequency, pulse width, polarity and treatment time significantly affected vitamin C of watermelon juice. In contrast, Salvia-Trujillo et al. (2011) observed that HPEF treatment did not affect the concentration of group B vitamins, but thermally treated beverages showed lower riboflavin (vitamin B<sub>2</sub>) concentration.

### High-pressure Processing

Similar to other non-thermal food processing operations, high-pressure processing (HPP) has a profound effect on the stability of vitamins in foods. For example, Barba et al. (2012) reported an increase of total tocopherol content (7%–28%) in orange juice-milk blend treated with HPP, mainly due to an increase in α-tocopherol content. These increases in α-tocopherol are supposed to result from an increased disruption of the chloroplasts where α-tocopherol is confined. Sánchez-Moreno et al. (2005) showed that HPP led to an increased vitamin A value (38.74%). Moreover, Sánchez-Moreno et al. (2006) showed that HPP of tomato puree showed the highest vitamin A value (39% ↑) among the samples. A possible explanation is this fact that HPP has the potential to enhance the release of vitamins from vegetables (Sánchez-Moreno et al., 2005, 2006). Toro-Funes et al. (2014) reported that ultra-high-pressure homogenization treatment of almond beverages led to a decrease in α-tocopherol content (83%–93%). On the other hand, Escobedo-Avellaneda et al. (2015) reported that higher vitamin C content than untreated controls were observed for high hydrostatic pressure-treated oranges. The researchers suggest that high hydrostatic pressure increases the release of vitamin C probably due to cellular disruption, making them more accessible for quantification. Similarly, Vega-Gálvez et al. (2012) reported that at 400 MPa, vitamin C showed the maximum retention (93%) and vitamin E increased compared with the initial value of the gel.

### Ultrasound Processing

Ultrasound processing is a technology that has been extensively investigated in recent years. Studies on the influence of ultrasound processing suggests that it has beneficial effects on vitamin C level in some juices. For instance, Tiwari et al. (2009) showed that greater vitamin C (74.5%) retention was happened in sonicated orange juice. Moreover, Cheng et al. (2007) revealed that guava juice treated with both sonication and carbonation showed the highest ascorbic acid contents. Jabbar et al. (2015) reported a significant increase in ascorbic acid of carrot juice treated with ultrasound at 20 °C when compared with fresh untreated juice samples. Aguilar et al. (2017) reported that the ascorbic acid was retained in fruit juices after the ultrasound processing. Moreover, Cruz et al. (2008) suggested that the thermosonication treatment was found to be a better blanching process, since it inactivates watercress peroxidase at less severe blanching conditions and therefore retains higher vitamin C contents.

Rawson et al. (2011) found a higher retention of ascorbic acid at low ultrasound treatments. The higher retention level of ascorbic acid due to thermosonication treatment might be attributed to the milder heat processing as compared to heat treatment. Another reason could be that samples treated with thermosonication helped to eliminate the dissolved oxygen; thus it delayed ascorbic acid degradation (Anaya-Esparza et al., 2017; Cheng et al., 2007; Jabbar et al., 2015). In contrast, Ordóñez-Santos et al. (2017) reported that ultrasound processing of gooseberry juice was found to result in 24.4%–78.81% vitamin C and 25%–96.24% provitamin A losses. Adekunle et al. (2010) showed that the concentration of ascorbic acid in tomato juice ranged from 96.9% to 60.7%. Furthermore, Gamboa-Santos et al. (2013) showed that conventional blanching treatments at high temperature gave rise to carrots with retention of vitamin C (37.5%–85%) higher than blanching with US-probe (4%). It is possible that the degradation of ascorbic acid is attributed to oxidation processes generated during ultrasonic treatments. Moreover, hydrogen ions, free radicals, and hydrogen peroxide are created during the sonolysis of water molecules. Therefore, it could be related to oxidation reactions, enhanced by the interactions with them (Adekunle et al., 2010).

## Strategies to Retain Vitamins During Food Processing Operations

Many studies considering the processing effects on vitamins showed that thermal treatments could adversely affect vitamins compared with non-thermal treatments. Therefore, protection of vitamin is an important task for food producers. In order to decrease degradation of vitamins, preparation of foods should be done according to appropriate procedures including avoiding overcooking; shortening cooking time; cooking with a minimum water, etc. Moreover, steaming, stirfrying, and pressure cooking bring about less vitamin losses than boiling or classical pan frying (Ball, 2005). Another promising approach for protecting vitamins can be micro/nano-encapsulation (Katouzian and Jafari, 2016). For example, Desai and Park (2005) reported that the vitamin C was found to be stable after encapsulation. Another study conducted by Abbasi et al. (2014) indicated that vitamin D<sub>3</sub> encapsulated in nanoparticles degraded less in the presence of oxygen. Assadpour et al., (2016a,b, 2017) and Assadpour and Jafari (2017) also reported that nanoencapsulation of folic acid within double emulsions could result in better protection of this vitamin resulting in more bioavailability of folic acid and targeted release in large intestine. Righetto and Netto (2006), furthermore, investigated the effect of the encapsulating materials on the stability of two sources of vitamin C, green West Indian cherry juice and synthetic ascorbic acid. They observed that the vitamin C of green West Indian cherry capsules was more stable than synthetic ascorbic acid. It has been shown that phenolic compounds present in the juice have an important role in vitamin C protection.

# Microbial Xylanases in Bread Making

Seema Dahiya and Bijender Singh, Maharshi Dayanand University, Rohtak, India

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Arabinoxylan** A hemicellulose found in both the primary and secondary cell wall of plants, including woods and cereal grains, comprising two pentose sugars viz. arabinose and xylose.

**Bake** Food cooking by dry heat without exposure of direct flame, typically in an oven.

**Bread** A food made of flour, water, and yeast mixed together followed by baking.

**Crumb** A small fragment of bread, cake, or other bakery products.

**Dough** A thick, moldable mixture of flour and liquid used for baking into bread.

**Enzyme** A protein catalyzing a specific biochemical reaction.

**Farinograph** A recording dough mixer that measures and records the torque developed by the action of mixer blades on the dough at time of mixing.

**Fermentation** Microbial breakdown of a substance that gives rise to effervescence and heat.

**Gluten** It is composed of two proteins present in wheat. It is also responsible for the elastic texture of dough.

**Knead** Mold/work the moistened flour into dough with hands.

**Loaf** A quantity of bread, which is shaped and baked in one piece and usually sliced before being eaten.

**Microorganism** A microscopic organism especially a bacterium, virus, and fungus, which is not seen by naked eyes.

**Proofing** It is the final rise of shaped bread dough before baking.

**Rheology** The branch of physics, which deals with the deformation and flow of matter, especially the non-Newtonian flow of liquid and the plastic flow of solids.

**Staling** Decrease in the palatability of bread and other bakery products, but microbial contamination is not included in this.

**Starch** A tasteless, odorless, and white substance occurs widely in plant tissues and chiefly obtained from cereals and potatoes. It is a homopolymer of glucose.

**Xylanase** A hydrolytic enzyme that cleaves the  $\beta$ -1,4 backbone of xylan found in plant cell wall.

## Introduction

Bread is a staple and basic food item, made by baking process in an oven. It is popular around the world and is one of the oldest artificial foods, having been of importance since the dawn of agriculture. Bread is considered as one of the most consumed baked product known to humans and also a good source of iron. Bread is served in different ways at any time of meal of the day, as a snack, as an ingredient for preparation of sandwiches, as a coating for fried items to prevent sticking. In market, breads are sold as white bread, brown bread, wheat meal bread, fruit bread, fancy bread, milk bread, and bun or masala bread or by any other name prepared from a mixture of wheat flour, water, salt, yeast or their fermentative medium, having one or more other ingredients such as milk (whole or skimmed or condensed), curd, gluten, whey, honey, sugar, liquid glucose, malt product, edible starches, margarine or refined edible oil of suitable type or butter or their mixture, protein concentrate, lime water, etc., and other desired components (Khetarpaul et al., 2005).

Wheat flour, a mixture of gluten, lipids, starch and nonstarch polysaccharides, and enzymes, is usually used as a raw material for bread making. The complex biochemical and biophysical processes begin after mixing flour, yeast, and water together and characterizing the dough phase. To improve the baking process, some exogenous enzymes are added in the dough to reduce bread preparation time, decrease staling rate, compensate flour variability, and replace chemical additives (Tramper and Poulsen, 2005). In bakery products, starch is the main component, which acts as a water binder, thickener, fat substitute, gelling agent, and emulsion stabilizer (Synowiecki, 2007). Rheological properties of dough are affected by other components of flour such as arabinoxylans and lipids (Goesaert et al., 2005; Georgopoulos et al., 2006; Gandikota and MacRitchie, 2005). Gluten makes dough more elastic, viscous, cohesive, and extensible with improved water absorption capacity (Wieser, 2007). Goesaert et al. (2009) reported that wheat flour has unique ability to make viscoelastic dough having gas holding properties because of its gluten protein. In addition to starch and gluten protein, nonpolysaccharides (arabinoxylans), enzymes, and lipids of wheat flour remarkably improve the bread making process (Stojceska and Butler, 2012; Peressini and Sensidoni, 2009; Goesaert et al., 2005, 2009). Pareyt et al. (2011) reported that lipids are also important components during bread making, as they have different valuable properties during storage and processing of bread. It was reported that 2% lipids were present in wheat flour either in free form or bounded with wheat components (Belitz et al., 2004), and further they were categorized into starch lipids and free or bound nonstarch lipids on the basis of solubility in different solvents with different polarities (van der Borgh et al., 2005).

## Bread Making Process

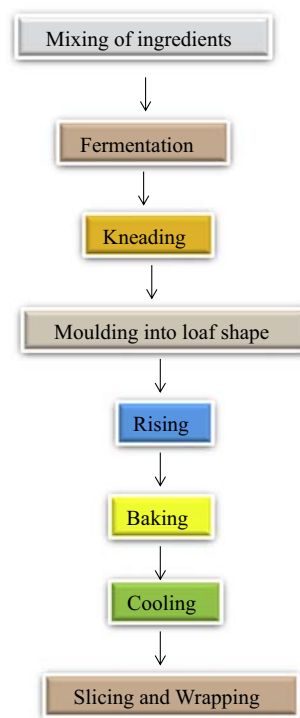

The process of bread preparation can be divided into three main steps that are mixing, fermentation, and baking (Fig. 1). Baking process modifies the taste, aroma, texture, and sensory properties of goods made of raw materials (Abdullah, 2008). Therefore, baking process started a chain of biochemical, chemical, and physical reactions in the product, which includes water evaporation, expansion of volume, denaturation of protein, gelatinization of starch, crust and porous structure formation, and browning reaction (Sablani et al., 2002). Bread is made of elastic, unstable, solid structure made of continuous elastic network of crosslinked molecules of gluten protein and of leached molecules of starch polymer, mainly amylose (Gray and Bemiller, 2003). The properties of final product are affected by mechanical and physical mixing, enzyme catalyzed chemical reactions, and by thermal effects, including baking time and temperature.

Principle stages of bread making process:

1. **Dough formation:** The difference between all kinds of bread making processes is due to the way of dough kneaded. On the basis of method of dough formation, the process is categorized into straight dough method, short dough method, sponge dough method, etc. In this stage, all the ingredients are mixed thoroughly and with the help of mixer the gluten development, air bubble incorporation, and production of dough with desired rheological properties are achieved.
2. **Fermentation and proofing:** During this stage, the yeast acts on fermentable sugars and produces carbon dioxide and ethanol. Ethanol evaporates completely during baking leaving no bad/adverse effect on bread quality, and gluten film entrapped the carbon dioxide gas, which expands during baking process and increases the volume of the bread with porous texture.
3. **Baking process:** This is the final stage of bread making in which because of action of heats the dough is firmed; its structure is stabilized and converted into final baked product (Khetarpaul et al., 2005). The whole process of bread making is summarized in Fig. 1.

## Bread Formulation

So far many different varieties of bread have been developed. In different regions these formulations developed on the basis of seven traditional food habits of the people. Enzymes play an important role in bread preparations by improving its properties. Xylanases have great use in baking industries because they enhance quality of the bread by improving volume of bread, bread crumb structure,

**Figure 1** Whole process of bread making.

**Table 1** Breads categorized on the basis of use

Bread	Features	Area of popularity
Pan bread	These breads are popular in economically developed countries, including Canada, United States, United Kingdom, and European nations.	USA, United Kingdom, Canada
Hearth or sour bread	These breads are produced with or without lactic acid fermentation in an open hearth and are becoming popular in France.	France
Flat bread or chapati/roti	They are unfermented and flat, baked on a flat hot pan. This category is popular in Asian countries.	Asian countries
Rolls and other small fermented breads	These breads generally have higher levels of fat and sugars in formulation. Thus they have sweeter taste and softer bite characteristics.	Europe especially in Germany, Australia, Sweden, Finland, Switzerland, etc.

decrease stickiness of bread, and also significantly increase shelf life and staling of bread when used at optimum levels. Therefore, in baking industries there is an increasing demand toward the application of xylanase for bread preparation (Butt et al., 2007). Xylanases (endo-1,4- $\beta$ -D-xylan xylanohydrolase) are the major group of enzymes, which hydrolyze xylan and release xylose, as well as long- and short-chain xylooligosaccharides (Kheng and Omar, 2005). Xylans are the main constituents of hemicellulose, the world's second resource after cellulose. In cereals, xylans constitute a large amount of L-arabinose, which is known as arabinoxylans. In food industries, major advantageous properties of xylanases are their high stability and optimum activity at acidic pH, and therefore, xylanases are widely applied in food industries (Polizeli et al., 2005; Butt et al., 2008; Harris and Ramalingam, 2010). In bread making, fundamental role of xylanase is the degradation of unextractable arabinoxylan to water-extractable xylan and thus allows the water redistribution in dough with formation of gluten network (Goesaert et al., 2005). This process improves the properties (extensibility, elasticity, and softness) of dry dough. Different breads are categorized on the basis of use in Table 1.

### Microbial Sources of Xylanases

Microorganisms have been regarded as an important source of enzymes, as they can reproduce in higher rates and make industrially important bioactive compounds. The application of enzymes as industrial biocatalysts has been increased exceptionally in recent years, as the enzymes offer more advantages over the application of traditional chemical catalysts. Enzymes exhibit high catalytic activity, are highly specific to substrate, can be produced in large amount at a time, are economically viable, and are not dangerous for our environment because of their highly biodegradable nature (Gote, 2004). In this context, xylanases of microbial sources are preferred biocatalyst for xylan hydrolysis because of their high specificity, negligible substrate loss, mild reaction conditions, potential application on feed, food, and other industries and have no side-product generation (Goswami and Pathak, 2013; Collins et al., 2005). Complete xylanolytic enzyme systems with all of these properties have been found in bacteria, fungi, and actinomycetes (Kulkarni et al., 1999; Sunna and Antranikian, 1997; Elegir et al., 1994). *Aspergillus*, *Trichoderma*, *Streptomyces*, *Clostridia*, *Chytridiomycetes*, *Fibrobacters*, *Phanerochetes*, *Bacillus*, and *Ruminococcus* are some of the important xylanase-producing microorganisms. Filamentous fungi are microorganisms of interest for production of xylanase and other accessory enzymes for xylan degradation, as fungi secrete enzymes into medium and level of enzymes production is higher as compared with yeasts and bacteria. Adsul et al. (2005) reported *Pichia*, *Trichoderma*, *Fusarium*, and *Aspergillus* as great xylanase producers. Qinnghe et al. (2004) reported that white-rot fungi produced extracellular xylanases acting on hemicellulosic substances and produced metabolites useful in different industries such as food, cosmetic, and pharmaceuticals. *Cunninghamella subvermispora* produced xylanase by using polysaccharides of plant cell wall as substrate (de Souza-Cruz et al., 2004). Noteworthy, Subramaniyan and Prema (2002) reported that *Bacillus* sp. produced high level of xylanase at alkaline pH and high temperatures. It was reported that xylanases from various microorganisms, such as *Bacillus firmus*, *Geobacillus thermolevorans*, *Actinomadura* sp. Cpt20, *Streptomyces* sp. S27, and *Saccharopolyspora pathunthaniensis* S582, showed optimum activity at higher (65 to 90°C) temperatures (Verma and Satyanarayana, 2012). Yoon et al. (2004) reported a xylanase from *Thermotoga* sp. having optimum temperature at 100 and 105°C. Mmango-Kaseke et al. (2016) reported xylanase production by *Micrococcus* sp. SAMRC-UFH3 isolated from sawdust under SmF condition. It was found that maximum (2487 U/mL) xylanase production was achieved when birch wood xylan (1% w/v) was used as a substrate at 25°C and pH 10.0. Bala and Singh (2017) reported xylanase production from thermophilic mold *Sporotrichum thermophile* strain BJAMDU5 in SSF at 45°C and pH 5.0 using mixed substrate, wheat straw and cotton cake in 1:1 ratio. They reported that enhanced 3455 U/g DMR (dry moldy residue) xylanase production achieved by the addition of Tween 80. Cerda et al. (2017) reported xylanase production at pilot scale in SSF using coffee husk by a specialized inoculum of bacteria (*Pseudoxanthomonas taiwanensis* and *Sphingobacterium composti*) and yeasts (*Cyberlindnera jadinii* and *Barnettozyma californica*) and obtained enzyme having activity 48  $\pm$  4 U/g DM. A newly isolated bacterium, *Pseudomonas boreopolis* LUQ1, was reported as potent xylanase producer by Lin et al. (2017). They reported that the enzymes have highest enzyme activity (25.61 U/mL) at pH 6.0 and 65°C after 96 h with wheat bran as substrate. Cunha et al. (2018) reported xylanase production under SmF by *Aspergillus foetidus* using soybean residues

and found maximum xylanase production (13.98 U/mL) at 28°C and pH 7.0 after 168 h. Xylanase production in SSF by *Aspergillus niger* CCUG 33991 in tray bioreactor using low-cost agro-industrial residues was reported by Khanahmadia et al. (2018). They found highest xylanase activity of  $2919 \pm 174$  U/g-IDW (initial dry weight) at 28–35°C and after 48 h using wheat bran with particle size within range of 0.3–0.6 mm. Xylanase producing various microorganisms have been enlisted in Table 2.

## Microbial Xylanases in Bread Making

Bread is one of the traditional and most common food items around the world and closely linked with enzymes. Owing to the demand of a wide range of bread types and increasing mechanization of the baking industry, there is a necessity to modulate structure and viscoelastic properties of dough. To improve bread-making performance, enzymes and chemicals are usually included in bread formulas (Dunnewing et al., 2002). On the other hand, nowadays consumers are aware about the relationship between diet and diseases and from this point of view, for bakers it's a great challenge to make nutritious bread, which is rich in bioactive compounds, high quality in terms of specific properties such as crumb and crust texture, volume, color, taste, and firmness (Paucean et al., 2016). Currently, the treatments with enzymes have been preferred over chemical additives, as enzymes do not have activity in final product (Caballero et al., 2007).  $\alpha$ -Amylases have been used for years in bakery industry. But now bakery industry is changed due to increased demand for natural products, and therefore, enzymes have gained more importance over chemicals because enzymes enhance bread quality by improving dough stability, flexibility, loaf volume, machinability, and crumb structure (Guy and Sarabjit, 2003; Baillet et al., 2003). Gray and Bemiller (2003) reported that xylanases and other enzymes have enhanced the strength of gluten network, directly or indirectly, and thus modified bread qualities. In bread, xylan plays a major role in quality improvement because of its water absorption capacity and its interaction with gluten (Nuyens et al., 2001). Xylanases make dough more forbearing to various processing parameters. Xylanases reduce the sheeting work requirements, reduce final bread volume, and make dough softer (Dervilly et al., 2002; Harbak and Thygesen, 2002). For the last few decades, the application of xylanolytic enzymes is increased due to their effectiveness in bread making. Bakery industry use enzymes that hydrolyze starch and nonstarch carbohydrate as a quality improver (Javier et al., 2007; Polizeli et al., 2005), and hydrolysis of nonstarch polysaccharides by enzymes resulted into enhanced rheological properties (specific volume, crumb firmness, etc.) (Martínez-Anaya and Jimenez, 1997). Water-insoluble hemicelluloses are transformed into water-soluble form by the action of xylanases and bind water in dough and resulted into decreased dough firmness, finer and more uniform crumbs, and increased volume. Xylanase application improves dough-making conditions, i.e., dough becomes machine friendly and does not stick to the machine parts (Rouau, 1993). During the process of gluten–starch segregation, gluten is formed initially as a result of gliadin–glutelin structures. Therefore, for studying the effects of xylanases, they can be added after mixing of other ingredients by simple alteration in glutomatic system. After mixing, reaggregation of gluten protein starts immediately during dilution of dough. Xylanase addition at this stage significantly affects

the formation of gluten. Addition of xylanases before mixing of dough can cause overdose effects, but when xylanases are added later at the time of agglomeration phase, this effect is not observed. Xylanases chiefly act during the reagglomeration of gluten followed by gluten structure break down and affect rheological properties of gluten (Wang et al., 2004). Endoxylanases have abilities for the transformation of water-unextractable arabinoxylan (WU-AX) to water-extractable AX (WE-AX), and they also have ability for the degradation of WE-AX. Endoxylanases of *A. niger* family GT10 and *Bacillus subtilis* family GT11 behave distinctly in bakery applications. Xylanases from *Bacillus subtilis* cleave AX backbone in unsubstituted region, but xylanases from *A. niger* cleave branched region and produce small units when compared with *Bacillus subtilis* xylanase (Biely et al., 1997). *A. niger* xylanase degraded WE-AX, decreased the molecular mass and dough viscosity, and solubilized AX, and the solubilized AX resulted into larger gluten aggregates formation (Romanowska et al., 2003). *Bacillus subtilis* xylanase particularly solubilized WU-AX, increased the viscosity of dough, and also have negative impact on agglomeration of gluten (Courtin and Delcour, 2002) (Table 3).

Xylanases and other enzymes, which hydrolyzed the complex cell wall, are used for improving bread quality and dough-handling properties by reducing staling rate and also to extend the shelf life of bread (Sorensen et al., 2001; Wang et al., 2004). Xylanases as an alternative or in combinations with other emulsifiers can be used for all types of breads (Olse, 1995; Sprössler, 1997), and xylanases also contributed in the replacement of chemical additives such as bromate. The gradual increase in crumb firmness is associated with staling of bread (Gray and Bemiller, 2003; Scanlon and Zghal, 2001), and during storage of bread, xylanases have an antistaling action. Xylanases used in bread making are mostly precise for insoluble AX, and those that are precise for soluble AX show negative effect on quality of bread. Courtin and Delcour (2002) reported that the application of xylanases enhanced the dough softness and tolerance; over spring; and shape, volume, and texture of bread. Baking trials were performed with six types of wheat and different enzymes, and their combinations were reported by Hilhorst et al. (1999). They found that dough containing xylanases and peroxidases showed best result on comparing bread volume, crumb structure, and dough properties. Martínez-Anaya and Jimenez (1997) prepared a bread sample using two laboratory samples and nine commercial enzyme preparations having activity for amylase and/or xylanase, and they found that enzyme addition significantly shortened fermentation with improved volume, aroma, and softer texture of the bread (Martínez-Anaya and Jimenez, 1997). Chemical and high-performance size-exclusion chromatography indicated that xylanase acted on both hot and cold water-extractable arabinoxylans (Hilhorst et al., 2002). Jiang et al. (2005a,b) reported that the addition of xylanase B (120 ppm) from *Thermotoga maritima* improved the specific volume up to 60.3%. It also improved the cell structure of the crumb and enhanced the fresh bread crumb texture. The firmness of the fresh bread was reduced to 42.1%–68.4% as compared with the control. Along with lipase,  $\alpha$ -amylase, and protease, xylanases are considerably effective for making bread with higher specific volume, improved texture profile, and reduced firmness of crumb in microwave oven (Mathewson, 2000; Ozmutlu et al., 2001; Keskin et al., 2004). Laurikainen et al. (1998) added 12 U/g flour of partially purified xylanase of *A. foetidus* at the time of mixing and found 72%–64% reduction in water absorption, increased dough softening, and reduced dough stability. Xylanases of *A. niger* var. *awamori* and *T. maritima* improved specific volume of bread as reported by Maheshwari et al. (2000). The softness of the baked products directly related with its moisture content, and for bread, the ideal level of moisture is in between 35%–40% (Kamaliya and Kamaliya, 2001). Pyler (1988) reported that breads having moisture content less than 30% cannot be refreshed even after heating. Supplementation of xylanase from *Thermomyces lanuginosus* CAU44 in wheat bread preparation increased the final moisture content from 29.4% to 34.5% in fresh bread (Jiang et al., 2005a,b). Shah et al. (2006) found positive influence of partially purified *A. foetidus* MTCC 4898 xylanase on dough. The evaluation of sensory properties showed the favorable effect of enzyme on whole wheat bread qualities. Endoxylanase (500–1000 U/kg flour) from *A. niger* IBT-90 resulted in increased loaf volume in whole meal and wheat–rye bread, which improved on kneading (Romanowska et al., 2003). It also resulted in higher moisture content, better crumb porosity, and extended shelf life without increasing total acidity (Romanowska et al., 2003).

Bread made of composite flour (CF, 60% wheat flour and 40% hull-less barley) showed increased total AX and total and soluble (1,3)-, (1,4)- $\alpha$ -D-glucan but decreased specific loaf volume of bread, but addition of xylanase significantly increased the loaf volume of CF bread and increased soluble AX of wheat flour and CF dough. The combination of xylanase with CF gave bread with increased total and soluble (1,3)-, (1,4)- $\alpha$ -D-glucan content (Trogth et al., 2004). In baking process of unleavened Indian flat bread, which is also known as South Indian parotta, role of different enzymes was studied by Prabhasankar et al. (2004). They compared the effects of xylanase, fungal amylase, protease, and glucose oxidase on microstructure and rheological properties of dough. They reported that the application of xylanase and protease improved the quality score of 92 and 82, respectively, when compared with control (74). A particular endoxylanase of *A. niger* showed effectiveness in improving specific volume of bread without any negative side effect on dough handling (Ahmad et al., 2014).

Novozymes has introduced Panzea, from a new generation of xylanases, claimed to be the first baking xylanase to significantly combine superior volume performance and desired texture and appearance with balanced and dry dough. These enzymes performed very well at very low dosages across a broad range of baked products, baking conditions, and flour types and are not inhibited by inhibitors commonly found in wheat. Bread improver companies and flour mills often have to use a variety of xylanases to find exactly the right combination to achieve the desired baking results. Panzea, produced by *B. licheniformis*, has been documented internally and externally to achieve the desired crumb structure, loaf volume, and dough characteristics at low dosages (Novozymes, 2013).

The comparison of the abilities of xylanases from *Aspergillus oryzae*, *Trichoderma reesei*, and *Humicola insolens* for quality improvement of wheat flour bread was studied by Basinskiene et al. (2006), and they found that *A. oryzae* was more effective among all and increase 8%–13% of specific volume of bread and decrease 15%–24% in crumb firmness, but xylanase from *T. reesei* showed maximum antistaling effect. Pescado-Piedra et al. (2009) reported the effect of enzymes on the rheological properties of dough

**Table 3** Effects of xylanases on nutritional properties of bread

Enzyme	Source	Flour type	Enzyme dose (U/kg flour)	Improvement in quality parameter	References
Xylanase	<i>Trichoderma reesei</i>	Wheat flour	5990	Softening, increased specific volume by almost 20%, reduced staling rate	Laurikainen et al., 1998
Xylanase	Ex <i>Trichoderma</i> (Biocake CX160)	commercial untreated cookie type flour	105,000	Improved handling properties of dough, improved crumb structure, and increased loaf volume increased,	Hilhorst et al., 1999
Xylanase	–	Wheat flour	–	Improve specific volume	Maheshwari et al., 2000
Xylanase	Shearzyme 500L BY NOVO Nordisk A/S (Madrid, Spain)	Wheat flour	14600	Softer crumb, high specific volume, and reduced firming rate	Haros et al., 2002
Xylanase	<i>Aspergillus niger</i> IBT-90	Wheat-rye and whole-meal	500–1000	Improved kneading, increased loaf volume, higher moisture in bread, improved crumb porosity, and extended shelf life.	Romanowsk et al., 2003
Xylanase	<i>A. niger</i> , Biocon, India	Wheat flour	175	Softer dough, delayed crumb formation, and water redistribution	Prabhasankar et al., 2004
Xylanase	<i>Thermomyces lanuginosus</i> CAU44	Wheat flour	26.63–1065.2	Decreased crumb firmness upto 21.4%, reduced firming rate 0.8–0.43 N d <sup>-1</sup> and showed anti-staling effect, improved specific volume (41.4%).	Jiang et al., 2005
Xylanase	<i>Aspergillus foetidus</i> MTCC 4898	Wheat flour	12000	11% decrease in water absorption, 28.5% increase in dough rising, 40.5% increase in final moisture content, 53% increase in volume and 56% in specific volume with better taste, softness and flavour	Shah et al., 2006
Xylanase	Megazyme International Ireland Ltd. <i>Trichoderma longibrachiatum</i>	Super bakers flour	9000	Improved crumb softness, loaf volume, and colour; reduced staling rate, and loered firmness.	Al-Widyan et al., 2008
Xylanase	<i>A. niger</i>	Wheat flour	600	Increased bread volume (610.0 ± 33.96 <sup>a</sup> cc), increased moisture content (36.5 ± 1.48 <sup>a</sup> ), and improved sensory attributes.	Ahmad et al., 2014
Xylanase	Pentomax (Prozyn Ind. e Com. Ltda., São Paulo, SP)	Whole grain-wheat flour	160	Higher specific volume, lowest crumb firmness ( $p \leq 0.05$ )	Jaekel et al., 2012
Xylanase	<i>Penicillium citrinum</i> MTCC9620	Whole-wheat flour	59.9	Increased specific volume (3.99 ± 0.035 mL/g), softer crumb, reduced staling rate, and brighter colour of bread	Ghoshal et al., 2016
Xylanase	<i>Penicillium occitanis</i> Pol6	Whole wheat flour	120	8% decrease in water absorption, 36.8% increase in dough rising, 37.50% increase in final moisture content, and improved volume (17.8%) and specific volume (34.9%)	Driss et al., 2013
Xylanase	Enzymes & Derivates, Neamt, Romania	Wheat/Wheat gram flour	135–162	Improved elasticity and porosity of bread improved the elasticity and porosity	Paucean et al., 2016
Xylanase	<i>P. citrinum</i>	Wheat flour	59.9	Reduced water absorption, softer dough, greater extensibility and less resistance to extension	Ghoshal et al., 2017
Xylanase	<i>Trichoderma stromaticum</i>	Wheat flour and whole grain flour	350	Increase in specific volume of both flour bread, improved stability and elasticity, and mixing tolerance of doug.	Carvalho et al., 2016
Xylanase	<i>Sporotrichum thermophile</i> BJAMDU5	Wheat flour	350	Increased (32.33%) moisture content compared to control (29.13%). Improved amount of metal ions (Na <sup>+</sup> , K <sup>+</sup> , Ca <sup>2+</sup> ), and higher soluble protein (11.23 mg/ml) and amino acid (10.43 mg/mL) amount as compared to control.	Bala and Singh, 2017

and qualities of bread and found increase in water absorption on addition of peroxidase and xylanase. Ahmad et al. (2014) investigated the various treatments of *A. niger* xylanase in bread-making process, during wheat kernels and dough mixing, on dough qualities, i.e., extensibility, dryness, elasticity, stiffness, coherency, bread volume, specific volume, moisture retention, density, and other sensory attributes. They observed that stiffness and dryness of dough were decreased but found increase in elasticity, coherency, extensibility, and volume but decrease in bread density. Xylanase treatment also resulted in improved sensory attributes of bread with higher moisture retention capacity. To analyze the impact of xylanases addition on frozen dough, wet gluten, and quality improvement in bread, a number of studies have been carried out (Steffolani et al., 2012; Cristina et al., 2005; Krishnarau and Hoseiney, 1994). Ren and Ma (2016) investigated the effects of xylanase on quality of frozen dough and steamed bread stored at a freezing temperature for different time intervals. They found that leavening power, specific volume, antistaling rate, and survival rate of yeast in frozen dough and steamed bread can be decreased on prolong frozen storage time. By contrast, addition of xylanase can significantly improve these properties. Supplementation of frozen dough with 80 mg/kg xylanase had low freezable water content ( $28.51 \pm 0.37\%$ ), which was lower than control ( $40.22 \pm 0.43\%$ ). Addition of xylanase significantly lowered the melting point and the melting scope of ice crystals resulted into similar crystal of ice in frozen dough with improvement in frozen dough and steamed bread quality. The influence of supplementation with different doses of xylanase on the properties of loaf bread made of white wheat flour or whole grain wheat flour was studied by Jaekel et al. (2012). They reported that the bread made of white wheat flour and xylanase had higher specific volume as compared with control. Xylanase addition to whole grain wheat flour increased the specific volumes significantly as compared with control. Driss et al. (2013) tested xylanase from *Penicillium occitanis* Pol6 as a quality improver for whole wheat bread and observed a significant increase in dough rising with decrease in water absorption and increase in moisture content (37.50%), specific volume (34.9%), and volume of bread (17.8%), and firmness was decreased more than twofolds. Evaluation of sensory properties showed improved taste, softness, flavor, and overall acceptability. Improved cohesiveness, decrease in gumminess and springiness were also observed. Zheng et al. (2011) studied and compared the effectiveness of two GH10 xylanases, XynA from *Glaciecola mesophila* and EX1 from *Trichoderma pseudokoningii* on bread making. The optimum dosages of both (0.9 U/kg flour XynA and 270 U/kg flour EX1) resulted into improvement if wheat flour dough as well as bread quality with 50% decrease in Brabender units. They also found that XynA more effectively reduced the time to reach maximum consistency as compared with EX1, but both enzymes had similar effects on increasing bread volume (30%).

## Conclusions

Bread is one of the major parts of food item all over the world. Xylanases have great potential to be used in baking industry. Literature have strong evidence, which supported the application of these enzymes in bread making resulted in reduced stickiness, increased bread volume and shelf life, and also increased nutritional value. These enzymes can replace the addition of various chemical additives and emulsifiers in baking industries.

## Glossary

**Aerobic gram-negative bacterial** These are a group of gram-negative bacteria that are able to grow under an air atmosphere and have an inner cell membrane surrounded by a thin layer of peptidoglycan which is a combination of proteins and sugars with the inner cell membrane unable to retain gram stain dyes typically used to identify bacteria.

**Glycoproteins** These are simply proteins with have sugar molecules attached and are usually found floating in or around the membrane of cells. The sugars may be attached to proteins in the endoplasmic reticulum, and in the Golgi apparatus.

**Isoelectric point** The isoelectric point of a molecule or surface refers to the pH at which a molecule or surface carries no net electrical charge.

**Isoenzymes** These are simply alternative forms of enzymes with different structures that are capable of catalysing the same reaction.

**Moiety** This is used to refer to a part of a molecule for instance the alkyl group of an organic compound responsible for the physical properties of a chemical compound.

**Nonsporogenic** Any fungi that does not produce spores.

**Saprophytic** This refers to the act of getting energy from dead or decaying matter. A saprophyte or saprotroph is therefore an organism which gets its energy from dead and decaying organic matter implying that saprophytes are heterotrophs.

## Nomenclature

List of nomenclature used including all definitions and units.

kDa kilodalton

BCL *Burkholderia cepacia* lipase

CALB (CALA) *Candida Antarctica* lipase B (A)

CRL *Candida rugosa* lipase

GRAS Generally Recognised as Safe status

RML *Rhizomucor miehei* lipase

ROL *Rhizopus oryzae* lipase

TLL *Thermomyces lanuginosus* lipase

## Introduction

Lipases (EC 3.1.1.3) are triacylglycerol ester hydrolases, considered as one of the two major classes of hydrolases, with the second class identified as the so called 'true' esterases (EC 3.1.1.1. carboxyl ester hydrolases). According to Vakhlu and Kour (2005), lipases were previously classified as serine hydrolases due to the presence of serine in the highly conserved domain of their active sites. This serine presents the only common feature shared by all identified lipases sequenced thus far (Vakhlu and Kour, 2005). Lipases are distinguishable from carboxyl esterases via spectral assessment of their substrates, since *p*-nitrophenyl palmitates are cleaved by lipases while *p*-nitrophenyl butyrates are cleaved by esterases. These two major classes of hydrolases can also be distinguished by assessing differences in stabilities in organic solvents, since lipases exhibit higher stabilities compared to esterases (Bornscheuer, 2002). Lipases are recognised as very important industrial inputs as illustrated by applications in the food processing industry (cheese ripening and flavour development) (Saxena et al., 1999), cosmetic industry (aroma production) (Metzger and Bornscheuer, 2006), bioenergy industry (biodiesel production), pollution remediation (oil spill management) (Nakamura and Nasu, 1990) and commercial cleaning industry (alkaline lipase from *Pseudomonas alcaligenes* M-1 used in removing oil stains) (Gerritse et al., 1998).

Lipases are characterised by molar weights ranging from 20 to 75 kDa with their optimal pH and optimal temperature conditions ranging from 6 to 8 and from 30 °C to 40 °C respectively (Giovana da Silva et al., 2012). Typically, the molecular weight of a lipases may be greater than 75 kDa, if the lipase has the capacity to form aggregates in solution (Gill and Parish, 1997). According to Gill and Parish (1997), the majority of lipases secreted by organism function extracellularly and are characterised by acidic glycoproteins containing between 2% and 15% carbohydrates and with the major glycoside residue being mannose. Most importantly, lipases are biocatalysts capable of acting on a range of substrates to enhance a multitude of reactions (Montero et al., 1993; Moura et al., 2017). Lipases are widely available in nature with extracts of lipases readily isolated from plant

**Table 1** Characteristics of some lipases obtained from different sources

Source organism	Organism source	Short description
<i>Burkholderia cepacia</i>	Bacteria (Thakur, 2012)	BCL lipase is highly tolerant to methanol and displays particularly high conformational stability under conditions employed during transesterification reactions for biodiesel production (Sasso et al., 2016). The lipase source is an aerobic gram-negative bacillus and is one of the most thoroughly studied lipase sources.
<i>Candida Antarctica</i>	Fungi (Thakur, 2012)	The organism produces two lipases namely CALB and CALA, characterised by a similar optimum pH of 7. CALB (CALA) is also characterised by a molecular weight, an isoelectric point and a specific activity of 33 kD (45 kD), 6 (7.5) and 435 (420) respectively (Kirk and Christensen, 2002). Most importantly CALB and CALA differ in terms of their positional specificity toward triglycerides, with a positional specificity of <i>Sn</i> -3 and <i>Sn</i> -2 reported respectively (Kirk and Christensen, 2002). Both lipases are characterised by an almost uniform activity towards straight-chain primary alcohols and carboxylic acids (Kirk and Christensen, 2002).
<i>Candida rugosa</i>	Fungi (Thakur, 2012)	The organism generates lipases that contain at least five isoenzymes of varying proportions and varying stabilities. It is speculated that the existence of these five related but non-identical isoenzymes enhances the adaptability to different substrate sources (Benjamin and Pandey, 1998). The CRL is popularly used in fat-splitting operations in the food industry due to its proven Generally Recognised as Safe (GRAS) status (Gurung et al., 2013) where the organism is nonsporogenic, pseudo-filamentous, unicellular and non-pathogenic in nature (Benjamin and Pandey, 1998).
<i>Rhizomucor miehei</i>	Fungi (Thakur, 2012)	RML is used for many applications in the conversion of fats and oils and in chemical processes. In its free and immobilised forms it has a very high activity and good stability under diverse conditions (Rodrigues and Fernandez-Lafuente, 2010). The lipase also has a high enantiospecificity.
<i>Rhizopus oryzae</i>	Fungi (Thakur, 2012)	The lipase produced by this fungi, ROL, also has GRAS status, which is responsible for its wide acceptance in the food and biotechnology industry (Cantabrana et al., 2015). It is a potent saprophytic and pathogenic fungus which can produce a spectrum of metabolites, such as esters, polymers and bioalcohols (Ghosh and Ray, 2011).
<i>Thermomyces lanuginosus</i> (TLL)	Fungi (Maheshwari et al., 2000)	TLL is used in large amounts in detergents and various synthetic applications. It is characterised by a molar mass of 31.7 kDa and an isoelectric point of 4.4 (Jha et al., 1999). It is a widely distributed thermophilic fungus, thriving at temperatures up to 60 °C but fails at temperatures lower than 20 °C (Singh et al., 2003). It has the capacity to produce high levels of cellulase-free thermostable xylanase, which has wide biotechnological applications (Singh et al., 2003).
<i>Pentaclethra macrophylla</i> Benth	African bean seeds (Enujiugha et al., 2004)	This lipase is characterised by a high thermal stability with lipolytic activity reported at temperatures up to 80 °C (Enujiugha et al., 2004). Optimum temperature and pH conditions have been reported to be 30 °C and 7 respectively. High sensitivity of the enzyme to salts has however been reported with the presence of mercury chloride and sodium chloride significantly inhibiting the catalytic ability (Enujiugha et al., 2004).

and animal sources (Sevil et al., 2012). Table 1 presents some examples of characteristics and sources of common lipases used in the biotechnology industry.

Lipases are also characterised by high bio-catalytic activities when acting on water-insoluble substrates, such as triglycerides composed of long-chain fatty acids, and are typically characterised by a high chemo-, regio- and stereoselectivity, in organic solvents (Barros et al., 2010). Crucially they are generally recognised as environmentally benign with their catalytic effect optimised when mild reaction conditions are imposed (Ferreira-Dias et al., 2013). The effectiveness of lipases in catalysing processes under mild condition also promotes its application in several reactions. Major reactions that can be catalysed using a lipase are presented in Fig. 1.

Fig. 1 shows that lipase can effectively catalyse acidolysis, alcoholysis, aminolysis, interesterification, glycerolysis and hydrolysis reactions, when a triglyceride molecule is the substrate (Pandey et al., 1999).

From Fig. 1, the interesterification reaction involves the exchange of an acyl radical between the parent triglyceride and a 'donor' triglyceride. If however the donor is a free fatty acid, then the reaction is considered as an acidolysis reaction. The exchange of acyl radicals is typically undertaken to improve the properties of the parent triglyceride molecule. On the other hand the displacement of the acyl moiety between the triglyceride and an alcohol (ROH) serves to generate biodiesel. Similar acyl moiety exchanges between the triglyceride and glycerol ( $C_3H_5(OH)_3$ ) is called a glycerolysis reaction. Such glycerolysis reactions serve to generate useful mono- $(C_3H_5(OH)_2(OOCR''))$  and di- $((C_3H_5(OH).(OOCR''))_2)$  glycerides, which are useful products used in the food industry since both products can be used as food stabilisers in air-in-liquid emulsions like cake batter or ice cream.<sup>1</sup> The hydrolysis reaction serves to split the triglyceride molecule into its glycerol backbone and constituent fatty acid ( $R''COOH$ ) fragments. The aminolysis reaction serves to split the parent triglyceride by reacting the triglyceride with ammonia ( $NH_3$ ) or amines ( $R-NH_2$ ) to form a fatty acid amide ( $R''CONHR$ ).

**Figure 1** Lipase catalysed reactions involving triglycerides as the substrate (where  $*C_3H_5(OOCR'')$  represents the parent triglyceride and  $C_3H_5(OOCR')$  represents the 'donor' triglyceride in the interesterification reaction).

According to Ribeiro et al. (2011) most lipase catalysed reactions are initiated by a nucleophilic attack on the carbon present in the ester bond of the susceptible substrate by an hydroxyl group in the serine residue of the active site of the lipase. Nucleophilic attack results in the formation of an acyl–enzyme complex and the release of alcohol from the triglyceride substrate. The regeneration of the lipase is achieved via the hydrolysis of the acyl–enzyme complex. This process may occur via complex or simple mechanisms, depending on several factors, such as temperature, presence of inhibitors and substrate concentration (Artoli, 2008).

The ability of the lipases to catalyse acidolysis, alcoholysis, interesterification, glycerolysis and hydrolysis reactions has been explored extensively in the biofuel industry as the basis for the development of an environmental friendly production process. According to Alonso et al. (2005), the versatility of lipases in enhancing the hydrolysis of ester–carboxylate bonds at the organic–aqueous interphases and esterification–transesterification reactions in water-restricted environments is responsible for its extensive use in the biodiesel (biofuel) industry.

### Lipase Application in Biodiesel Production

The utilisation of lipases in catalysing transesterification (alcoholysis) reactions for biodiesel production processes was first reported by Mittelbach (1990). Mittelbach demonstrated the utilisation of *Pseudomonas fluorescens* lipase to enhance the alcoholysis of sunflower oil using methanol (Mittelbach, 1990). Over the years, more research has been undertaken to explore the activity of lipases in biodiesel production processes when different oil substrates are utilised (Rodrigues et al., 2016; Amini et al., 2017).

This is largely due to the ability of lipases to act on a wide range of oils including low grade oils characterised by a high free fatty acid content, such as dissolved air flotation sludge oil extract (Okoro et al., 2017a), without initiating unwanted side saponification reactions occurring (Rodrigues et al., 2016; Okoro et al., 2017b). Table 2 presents some examples of previous work that have explored lipase utilisation in biodiesel production processes.

### Lipase Immobilisation

Table 2 suggests that high biodiesel yields are feasible when lipases in different forms are used as biocatalysts. However current applications have suggested the preference of the immobilised lipase forms as a means of circumventing several biofuel production limitations identified when lipases in their free forms are utilised (Zhao et al., 2015). Some of these limitations include an escalation of the production costs due to the difficulty of lipase recovery and reuse and the increased possibility of production promoting product contamination with residual enzyme (Ribeiro et al., 2011). Other benefits arising from the application of immobilisation techniques includes an improvement in the thermal stability, pH stability of the lipase and an enhanced tolerance of the lipase to chemical species in the reaction mixture (Zhao et al., 2015; Silva et al., 2013). Such improvements in the properties of the lipase via the application of immobilisation methods will increase the applicability of lipase in continuous biofuel production systems as a result of the enhanced lipase adaptability (Silva et al., 2013).

Lipase immobilisation, in the simplest terms may be considered as the confinement of the lipase in a region or a defined space while simultaneously ensuring that the catalytic activity of the lipase is maintained (Tan et al., 2010). Lipase immobilisation is usually achieved by tethering the lipase to a suitable supporting matrix which must be hydrophilic, inert (to the lipase), biocompatible, resistant to microbial attack, resistant to compression and readily accessible at a low cost (Mohamada et al., 2015). According to Cao

**Table 2** Biodiesel production using lipase as catalyst

Substrate	Alcohol used	Lipase	Form	Temperature (°C)	Reaction time (h)	Performance (%)	References

(2006), several factors influence the performance of an immobilised lipase such as the pore size of the carrier, the microenvironment of the carrier and the strength of the hydrophobic partition. These factors influence the extent of catalytic activity retention, the lipase stability and the rate of action on a hydrophobic substrate respectively. Thus although the introduction of immobilisation strategies will enhance the ease of the lipase separation for recovery and reuse (Ribeiro et al., 2011), leading to lower operating process cost, the technique and nature of immobilisation must be properly selected based on specific processing targets.

### Immobilisation Methods

There are five major lipase immobilisation methods identified in the literature, namely, covalent, adsorption, cross linking (or aggregation), entrapment and encapsulation methods (Sirisha et al., 2016; Bickerstaff, 2009). These methods have been summarised and illustrated in Table 3 and Fig. 2 respectively.

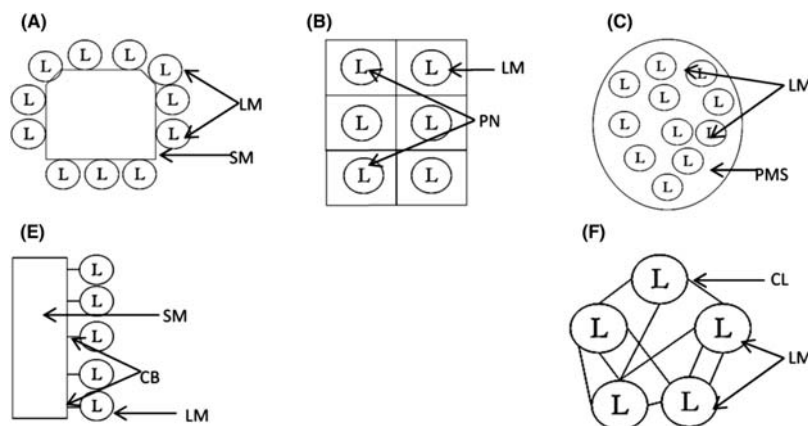

### Future Prospects

It is recognised that the utilisation of lipases in enhancing reactions provides a pathway that is comparatively more environmentally benign compared to reactions that utilise chemical catalysts (acid or alkaline). The high cost of lipase has however thus far limited its use in large scale processes (Poppe et al., 2015). Lipase high cost is exacerbated by lipase deactivation that typically occurs in the presence of alcohols for biodiesel production thus limiting lipase reuse options (Abdelmoez and Mustafa, 2014). Although there have been reports of an improved recoverability of the lipase for reuse via the incorporation of immobilisation techniques, current immobilisation systems are still limited by several factors. Some of these factors include possible losses in catalytic activity of the lipase, high cost of more suitable lipase supports, reduced stability of the immobilised lipase catalyst in oil–water subsystems and increased mass transfer restrictions in the immobilised lipase reaction system (Zhao et al., 2015).

Genetic engineering has therefore been proposed as a tool that can enable improved yields of better performing lipase strains at reduced production cost. This is because lipases can be genetically engineered to have high catalytic activities, to be stable in organic solvents, and enhance product recovery (Abdelmoez and Mustafa, 2014). Examples of successful recombinant DNA technology application include the improvements introduced to *Aspergillus oryzae* and *Pichia pastoris* strains which have been genetically modified to express the properties of several microbial lipases which can be used in biodiesel production (de Simone et al., 2016). The utilisation of whole cells as biocatalyst is also expected to reduce lipase catalysed biofuel production processes since the need for

**Table 3** Major enzyme immobilisation methods

Immobilisation methods	Short discussion
Adsorption bonding [Fig. 2A]	This immobilisation bonding method is recognised as the most straightforward immobilisation method since lipase attachment is achieved in the absence of any chemical transformations. The tethering of the lipase to the support or carrier is achieved using weak intermolecular forces such as van der Waals or dispersion forces (Jegannathan et al., 2008). It is the most widely used immobilisation technique due to its simplicity and low cost (Lukovic et al., 2011). This immobilisation method is however limited by changes in ionic strength during the catalysing process, which may lead to lipase desorption (Rai, 2012). The lipase may also be susceptible to microbial or proteolytic attack.
Entrapment bonding [Fig. 2B]	Entrapment describes the immobilisation of the lipase via the ‘sealing’ of an enzyme within a polymeric network (Brena and Batista-Viera, 2006). The polymeric network enables the transfer of substrate and products across the polymeric network barrier while retaining the lipase within the polymeric network (Mohamada et al., 2015). This immobilisation method is considered as irreversible since the separation of the lipase from the polymeric matrix may require the destruction of the matrix (Mohamada et al., 2015). This immobilisation method is simple and is characterised by no intrinsic changes in lipase properties from chemical modification. This method is however limited by the possibility of enzyme leakage and diffusional constraints of the products and reactants. Furthermore the mass of lipase that can be immobilised within the polymeric network is clearly limited (Mohamada et al., 2015; Brena and Batista-Viera, 2006).
Encapsulation bonding [Fig. 2C]	Encapsulation is the confinement of the enzyme within a porous membrane forming a bilayer (Jegannathan et al., 2008). Encapsulation does not require any interaction between the catalyst and the support, with the size of the pore opening of the support considered crucial as it determines the mass transfer resistance of the reactants and products while also preventing any losses in the encapsulated lipase (Zhao et al., 2006). Several reports have however suggested that such encapsulation may occasionally lead to the inactivation of the lipase molecule (Dwevedi, 2016).
Covalent bonding [Fig. 2D]	This method is based on the formation of covalent bond between the lipase molecule and the support material using side chain amino acids such as histidine with the reactivity of the immobilised lipase influenced by the functional group that is present in the side chain (Sirisha et al., 2016). In cases where the bonds existing between the lipase molecule and the support are due to the presence of strong electrostatic (ionic) forces, such an immobilisation method is referred to as ionic bonding (Tor et al., 1989). The utilisation of such strong (covalent) bonds may however lead to significant changes in the conformational and catalytic properties of the lipase molecule (Dwevedi, 2016).
Cross linking [Fig. 2E]	This method involves the utilisation of bi- or multifunctional reagents to stimulate the aggregation of lipase molecules such that the lipase molecule does not undergo any denaturation (Talekar et al., 2012). This method ensures that the activity or the catalyst productivity is not negatively influenced since the cross linking agent is typically characterised by a molar mass that is large compared to the molar mass of the lipase molecule (Talekar et al., 2012). There is however increased possibility of catalyst loss due to the non-regulation of the aggregation reaction and reduced reactivity due to limitations caused by diffusion (Dwevedi, 2016).

**Figure 2** An illustration of the major immobilisation methods (LM represents lipase molecule; SM represents support matrix; PN represents polymeric network; PMS represents porous support matrix; CB represents covalent bond; CL represents the cross linkage).

lipase recovery and purification is avoided (Soares et al., 2017). Future modifications in existing immobilisation technologies such as the use of biopolymers as mobilisation supports will also enhance lipase recovery and improved product separation while also enhancing the environmental performance of biofuel production processes (Ravindra and Jegannathan, 2015).

Another possible future prospect is the incorporation of intensification approaches, such as the utilisation of ultrasonic and microwave radiation to optimise the activities of immobilised lipases (Subhedar and Gogate, 2017). This is because the application of ultrasonic and microwave radiation provide a low cost option for energising the lipases (Subhedar and Gogate, 2017). Finally, appreciating that the performance and economics of lipase catalysed biofuel production processes are dependent on a proper integration of the aforementioned improvements any future lipase aid biofuel production technology must incorporate an optimisation protocol with the production cost identified as an important objective function (Luna et al., 2016).

## Conclusion

This chapter has highlighted the role of lipases as important biocatalysts in several industries, largely based on their abilities to reduce waste generation and thus lead to favourable environmental outcomes. The importance of lipases to the biofuel industry has been emphasised. Published studies that investigated the applicability of lipases (free and immobilised forms) in the biofuel industry were also highlighted. Enhanced performances of reactions catalysed using immobilised lipases compared to the lipases in free forms, were reinforced and discussions highlighting the benefits of lipase immobilisation, presented. Major immobilisation techniques were also briefly explained. As explained in this chapter, although the utilisation of lipases in catalysing biofuel production processes has many associated advantages, several limitations persist that have thus far hindered large scale applicability. It was suggested that these limitations are largely due to the high cost of lipases, with future perspectives focused on reducing the unit lipase cost. These future perspectives were therefore initially discussed.

### Glossary

**Acidolysis** A chemical reaction involving the decomposition of a molecule, with the addition of the elements of an acid to the molecule, analogue to hydrolysis in which water plays a similar role to that of acid.

**Carboxylic ester hydrolases** An enzyme catalysing the hydrolysis of an ester bond resulting in the formation of an alcohol and a carboxylic acid in the presence of water.

**Interesterification** Redistribution of the fatty acid moieties present in a triacylglycerol molecule or between two ester molecules.

**Kinetic resolution** A process of differentiating two enantiomers in a racemic mixture with a chiral catalyst or reagent.

**Solid state fermentation** Fermentation process in which microorganisms grow on solid material without the presence of free liquid.

**Structured lipid** Lipids that have been modified from their natural form for specific food and nutraceutical applications.

**Submerged state fermentation** Fermentation process in which microorganisms are grown in free flowing liquid substrate such as corn steep liquor, molasses and nutrient broth

### Nomenclature

API Active pharmaceutical ingredient

CAGR Compound annual growth rate

CALB *Candida antarctica* lipase B

CBE Cocoa butter equivalent

CBS Cocoa butter substitute

DAG Diacylglycerol

DHA Docosahexaenoic acid

EPA Eicosapentaenoic acid

FAE Ferulic acid esterase

FE Feruloyl esterase

FFA Free fatty acid

GLY Glycerol

HCA Hydroxycinnamic acid

HMF Human milk fat

HMFS Human milk fat substitute

 VLCT Very long-chain triacylglycerol  
 w/o Water-in-oil

## Sources and Classification of Lipases and Esterases

### Animal Sources of Lipase and Esterase

Lipases exist in various organs and tissues of human and animal species. Among the various types of lipase, the most widely studied lipase is the pancreatic lipase. Human pancreatic lipase is secreted by the pancreas into the duodenum to hydrolyse the dietary triacylglycerol (TAG) into free fatty acids (FFA), monoacylglycerol (MAG), diacylglycerol (DAG), and glycerol (GLY). Unlike nonhuman pancreatic lipase, human pancreatic lipase does not exhibit phospholipase activity. Apart from pancreatic lipase, the digestion of dietary TAG is also aided by other lipases secreted from gastric, lingual and pharyngeal which accounted for 50% of the dietary fat breakdown (Bauer et al., 2005; Mukherjee, 2003). Besides pancreatic, gastric, lingual, pharyngeal lipase, human milk lipase or the so-called bile salt stimulated lipase which is present in 1% of human milk is also responsible in helping the premature infant to digest and absorb human milk fat. The structure of human milk lipase is unique in such a way that it is considered a glycoprotein having around 10% of carbohydrate attached to the protein moiety (Olivecrona et al., 2003). Further, there are also lipases such as human lipoprotein lipase and hepatic lipase that are involved in the degradation and metabolism of lipoprotein.

Similarly, esterases can also be found in various organs and tissues of human and primate animals (Rhesus monkey, cynomolgus monkey, dog, guinea pig, rabbit, mouse, Nile Tilapia). They are present in the plasma, brain, liver, lung, small intestine, kidney, muscle tissue, saliva and oviducts (Bahar et al., 2012; Li et al., 2007; Valocky et al., 2007; Yue et al., 2009). In humans and animals, esterases are essential in activating drug from pro-drug, inactivating the active therapeutic drug, detoxifying potential toxicants and maintaining the physiological function of the body (Fukami and Yokoi, 2012). Examples of esterases includes cholesterol esterase, cholinesterase, leukocyte esterase, thioesterase, acetylcholinesterase. Among them, cholinesterase and carboxylesterase are the major types of esterases that can be found in the plasma of humans and rodents (Rudakova et al., 2011). Interestingly, arthropod species especially plant bugs such as wild silkworm *Antheraea polyphemus*, *Lygus lineolaris*, *Spodoptera litura*, tobacco hornworm, *Manduca sexta* also contain enzyme esterase (Shankarganesh et al., 2012; Srigiriraju et al., 2009; Zhu and Luttrell, 2012). Among them, the most common insect's esterase is juvenile hormone esterase. This esterase provides bugs with pesticide resistant properties besides maintaining the physiological activity of insects such as digestion, reproduction, and hormone regulation (Kamita and Hammock, 2010).

### Plant Sources of Lipase and Esterase

Plant lipases received very little attention as compared to other sources of lipase. Lipases from plant origin are commonly found in oilseed, cereal, latex-producing plant species, and even marine seaweed (Bele et al., 2014; Keqin and Xinxin, 2008). This includes peanut, linseed, rapeseed, palm, soy castor bean, oat, grain, wheat, rice and so on (Villeneuve, 2003). The most ubiquitous types of plant lipase are oilseed lipases (Barros et al., 2010). They are mainly located on the aleurone (bran) of the lipid bodies and cellular components (embryo). The lipase activity was found to be exceptionally high particularly in germinating oilseeds since they are necessary to hydrolyse the stored TAG into FFA and GLY for the synthesis of sugars, amino acids, and carbon chains in order to meet the energy demand for embryonic growth. A review of different sources, applications, and properties of seed lipases was reported by Barros et al. (2010).

Meanwhile, plant esterases are found in vegetables and fruits such as soybean, rice, sorghum, wheat, papaya, orange peel maize (Hou et al., 2012; Jianke, 2008; Keqin and Xinxin, 2008). Esterases are widely distributed along the cell wall of the plant cell. The most common plant esterases are ferulic acid esterase (FAE) and pectin methyl esterase (PME) (Yeom et al., 2002). They display a diverse role in the biological process and regulation of bioactivity of endogenous products activation. This includes hydrolysis of ester containing xenobiotic molecule, growth, and development, stomatal movement, insecticidal resistance against infection, ripening, cell expansion, reproduction and spoilage.

### Microbial Sources of Lipase and Esterase

Microbial lipases/esterases encompass all classes of microorganisms ranging from fungi, bacteria to actinomycetes (Patil et al., 2011). A review on the up-to-date list of microbial lipases was provided by Hasan et al. (2006). The microbial lipases/esterases can either be isolated from the environment, sourced from culture collection centres or industry manufacturers. There is a prominent interest lately in utilizing microbes for large scale production of lipases which is in line with the high demand of microbial lipases for various industrial applications. Microbial lipase offers multifold advantages ranging from its versatility, availability to its

stability. Additionally, the extracellular nature of microbial lipase in which the lipase is secreted from the microbial cell into the culture medium allows convenient and easier isolation, separation and purification process. The move has prompted several large conglomerates such as Novozymes (A/S Bagsvaerd, Denmark), Amano Enzyme Inc. (Nagoya, Japan), Meito Sangyo (Tokyo, Japan) to manufacture and commercialise microbial lipases for industries.

The diversity of the microbe's Kingdom allows new lipases/esterases with desired functional properties to be isolated from different sources. There is high possibility that microbial lipases/esterases can be found in oil containing substances or oil contaminated areas. Some researchers managed to isolate microorganisms having esterase activity from the surface of cheese, oil contaminated areas and desert (soil, sand, stone and monument) (Essoussi et al., 2010; Heath et al., 2009; Soliman et al., 2007; Xue et al., 2012). Examples of microbial species having esterase activity include *Bacillus licheniformis* S-86 and lactic acid bacteria (Torres et al., 2009).

The presence of active lipases/esterases can be identified using agar plate assay (Hasan et al., 2009). Identification of esterase is conducted using chromophoric substances (*p*-nitrophenyl ester) or tributyrin supplemented agar plate whereas that of lipase is performed using substrate spectra (*p*-nitrophenyl palmitate and *p*-nitrophenyl butyrate). A halo formation on the agar plate is associated with the presence lipases/esterases. Sometimes, fluorescent substances like rhodamine B, Lugol's iodine solution are used to detect and enhance the clear zone. Lately, a metagenomic approach was used to screen for lipase (Reis et al., 2009).

The microbial lipases/esterases isolated are then cultured either in solid state or submerged state fermentation in order to optimise its culture conditions to obtain a high yield of enzyme lipase/esterase prior to large scale production which is usually performed in a bioreactor (Treichel et al., 2010). Several vital parameters that affect the growth of microbes which comprises of 1) nutritional factors such as nitrogen source, carbon source, lipid source, surfactants and metal ions, 2) physical factors like incubation time, pH, temperature, inoculum size, shaking condition, aeration will then be studied. Sometimes, lipid and fatty acids are introduced into the culture media to stimulate the secretion of lipase. Since purification of lipase is an important process in ensuring its high activity, therefore it is common that upon isolation from cells and mycelium, the enzyme lipase is purified to separate from other contaminants using ammonium sulphate followed by ion exchange/affinity/gel filtration column chromatography (Tan et al., 2015). Lately, with the advancement in biotechnology, the performance of lipase can further be enhanced through techniques such as chemical and physical mutagenesis as well as genetic modification (Anobom et al., 2014; Hoesl et al., 2011).

## Properties of Lipase and Esterase

Both esterase and lipase are made-up of  $\alpha/\beta$  hydrolase protein folding consisting of  $\alpha$  helices and  $\beta$  sheets. Lipase shows high activity toward insoluble or heavily aggregated long chain fatty acid esters. As such, lipase activity is largely dependant on the substrate area rather than the concentration of the substrate. Lipases catalyse both forward and reverse reactions. In the presence of water, lipase shows preferences for carrying out hydrolysis, alcoholysis, and aminolysis of ester bonds to breakdown TAG into FFA and partial acylglycerols. Under limited amount/absence of water, lipase-catalysed esterification reaction will occur which involves the formation of either TAG, DAG or MAG from fatty acid and GLY. Meanwhile, esterases display broad substrate specificity catalysing not only the hydrolysis of ester bond of short chain fatty acid ester but also non-ester bonds such as thiols, amides, and carbamates. Compared to lipase, esterase acts on water soluble substrate. Lipase and esterase have high stability and activity at pH above 8 (alkaline) and pH around 6 (acidic), respectively.

The enzymatic reaction takes place at the active site of lipase which comprises of a catalytic triad containing Ser-His-Asp residue. The active site of lipase is covered by mobile lid domain that is in the form of loop and helices which is amphiphilic in nature. The lid is positioned in such a way that hydrophilic side faces the solvent and the hydrophobic site is arranged towards the catalytic pocket. The activity of lipase as such is predominantly controlled by the lid domain. In non-aqueous media, the hydrophobic layer triggers the confirmation of lid to open, allowing the substrate to enter the active site. However, in pure aqueous media, the lipases are inactive as the lids are in closed position and the active sites are inaccessible to the environment substrate. Since the lid domain is involved in the determination of the activity of lipase, several studies were conducted to alter the lid through protein engineering in order to intensify the activity of lipase (Khan et al., 2017). Although most of the lipase contains one or more lids in the form of helices/loops with different sizes, certain lipase from genuine pig was found to have no lid domain. Lipase activity is activated only at lipid water-interface giving rise to its interfacial activation property (Reis et al., 2009). The activity of lipase occurs in emulsion system either in normal phase emulsion (water-in-oil) or invert phase emulsion (oil-in-water). Unlike certain enzyme lipase that may require cofactors to remain active, esterase does not require a cofactor.

Meanwhile, esterases have either no lid or a small lid covering its active site. The active site of esterase is comprised of Ser, His, and either Asp or a Glu residue. Study found that the lid covering the active sites of cholesterol esterase from *Ophiostoma piceae* OPE is made up of one  $\alpha$ -helix and two  $3_{10}$ -helices flanked by two loops. During esterase activation, lid displacement occurs to change the loop  $\alpha 16$ -  $\alpha 17$  from a close to open structure which in turn leads to the exposure of the catalytic site (Gutiérrez-Fernández et al., 2014).

## Selectivity of Lipase and Esterase

Lipase can be classified into three different classes based on its positional and fatty acid specificity. Most of the lipases belong to sn-1,3 specific lipase. These lipases hydrolyse/esterify fatty acid specifically at the either/both sn-1 and sn-3 position. The sn-2 fatty

acids are prevented from binding to the active site of lipase due to steric hindrance effect. Example of this group of lipase includes human pancreatic lipase, *Aspergillus niger*, *Rhizomucor delemar*, *Rhizomucor miehei*, and *Mucor javanicus*. Meanwhile, another group of lipase which belongs to non-specific lipase catalyses the hydrolysis/esterification of fatty acid in a random manner regardless of its position. Examples of these lipases are *Candida rugosa*, *Corynebacterium acnes*, *Staphylococcus aureus*. Additionally, lipases showing fatty acid specificity is much less common compared to other groups of lipases. *Geotrichum candidum* is the most common fatty acid specific lipase that shows preferences toward oleic acid. There are also lipases which show negative specificity. For instance, lipase from *Candida cylindracea* which discriminates against docosahexanoic acid, *G. candidum* against  $\gamma$ -linolenate in borage oil and *Mucor miehei* against polyunsaturated fatty acid GLA and DHA. Lipases of negative selectivity are often being utilized to concentrate and enrich certain polyunsaturated fatty acid (PUFA) in TAG.

Esterase can be classified into three classes mainly A-, B- and C-esterase based on its specificity towards organophosphate substrate. Esterase A (paraoxonase) is responsible for the hydrolysis of organophosphate, esterase B (carboxyl esterase, butylcholinesterase, acetylcholinesterase) is inhibited by organophosphate whereas esterase C (acetyl esterase) do not interact with organophosphate. Additionally, according to its ability to hydrolyse the artificial alpha and beta naphthyl acetate, esterase can be divided into alpha and beta esterase. Additionally, albumin protein which can hydrolyse  $\alpha$ ,  $\beta$ -naphthylacetate is also considered as a type of esterase (Bahar et al., 2012).

## Industrial Applications of Lipase and Esterase

The global industrial enzymes market value has reached USD 5 billion in year 2016 with enzyme lipases and esterases accounting for approximately 10% of the global industrial enzyme, ranking third after carbohydrases and proteases (Guerrand, 2017; Singh et al., 2016). The market is projected to expand at 6%–8% compound annual growth rate (CAGR) for the next five years, achieving around USD 7 billion in year 2020 (Guerrand, 2017). The rapid advances of the global biocatalyst market are driven by their capability to catalyse reactions with higher efficiency and stability, their chemo-, regio- and enantioselectivity as well as their eco-friendly characteristics as compared to conventional chemical process, rendering them to be attractive and versatile enzymes from the industrial point of view (Bornscheuer, 2002; Choi and Lee, 2001; de Godoy Daiha et al., 2015; Hasan et al., 2006; Singh et al., 2016). Enzyme-mediated processing technologies have therefore gained interests among academia and researchers from food and pharmaceutical industries.

Both lipases and esterases are generally considered as carboxylester hydrolases with the latter being capable of hydrolysing mostly water-soluble esters bearing short-chain acyl residues (<8 carbons). On the other hand, the former exhibits substrate specificity against water-insoluble esters, releasing long-chain fatty acid (>8 carbon atoms) as mentioned earlier (Bornscheuer, 2002; Panda and Gowrishankar, 2005; Pleiss et al., 1998; Romano et al., 2015). However, classification of both lipases and esterases remains a subject of debate to date. Several attempts have been made at differentiating lipases from esterases based on various benchmarks such as primary sequence, structural features, kinetics and use of specific inhibitors, but all these efforts ended in vain (Ali et al., 2012; Lopes et al., 2011; Romano et al., 2015). Both terms will therefore be used interchangeably in the following section. Lipases and esterases find many applications in the food, cosmetic and pharmaceutical industries not to mention detergent industry as well as oleochemical industry. The present monograph only focuses on these following sectors: emulsifier and surfactant, flavour development, functional food and ingredient and pharmaceutical drug.

## Emulsifier and Surfactant

A recent report on the global emulsifier market revealed that the market size was estimated to be USD 4.35 billion in year 2015. The market is expected to grow steadily for the next decade, owing to the increasing demand for these colloidal products in the bakery and confectionary industry (Report, 2017). Mono- (MAG), diacylglycerol (DAG) and their derivatives contribute the highest revenue share of the total industry. These products are glycerol-based fatty acid esters that help in improving the surface activity required for proper stabilization of the processed food as well as in the cosmetic industry to improve the consistency of creams and lotions. Other emulsifiers include lecithin, sorbitan esters, fatty acid lactylates and so on.

MAG are manufactured on an industrial scale through chemical glycerolysis of fats and oils which encounter several drawbacks such as low yield coupled with burnt taste and undesired colour. Enzymatic synthesis of MAG was reported to be an alternative in overcoming these limitations. Kaewthong et al. (2005) have been studying different types of lipases namely (*Pseudomonas* sp. (lipase PS), *Pseudomonas fluorescens* (lipase AK), *C. rugosa* (lipase AY), *Rhizopus delemar* (lipase D), *Mucor javanicus* (lipase M), *Rhizopus oryzae* (lipase F), *C. rugosa* (lipase OF) *Alcaligenes* sp. (lipase PL) and *Chromobacterium viscosum* (lipase LP) for the production of MAG. It is worth-mentioning that some specific MAGs (e.g. monoolein, monolaurin or monocaprin) exhibited specific activities such as anti-bacterial, anti-fungi and anti-viral activity and as antioxidant (Kyung-Hyun et al., 2010; Silalahi et al., 2014; Widiyarti et al., 2010). Chamgui et al. (2006) reported that conversion yield of 70% was achieved via direct esterification of oleic acid with glycerol using immobilized *Staphylococcus simulans* lipase. In recent years, there has been a significant shift towards enzymatic preparation of MAGs containing PUFAs through ethanolysis of different edible oils using commercial lipases as the biocatalysts (Wang et al., 2014).

Sugar fatty acid esters (SFAE) are receiving attention as non-allergic, nontoxic and biodegradable non-ionic surfactants. SFAEs possess outstanding surface-active properties such as remarkable surface tension-reducing capacity, penetrability into lipid bilayers, easiness of dispersion and remarkable emulsifying power when compared to surfactants derived from petrochemical industry

(Becerra et al., 2008; Ferrer et al., 2002; Neta et al., 2012; Sanchez et al., 2011). Zhang et al. (2014) investigated the synthesis of disaccharides of monolaurate, monodecanoate and monooctanoate using Lipozyme TLIM through transesterification. The mono-ester synthesised exhibited promising surface properties as well as antimicrobial activities against *Escherichia coli* O157:H7 (gram-negative bacteria) (Zhang et al., 2014). Besides, Neta et al. (2012) also showed the potential application of *Candida antarctica* type B (CALB) lipase immobilized on chitosan in producing fructose, sucrose and lactose esters which were capable of stabilising coconut milk emulsions. Another research study also described the synthesis of a series of oligofructose monoesters with fatty acids of different chain lengths (C8–18) to obtain superior food-grade surfactants with a range of amphiphilicity via CALB-catalysed esterification (van Kempen et al., 2013, 2014).

Lysolecithin (or lysophosphatidylcholine) is another type of attractive emulsifier by virtue of its strong hydrophilicity. It is produced from the hydrolysis of egg yolk lecithin after treatment with phospholipases A (aliphatic esterases), which is then incorporated for the formation of stable oil-in-water (O/W) type emulsions such as mayonnaise (Borrelli and Trono, 2015). The use of immobilized phospholipase A<sub>2</sub> (PLA<sub>2</sub>) in alginate-silica sol–gel matrix was found to be capable of producing egg yolk lysolecithin (Kim et al., 2001). Commercial porcine pancreas PLA<sub>2</sub> (Lecitase, Novozymes) and *A. niger* PLA<sub>2</sub> (Maxapal, DSM) have also been successfully developed for this purpose (Casado et al., 2012).

Interest in the production of structured phospholipid (PL) containing specific fatty acid residues has also increased significantly in recent years. For instance, Vikbjerg et al. (2007) reported the PLA<sub>2</sub>-catalysed synthesis of PL with caprylic acid by acyl modification of the sn-2 position in PLs. Another work conducted by Zhao et al. (2014) also reported the potential of phospholipase A<sub>1</sub> (PLA<sub>1</sub>) immobilized in Lewatit VP OC1600 in synthesising n-3 PUFA enriched-phosphatidylcholine. Besides delivering the emulsifying properties, replacement of fatty acid residues present in the native PL by fatty acids with beneficial physiological effects can lead to tailored PLs that offer intriguing marketing opportunity for manufactures of nutraceuticals.

### Flavour Development

Flavouring and aromatic compounds are generally considered as short-chain aliphatic esters which are important food additives to be added into the food, cosmetic and pharmaceutical industries. Despite the availability of these esters in natural sources (fruits), the concentration is relatively low and the composition changes upon maturation (Su et al., 2016). Enzymatic approach has therefore offered some advantages of being environmental friendly, highly selective and efficient in synthesising these aromatic esters.

Bayramoğlu et al. (2011) investigated the use of immobilized *C. rugosa* lipase in hexane to synthesise ethyl valerate (ethyl pentanoate) (fruity flavour) and high esterification yield of 67.2% was achieved as compared to previous study conducted by Karra-Chaabouni et al. (2006) with 51% of ethyl valerate being produced using *S. simulans* lipase. The isoamyl acetate (banana flavour) was also synthesised using *C. antarctica* lipase (Novozyme 435) with conversion of 80% under optimal conditions (Güvenç et al., 2002). Shieh and Chang (2001) achieved a hexyl acetate (fruity flavour) conversion of 86.6% by transesterification of hexanol with triacetin in hexane using immobilized *Mucor miehei* lipase (Lipozyme IM-77) under optimum synthesis conditions. The high conversion yield was obtained when using immobilized *Staphylococcus xylosus* lipase (80%) and its mutant (LK-SXL1) (95%) as biocatalysts to catalyse the esterification reaction between acetic acid and butanol to produce butyl acetate ester (pineapple flavour) (Ben Salah et al., 2007). Su et al. (2016) also discovered the potential application of cutinases, the smallest members of the  $\alpha/\beta$  hydrolase superfamily which displayed intermediate characteristics between lipases and esterases, in producing high yield (99.2%) of ethyl caproate (fruity flavour).

Terpene alcohol esters (such as geraniol and citronellol esters) are important components of essential oils found in several aromatic plants, giving fruity rose and lavender aroma. These esters can be produced chemically but these synthetic products formed are inferior to the natural ones (Claon and Akoh, 1994a,b). On the other hand, products of lipase-catalysed reactions have a higher quality and stability under certain conditions. Lipase-catalysed synthesis of terpene esters by direct esterification (Claon and Akoh, 1993, 1994a; Oguntimein et al., 1995; Salvi et al., 2017) and transesterification (Claon and Akoh, 1994b; Shieh et al., 1996; Yee et al., 1995) using different substrates as the starting materials in either solvent or solvent-free systems have been well described. However, some researchers claimed that lipases showed low affinity towards the synthesis of short-chain fatty acid esters of geraniol especially when acetic acid (C<sub>2</sub> carbon) was used as acyl donor during esterification (Oguntimein et al., 1995). Nevertheless, these low molecular weight geraniol esters (geraniol acetate) could be synthesised successfully with esterase derived from *Fusarium oxysporum* (Christakopoulos et al., 1998; Karra-Chaabouni et al., 1996). Macrocyclic lactones, an expensive aromatic substance of musky fragrance can also be produced using *Pseudomonas* sp. lipase (Kageyama et al., 1990) and *Starmerella bombicola* lactone acetyl esterase (Ciesielska et al., 2016) with high conversion yield.

Esterases and lipases from *Lactobacillus casei* CL96 were used significantly for hydrolysis of milk fat for the purpose of flavour enhancement in the manufacture of cheese-related products (Choi and Lee, 2001). An acylesterase from *Saccharomyces cerevisiae* was also reported to play an important part in the production of isoamyl acetate which has a major role in the determination of sake flavour during the fermentation stage (Fukuda et al., 1998).

Hydroxycinnamic acids (HCA) such as ferulic, sinapic, caffeic and *p*-coumaric acids, are widely applied in food, cosmetic and pharmaceutical industries due to their desirable flavour profiles. More interestingly, previous literature revealed that HCAs exhibit potent antioxidant properties (Graf, 1992) with powerful scavenging activities towards peroxynitrite and have good capability in oxidising low density lipoprotein (LDL) which translates to potential in treating cardiovascular diseases and neurodegenerative disorders such as Alzheimer's disease (Topakas et al., 2007). As a result, there is a growing interest in converting these ferulic acids into various valuable molecules such as catechol, vanillic acid derivatives and vanillin being the most universally used aromatic

molecules (Havkin-Frenkel and Belanger, 2009; Walton et al., 2000). Pentylferulate ester, a flavour precursor in food and cosmetic industries can be produced using feruloyl esterase (FE) from *A. niger* in water-in-oil (W/O) microemulsions (Giuliani et al., 2001) and commercial immobilized enzyme from *C. antarctica* (Chirazyme L-2) (Yoshida et al., 2006). On the other hand, feruloyl and cinnamoyl esterase, synergistically with pectinases, celluloses and xylanases can also be employed to hydrolyse esters from agro-industrial residues such as wheat bran, maize bran and fibre, rice bran, brewer's spent grain, sugar cane, bamboos, sugar beet pulp and various agro-industrial by-products, and releasing the beneficial HCAs (Asther et al., 2002; Topakas et al., 2007).

### Functional Food and Ingredient

The potential use of lipases and esterases in the production of food ingredients with functional properties is well documented. Over the past few decades, increased focus has been placed on the obesity epidemic owing to its high prevalence and considerable contribution to overweight-related disease burden. The search for cost-effective techniques for the production of functional oils such as DAG-enriched oil (Phuah et al., 2015), medium-and-long chain triacylglycerol (MLCT) oil (Akoh and Kim, 2008; Lee et al., 2012), very long-chain triacylglycerol (VLCT) oil (Speranza and Macedo, 2012), medium-chain triacylglycerol (MCT) oil (Langone and Sant'Anna, 1999; Langone and Sant'Anna, 2002) and PUFA-enriched TAG oil (Lee and Akoh, 1998) via lipase-catalysed reaction to help tackle obesity as the consequence of excessive edible oil consumption has therefore been intensified and reviewed periodically. Commercially available modified fats include 1) Caprenin (Procter & Gamble Co., United States), a low caloric fat product composed of carpylic (C8:0), caproic (C10:0) and behenic (C22:0) acid (Adamczak, 2004; Speranza and Macedo, 2012); 2) SALATrim/Benefat (Nabisco Foods Group, United States), a fat consists of a mixture of short chain fatty acids namely acetic (C2:0), butyric (C4:0) acids and long chain fatty acid like stearic acid (C18:0) with reduced calorie value (Speranza and Macedo, 2012); 3) Econa/Enova oil (Kao Corporation, Japan), a fat with two fatty acids esterified to a glycerol backbone, forming DAG with potential anti-obesity properties (Katsuragi et al., 2004); 4) Resetta™ (Nisshin Oillio Group Ltd, Japan), a fat containing both medium chain and long chain fatty acid in the same TAG molecule for overweight management (Lee et al., 2012); Neobee® (Stepan Co., United States), a fat consists predominantly of medium chain fatty acid (MCFA) with low energy value. These functional oils mentioned above can be synthesised with ease in the presence of the lipases. The current research trends on the enzymatic synthesis of these functional oils have been reviewed comprehensively by Kim and Akoh (2015).

The synthesis of human milk fat substitute (HMFS) to mimic the natural human milk fat (HMF) is of great interest when breast feeding is not possible in order to ensure a supply in infant nutrition with similar TAG composition to that of mothers milk (Soumanou et al., 2013). Ever since the commercialisation of Betapol® (Loders Croklaan, Netherlands) as the first available HMFS in the market produced using sn-1,3-specific lipase (such as Lipase RMIM), extensive researches have then been carried out in modifying milk fats with enhanced absorbability besides delivering a reduced calorie value as well as providing protection to bacterial and viral infection for new born, term and preterm infants (Zou et al., 2016). Previous literature studies indicated that the presence of long-chain saturated fatty acid at position sn-1 and sn-3 reduces the absorbability of milk fat due to the formation of insoluble calcium soaps of these fatty acids in the intestinal tract, leading to the loss of energy and calcium intake and in the worst case scenario, influence the bone mineralisation (Gerritsen et al., 2005; Li et al., 2010). Some researchers have therefore focused on the enzymatic preparation of HMFS-enriched with MCFA. For instance, Ilyasoglu et al. (2011) studied the lipase-mediated synthesis of HMFS-enriched with MCFA by Lipozyme using reaction substrates such as tripalmitin, hazelnut oil fatty acids and Neobee® fatty acids (carpylic and capric acids). In another study, Álvarez and Akoh (2015) produced capric acid enriched-HMFS in two enzymatic inter-esterification stages using Lipozyme TLIM by reacting high melting point palm stearin, high oleic oil and tricaprin. Incorporation of PUFA into milk fat at 1,3-position had also been reported to be possible through lipase-catalysed interesterification of tripalmitin and omega-3 fatty acid (Tecalão et al., 2010), interesterification between tripalmitin, hazelnut oil fatty acid and  $\gamma$ -linolenic acid (Sahin et al., 2005) and interesterification between stearidonic acid-enriched soybean oil with tripalmitin (Teichert and Akoh, 2011) in order to deliver essential fatty acids for proper brain growth and functioning in infants. The advances on lipase-catalysed processes currently conducted for the synthesis HMFS, namely types of enzyme, reaction conditions, reactor types and mode of operation, were reviewed by Soumanou et al. (2013) and the future outlook on the development of HMFS were discussed by Zou et al. (2016).

Cocoa butter is the most expensive TAG which consists of saturated fatty acid (palmitic or stearic acid) located predominantly at its 1,3-positions and unsaturated fatty acid (oleic acid) at its 2-position. The cocoa butter is widely used in the chocolate and confectionary industry owing to its unique sensory characteristic and sharp melting profile between 25–35 °C. It has therefore provided an opportunity for sn-1,3-specific lipases in the manufacturing of structured lipid (SL) with favourable physicochemical properties (such as cocoa butter substitute (CBS) and cocoa butter equivalent (CBE)). The production of CBS via transesterification or acidolysis of inexpensive oil such as palm mid fraction with tristearin or stearic acid using 1,3-specific lipases was initiated by Unilever and Fuji Oil when they filed their patent applications (Neil, 1981). The research continues in this area thereafter. Borhan et al. (2011) reported the possibility of using commercial immobilized sn-1,3-specific lipase from *R. miehei* (Lipase IM 60) in synthesising CBS through interesterification of palm mid fraction, palm stearin and MCT. The resulting interesterified fat showed comparable solid fat content to that of cocoa butter. Kim et al. (2014) produced CBE high in 1-palmitoyl-2-oleoyl-3-stearin (a major component in cocoa butter) via lipase-catalysed transesterification of high oleic sunflower oil with a mixture of ethyl palmitate and ethyl stearate.

Phenolic acids are of great commercial potential in food and pharmaceuticals as mentioned earlier. However, the partial solubility of these natural antioxidants limits their clinical effectiveness. Feruloyl esterases (FE) can act as biosynthesis tools used to produce phenolic acid sugar esters via esterification with aliphatic alcohols, resulting in the formation of more lipophilic derivatives. Lipases are unable to catalyse the esterification reaction in this scenario if aromatic cycle is parahydroxylated and lateral chain

is not saturated. Therefore, the reaction can only be carried out using FE. FE from *S. thermophile* was proven to be able to catalyse the transfer of feruloyl group to L-arabinobiose (Vafiadi et al., 2006).

Phytosterols (plant sterols and stanols), a naturally bioactive compound found in edible vegetable oil, are well known for their LDL cholesterol-reducing potential and antioxidant activity (Plat and Mensink, 2005; Zheng et al., 2012). These attractive properties of phytosterols have led to the recent commercialisation of phytosterols as Benecol® food supplement by Raisio Corporation (Finland) and the attempts of incorporating this product into various food matrixes such as margarine, mayonnaise, dairy products and others has thereafter increased significantly (Dutta, 2003). Despite its beneficial health effects, phytosterols in free form have limited interest owing to their low solubility, stability and low absorption rate (Villeneuve et al., 2005). Therefore, fatty esters of sterols are more advantageous as functional ingredients in food formulation. These phytosterol esters can be produced enzymatically using microbial lipases (Zheng et al., 2012), plant lipases (Villeneuve et al., 2005) and microbial sterol esterases (cholesterol esterases) (Vaquero et al., 2016) with high efficiency.

## Pharmaceutical Drug

Among the applications of lipases and esterases, the synthesis of enantiomerically pure active pharmaceutical ingredients (APIs) and their intermediates using these enzymes is a subject of continuing interest. It is noteworthy that most of the drugs are chiral, and only certain active stereoisomer has the desired biological activity while the other stereoisomer might pose deleterious side effects on health (Carvalho et al., 2015). One of the important properties of lipases and esterases is their ability to differentiate between enantiomers of chiral molecules, making them interesting as biocatalysts in the pharmaceutical field.

Microbial lipases are used in kinetic resolution of chiral compounds that serve as synthons in the synthesis of chiral pharmaceutical products in which hydroxyl acids and their derivatives are major target molecules because they constitute the framework of many chiral natural products and biological active agents. Lipases are used in the synthesis of chiral synthon as intermediates for the synthesis of paclitaxel (taxol) from 3-methoxytulene which exhibits a unique mode of action on microtubule proteins that are responsible for the formation of the spindle during cell division and therefore it has been used to treat various cancers especially ovarian cancer (Fukaya et al., 2016). Another study also demonstrated the potential application of lipases in production of intermediates for the synthesis of an antihypertensive drug namely Captopril which prevents the conversion of angiotension-I to angiotension-II by inhibition of an angiotension-converting enzyme. Immobilized lipases from both *Pseudomonas cepacia* and a *Pseudomonas* sp. catalysed the production of the S-isomer at greater than 32% yield and 96% optical purity (Patel et al., 1996). Lipases are also used in the production of a stereospecific isomer for the production of a  $\beta$ -blocker which contains aryloxypropanol-amine structure (such as (S)-propranolol and (S)-metoprolol) with an asymmetric carbon that can be used to treat hypertension, migraine headaches and cardiovascular related diseases (Schaechter, 2009). To enhance the bioavailability of the  $\beta$ -blocker, synthesis of metoprolol- or propranolol-saccharide conjugates by using combination of lipase and protease in two steps has proven to be a promising approach (Zheng et al., 2011). A review on lipases and its biocatalytic applications in pharmaceutical industries inter alia the synthesis of paroxetine hydrochloride, diltiazem hydrochloride, chiral  $\beta$ -azidoalcohols, vitamin D<sub>3</sub> derivatives, primary amines and amides, was provided by Angajala et al. (2016).

Esterases also play a major role in the synthesis of chiral drugs (Bornscheuer, 2002). For example, an esterase from *Trichosporon brassicae* has been used extensively for the production of optically pure (S)- and (R)-ketoprofen, which is effective in reducing inflammation and relieving pain resulting from arthritis, sunburn, menstruation, and fever (Shen et al., 2002). In another study, Kim et al. (2015) also showed that esterases derived from *Archaeoglobus fulgidus* mutants, displays high thermostability and improved enantioselectivity toward (S)-ketoprofen ethyl ester, enabling the production of (S)-ketoprofen with better pharmaceutical activity and lower side effects through hydrolysis of the ester bond of (R,S)-ketoprofen ethyl ester. In addition, research studies also disclosed the potential applications of esterases from *T. brassicae*, *Rhodococcus* sp., *Bacillus circulans* and *Pseudomonas* sp. in producing substantial amount of chiral compounds with therapeutic effect such as ibuprofen (Kim et al., 2002).

Similarly, an esterase from *Bacillus coagulans* catalyses the enantioselective hydrolysis of the racemic ester of 1,2-O-isopropylidene glycerol (IPG) (solketal ester), yielding IPG with high enantiomeric excess. IPG is an important chiral synthon in the synthesis of glyceryl phosphate, tetraoxaspirodecane and other biological active compounds such as prostaglandins, leukotrienes and  $\beta$ -blockers (Molinari et al., 1996). Carboxylesterase from *Bacillus subtilis* was also used in the resolution of (R,S)-ibuprofen methylester (Quax and Broekhuizen, 1994) and exhibited higher selectivity as compared to lipase from *C. rugosa* (Mustranta, 1992). An up-to-date application of esterases as stereoselective biocatalysts in pharmaceutical field has been reviewed thoroughly by Panda and Gowrishankar (2005) and Romano et al. (2015).

## Conclusion

The present monograph provides brief descriptions of the recent developments about the potential applications of lipases and esterases in various sectors namely pharmaceuticals, functional food or nutraceuticals, emulsifier or biosurfactants as well as flavour and fragrance. Besides, the different sources of lipases and esterases, their catalytic behaviours and selectivity have also been reviewed extensively. Nevertheless, relatively high cost of enzyme lipases and esterases coupled with low operational stability remains a major techno-economic bottleneck that limits their widespread industrial applications. Several points should therefore be taken into consideration in order to alleviate the barriers such as 1) fermentation technology, allowing for a feasible production process of

the enzyme on a large scale basis; 2) immobilisation techniques, improving the stability and activity of the enzymes besides adding to the possibility of the continuous use of the biocatalysts and 3) protein engineering, enhancing and developing the desired catalytic properties of the enzymes lipases and esterases. Furthermore, the applications of enzyme lipase and esterase particularly in the food and pharmaceutical sector can be further be explored in order to cope with the consumers demand for a safe, healthy and nutritious food.

# Holistic Control of Fats and Oils by NMR Spectroscopy

Elina Zailer, Spectral Service AG, Cologne, Germany

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Fats and oils are important factors of our daily diet which are used for cooking, frying, and as ingredients in several manufactured foods such as margarine, chips, ice cream and cookies. Depending on their composition oils and fats show different physicochemical and nutritional properties concerning their melting point, oxidative stability and influence on consumer health. Furthermore, expensive oils show a great potential for being adulterated with the objective of increasing the profit. This is one of the many reasons why the quality control of edible oils and fats is a very important task of customer safety. Quality control of lipids has been classically undertaken by several official methods, approved by the German Society for Fat Science (Deutsche Gesellschaft für Fettwissenschaft e.V.; DGF) and the American Oil Chemist Society (AOCS), including chromatography and titration to determine the fatty acid profile, acid value, peroxide value, iodine value, secondary substances, etc. Many of these methods have been developed and standardized several decades ago undergoing only minor changes since then. Some of them are not only cumbersome and error-prone, but also time-consuming and expensive. Taking this into account, the development of a fast and non-destructive quality control is of great interest. Former researches have described the nuclear magnetic resonance (NMR) as a technique extending the analysis of edible fats and oils (Diehl and Skiera, 2013; Diehl, 1998; Skiera et al., 2012a, 2012b, 2012c; Guillén and Ruiz, 2003). NMR spectroscopy enables a rapid, simultaneous, non-invasive, and non-destructive holistic control of oils and fats requiring small amounts of sample (about 200 mg) and solvents (about 1 mL). NMR spectroscopy can be used for the quality control of different kinds of lipids from vegetable and marine source. Lipid ingredients are identified with  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy without requiring any standards. The quantification is performed by integrating the appropriate signals. These integrals are directly proportional to the molar amount of the component. Since there is no need of chemical modification such as derivatization, degradation processes of sensitive components are avoided and the sample can be recovered unmodified after the analysis.

## Fatty Acid Distribution

Fats and oils are mainly made up of 95% to 99% of triacylglycerols (TAGs). The rest is composed of oil specific secondary substances, free fatty acids (FFAs) and processing products. The concentration and relation of the different fatty acids (FAs) such as saturated and unsaturated FAs provides information about the oil type. NMR spectroscopy is a powerful tool for the determination of the FA composition in lipids.  $^1\text{H}$  NMR spectroscopy provides qualitative and quantitative information about several quality parameters such as the saturation grade, peroxides and aldehydes.  $^{13}\text{C}$  NMR spectroscopy enables a detailed look into the chemical structure of the individual FAs as well as their regioselective distribution.

## Fatty Acid Profile by $^1\text{H}$ NMR Spectroscopy

A TAG is an ester derived from glycerol and three FAs which are categorized into saturated and unsaturated FAs. The signal assignment for  $^1\text{H}$  NMR spectra is presented in Table 1. The structure of the major TAGs is presented in Fig. 1 where from the spectroscopic

**Table 1** Signal assignment of vegetable oils in  $\text{CDCl}_3/\text{DMSO}$  (4:1);  $^1\text{H}$  NMR spectra (500 MHz)

Signal no.	Type	Functional group	Chemical shift [ppm]
1	free fatty acids (FFAs)	$-\text{COOH}$	12.0–11.1
2	hydroperoxide	$-\text{OOH}$	11.1–10.2
3	aldehyde	$-\text{CHO}$	9.8–9.0
4	Cis/trans conjugated	$-\text{CH}=\text{CH}-$	7.5–5.5
5	Allylic	$-\text{CH}=\text{CH}-$	5.5–5.3
6	Glycerin backbone	$-\text{CH}-$	5.3–5.2
7	Glycerin backbone	$-\text{CH}_2-$	4.4–4.0
8	C18:3	$-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$	2.80
9	C18:2	$-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$	2.75
10	TAG	$-\text{COO}-\text{CH}_2-$	2.4–2.2
11	TAG	$-\text{CH}=\text{CH}-\text{CH}_2-$	2.1–1.9
12	TAG	$-\text{COO}-\text{CH}_2-\text{CH}_2-$	1.7–1.5
13	TAG	$(-\text{CH}_2-)_n$	1.5–1.1
14	$\omega$ -3	$-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}_3$	0.99–0.94
15	TAG	$-\text{CH}_3$	1.0–0.7

**Fig. 1** Chemical structure of TAGs in edible oils. Based on [Salinero et al. \(2012\)](#).

**Fig. 2** 600 MHz  $^1H$  NMR spectrum of an olive oil in  $CDCl_3/DMSO$  (4:1).

point of view, the most important hydrogens are highlighted. **Fig. 2** presents a typical  $^1H$  NMR spectrum of an edible oil. Based on the anisotropic properties, the multiplet of the vinylic hydrogens ( $H_v$ ) is shifted to  $\delta$  5.5–5.3 ppm. This signal is used for the determination of the saturation grade. With increasing distance to the  $C=C$  bond the anisotropic properties decrease continuing to separate the signals from allylic ( $H_a$ ) and bisallylic hydrogens ( $H_b$ ). By comparing  $H_a$  with  $H_b$ , mono- and polyunsaturated FAs can be differentiated. The ratio of the double bonds and the  $\alpha-CH_2$  group at  $\delta$  2.3 ppm determines the mean number of double bonds in each FA and thus the iodine value (IV). Terminal methyl groups show triplets at  $\delta$  1.0–0.7 ppm, whereby the chemical shift depends on the distance to the next double bond. Especially the methyl group of  $\omega$ -3 FAs is influenced by the anisotropy of the close double bond leading to a signal with a chemical shift of  $\delta$  0.99–0.94 ppm. To determine the molar part of  $\omega$ -3 FAs, all signals of the terminal methyl groups are normalized to 100. By splitting the integral, the value of the  $\omega$ -3 integral determines the molar ratio in %.  $\omega$ -6 and  $\omega$ -9 signals overlap and cannot be quantified separately in the  $^1H$  NMR spectrum, even by using a 600 MHz spectrometer. However, this challenge can be met by the  $^{13}C$  NMR spectroscopy. By normalizing the methyl group to 300 the relative molar ratio of several compounds such as C18:2 and C18:3 FAs can be determined. In the presented research work, FA profiles of 24 vegetable oils have been analyzed (**Figs. 3–6**). Here total saturated FAs and unsaturated FAs, especially C18:1, C18:2 and C18:3 FAs are compared in mol-%. The total saturated FAs of the analyzed vegetable oils were determined in a range of 6.98% to 21.45%, monounsaturated C18:1 FAs of <LOD to 80.66%, C18:2 FA of 0.68% to 72.22% and C18:3 FA of 0.24% to 57.50%. The characteristic FA profile is used for the determination of the lipid source.

Since some of the analyzed vegetable oils show a comparable FA profile, adulterations and contaminations cannot be detected without any statistical procedures. With the use of multivariate models like Principal Component Analysis (PCAs) the genuineness

**Fig. 3** Saturated FA of different kinds of edible oils (mean  $\pm$  deviation).

**Fig. 4** Monounsaturated FA of different kinds of edible oils (mean  $\pm$  deviation).

of edible oils can be distinguished by visualizing the separation of the different oil types (Fig. 7). The use of chemometric methods is presented in the section on **Adulteration Control**.

### Fatty Acid Distribution by $^{13}\text{C}$ NMR Spectroscopy

The  $^{13}\text{C}$  NMR spectroscopy provides information on the chemical structure of the TAGs and FAs showing an individual signal for each carbon. The  $^{13}\text{C}$  NMR spectra can be compared with chromatograms where each signal can be assigned to an appropriate substance. Fig. 8 illustrates a typical 600 MHz  $^{13}\text{C}$  NMR spectrum of walnut oil. In the spectrum four main regions can be identified: carbonyl region ( $\delta$  174–172 ppm), olefinic signals ( $\delta$  134–126 ppm), glycerol region ( $\delta$  74–60 ppm), and aliphatic region ( $\delta$  35–19 ppm). Since the position of the double bond within a FA causes an anisotropic shift of the neighbored carbon atoms,  $\omega$ -3 as well as  $\omega$ -6,  $\omega$ -7,  $\omega$ -9 and saturated FAs can be identified in highly resolved  $^{13}\text{C}$  NMR spectra by their separated signals. By normalizing

**Fig. 5** C18:2 FA of different kinds of edible oils (mean  $\pm$  deviation).

**Fig. 6** C18:3 FA of different kinds of edible oils (mean  $\pm$  deviation).

all signals of the same carbon group to 100, the molar ratio of each FA can be determined. In **Fig. 9** the FA distribution of a linseed oil is analyzed by using deconvolution for quantification. The results show that the analyzed linseed oil consists of 58.1%  $\omega$ -3, 14.9%  $\omega$ -6, 0.2%  $\omega$ -7, 17.5%  $\omega$ -9 and 9.2% saturated FA. Since the chemical structure of saturated FAs differs only in the chain length, signals of individual saturated FAs cannot be separated. Thus, saturated FAs are quantified in total.

Besides the general FA distribution, the  $^{13}\text{C}$  NMR spectroscopy provides information on the regiospecific distribution of FAs in TAGs. Since the anisotropy makes the carbonyl signals sensitive to double bonds within the FA chain, carbonyl signals of a neighboring single and double bonds show a difference of the chemical shift of approx.  $\delta$  0.5 ppm. This effect decreases according to the distance to the next double bond. A signal separation is still possible at a double bond distance up to eleven carbon atoms in the chain. Thus, the carbonyl region is very sensitive for regioselective analysis. Distinction of sn-1/3 and sn-2 are possible for TAGs, phospholipids and glycolipids (**Fig. 10**). Free and esterified FAs are also determined by evaluating the carbonyl region. Here, we

**Fig. 7** PCA scores plot on the first and the second principle components for 500 MHz  $^1\text{H}$  NMR integrals of the FA profile of ten vegetable oils.

**Fig. 8** 600 MHz  $^{13}\text{C}$  NMR spectrum of walnut oil.

can distinguish between total free (FFA) and total esterified FAs including mono-, di- and triacylglycerides. By integrating both regions and normalizing them to 100, the molar ratio (in %) of free and esterified FAs is determinable. Furthermore, individual FFAs are assigned, as presented in **Fig. 11**. After methylation the total content of individual FAs can be examined, irrespective of whether they existed in the free or esterified form in the lipid before (**Fig. 11**).

### Trans-fatty Acids

*Trans* fatty acids have been of increasing concern to the consumers since unfavorable effects in the diet were confirmed ([Katan et al., 1995](#)). Thus, the US Food and Drug Administration (FDA) decided to put the content of *trans* FAs on the list of nutritional labeling ([Food and Drug Administration \(FDA\), 2003](#)). Food manufacturers commonly used GC to separate *cis* and *trans* FAs to examine the *trans* FA content. However, GC analysis is time-, cost- and solvent-consuming, and the results are strongly impacted by the sample pretreatment and the instrument performance. To overcome this problem, NMR spectroscopy is applied as a rapid, nondestructive method for determining the *cis* and *trans* composition of unsaturated lipids. Since resonances of neighboring hydrogens are shifted, due to the magnetic anisotropy of a double bond, to the downfield, allylic methylene groups are easily distinguishable from

**Fig. 9** 600 MHz  $^{13}\text{C}$  NMR spectrum of linseed oil, terminal methyl group.

**Fig. 10** 600 MHz  $^{13}\text{C}$  NMR spectrum of a vegetable oil, carbonyl group.

saturated parts of the FA. In nature, polyunsaturated FAs show predominantly *cis* homo conjugated double bonds. However, some oils and fats show extraordinary, characteristic FAs with *trans*-double bonds. As an example, conjugated linoleic acid (CLA; **Fig. 12**) can be found in food products from grass-fed ruminants as well as in eggs after feeding chickens with CLA. In 2008, the FDA categorized CLA as generally recognized as safe ([Food and Drug Administration \(FDA\), 2003](#)). CLA contains a *cis* double bond in position C9 or C12, and a *trans* double bond in C11 or C10, respectively. *Cis* and *trans* double bonds of linoleic acid and conjugated linoleic acid can be distinguished by their  $^1\text{H}$  NMR spectra. **Fig. 13** illustrates the  $^1\text{H}$  NMR signals of the double bonds of CLA in butter and linoleic acid in hazelnut oil, respectively. Signals of *cis/trans* conjugated double bonds shift to  $\delta$  6.4 ppm – 5.5 ppm, whereby other allylic protons show a multiplet at  $\delta$  5.5 ppm – 5.3 ppm. The content of *trans* FAs can be determined if the molecular weight of the appropriate FA is known. Two other *trans* FAs which occur rarely in nature are the  $\alpha$ -eleostearic acid (C18:3 9c11t13t; **Fig. 12**) in cherry stones and bitter melon seed oil (30%–60%), and the punicic acid (C18:3 9c11t13c; **Fig. 12**) in pomegranate seeds

**Fig. 11** 600 MHz  $^{13}\text{C}$  NMR spectra of a fish oil, before (bottom) and after methylation (top).

**Fig. 12** Chemical structure of *trans*-FAs.

(55%) (Saha et al., 2012; Melo, 2012). Their  $^1\text{H}$  NMR spectra are presented in Fig. 14. Each of these FAs gives a characteristic signal fingerprint. Most naturally occurring lipids exhibit only *cis* FAs which are modified by several processes like oxidation and technical processing such as microbial hydrogenation, fat hardening, deodorization and frying leading to artificial configuration known as *trans*. During these processes *cis* double bonds isomerize to the *trans* form. Thus, *trans* FAs indicate either a technical modification of the oil sample or a strong oxidation. Fig. 15 illustrates the comparison of sunflower oil before and after the refining process. Crude oils such as sunflower oil show some *trans* FAs in the region  $\delta$  6.5–5.6 ppm. These signals result from oxidation and microbiological processes showing “undefined signal mountains”. Since, in refining processes, defined *trans* FAs are formed, refined oils show defined *trans* FA signals in the appropriate  $^1\text{H}$  NMR region (Fig. 15).

**Fig. 13**  $^1\text{H}$  NMR spectrum of hazelnut oil (top) and butter (bottom).

**Fig. 14**  $^1\text{H}$  NMR spectrum of extracted pomegranate seeds (top) and extracted cherry stones (bottom).

Since the high-resolution  $^{13}\text{C}$  NMR spectroscopy provides detailed information of the chemical structure of the FAs, it is proposed as a powerful tool for the rapid determination of *cis*- and *trans*-FAs in unsaturated lipids. Another possibility to determine the isomerization is the two-dimensional homonuclear J-resolved NMR spectroscopy (JRES) where the chemical shift is along one axis and the proton–proton coupling along the other axis. Based on the chemical shift and the coupling pattern the FA can be determined like presented in Fig. 16 where oleic acid (C18:1 9c) and elaidic acid (C18:1 9t) are compared with each other. JRES is

**Fig. 15**  $^1\text{H}$  NMR spectrum of refined (top) and crude sunflower oil (bottom).

a powerful tool for analyzing overlapped signals for which resonances and splitting patterns are unknown. By running a JRES analysis, the number of *trans* FAs can be determined.

### Quality Control

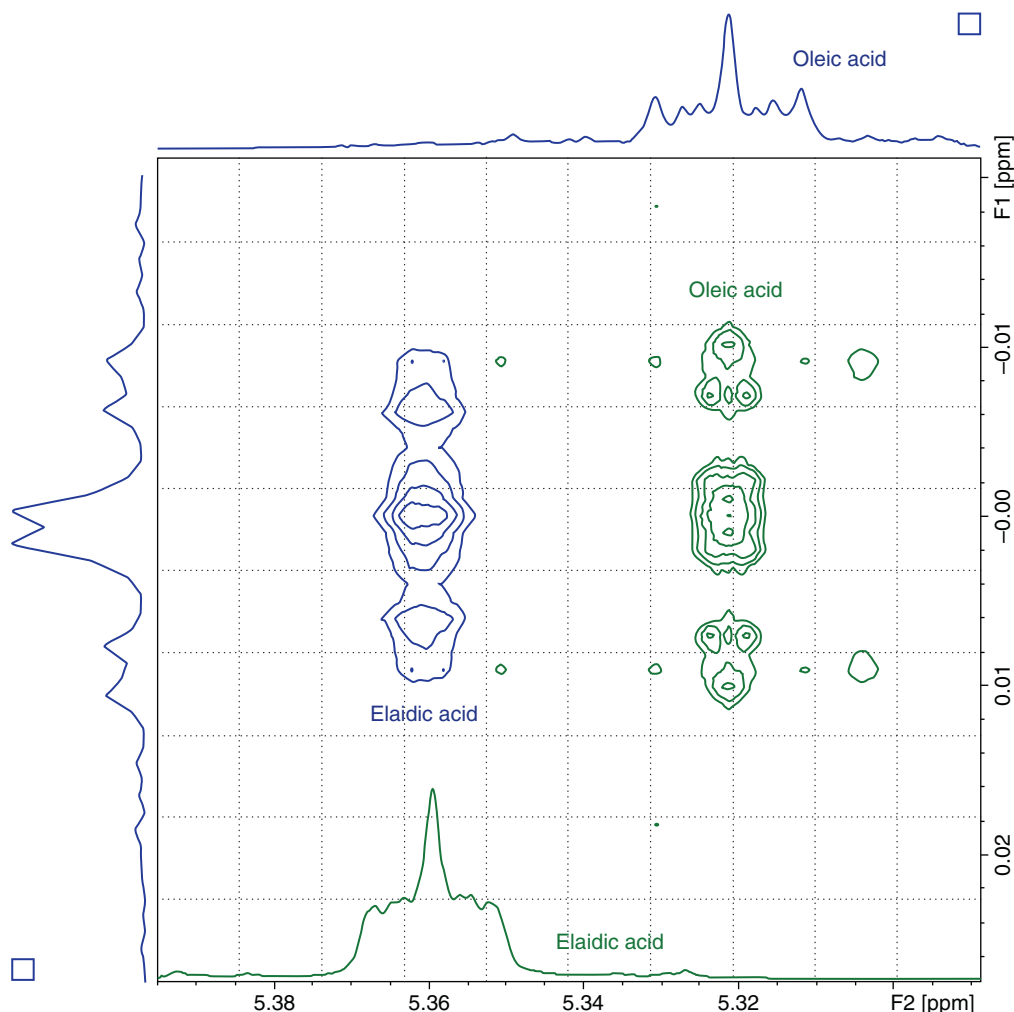

Quality control and quality assurance testing are important at every point in the food supply chain. Since quality of a product determines price, several parameters have to be assessed. Volumetric and UV/Vis spectroscopic techniques are the key elements of the analytical methods which are used for the quality control of lipids including the analysis of the peroxide value, anisidine value, acid value, saponification value and iodine value. These techniques were developed and standardized several decades ago undergoing only minor changes since then, showing several disadvantages such as poor specificity, the demand of a high amount of sample and solvents and the low robustness concerning external influences (Kamal-Eldin and Pocorny, 2005; Shahidi and Zhong, 2005). To overcome these problems, an alternative  $^1\text{H}$  NMR method was developed.

### Free Fatty Acids

The acid value can be determined by the amount of free fatty acids in oil by integrating the carboxylic group proton ( $\text{COOH}$ ) signal which appears at  $\delta$  12–11 ppm and the methylene proton signal resonating at  $\delta$  2.4–2.2 ppm in the  $^1\text{H}$  NMR spectrum, obtained from a lipid dissolved in a solvent mixture of  $\text{CDCl}_3$  and  $\text{DMSO}-d_6$ . By analyzing a total of 305 oil and fat samples, the  $^1\text{H}$  NMR technique showed a strong correlation with the conventional titration method with the exception of hard fat which showed significant deviations (Diehl and Skiera, 2013; Skiera et al., 2012).

### Peroxides and Aldehydes

Lipid peroxidation is considered as the main process leading to oxidative damage of lipids. It is initiated by the formation and propagation of free lipid radicals, even during enzyme-catalyzed lipid oxidation. Heat energy, natural radioactivity, singlet oxygen and metals achieve the high activation energy which is required for the formation of the first free radical. By a hydrogen abstraction or addition of an oxygen-radical the chain reaction of the lipid peroxidation is initiated. Since the double bonds in polyunsaturated fatty acids (PUFAs) are adjacent to a methylene group, the methylene C–H bond becomes weaker which makes the hydrogen more susceptible to abstraction. This is the reason why PUFAs are more oxidation affected than saturated FAs. Oxygen reacts with the free carbon-centered lipid radical forming a peroxy radical which possesses enough energy to abstract a hydrogen atom converting it into a lipid hydroperoxide. The general process of lipid oxidation is presented in Fig. 17.

**Fig. 16** JRES NMR spectrum of oleic acid and elaidic acid.

**Fig. 17** General lipid oxidation process. Based on [Kamal-Eldin and Pocorny \(2005\)](#).

During the complex process, the formation and propagation of lipid radicals, the uptake of oxygen as well as a rearrangement of the double bonds in unsaturated lipids are involved in the formation of the first oxidation product, such as hydroperoxides, and secondary oxidation products, such as alcohols, ketones, alkanes, aldehydes and ethers. Since the chemical structure of lipids determines the structure of the hydroperoxides, several kinds of hydroperoxide isomers are formed. Based on the fatty acid profile, the number and type of hydroperoxides differ. The total amount of peroxides are examined as the peroxide value (PV). The PV is classically titrated according to Wheeler, being expressed in the units of milli equivalents of active oxygen per kilogram (meq/kg) ([Wheeler, 1932](#)). PV covers all compounds which oxidize potassium iodide under certain defined conditions ([ISO 3960, 2017](#)). This value is used as an indicator of the early oxidation stages in lipids. Over the past decades, several new methods such as colorimetric, chromatographic, and IR have been developed to determine hydroperoxides in oils and fats ([Kamal-Eldin and Pocorny,](#)

**Fig. 18**  $^1\text{H}$  NMR spectra of fresh chia oil (top), low oxidized olive oil (middle), and high oxidized almond oil (bottom); details: hydroperoxides.

2005; Yildiz et al., 2003). A very powerful tool for the analysis of the hydroperoxides is the NMR spectroscopy. Several authors found a good correlation between olefinic and aliphatic protons as well as between aliphatic and diallylmethylene protons in fatty acids and the classical PV (Saito, 1987; Shahidi and Wanasundara, 1997; Abou-Gharbia et al., 2000). Skiera et al. presented another alternative  $^1\text{H}$  NMR spectroscopic method to determine the hydroperoxide amount in edible oils by quantifying the  $-\text{OOH}$  signals (Skiera et al., 2012). By setting the  $\alpha\text{-CH}_2$ -integral value to 2000, the integral value of peroxides ( $\delta$  11.5–10.5 ppm) presents the amount of peroxides in mol-% (Fig. 18). An equation was established which related the PV to the NMR results. According to a Deming regression line the PV can be recalculated into the classical unit meg/kg. It is noticed that some oil types, especially olive oil and black seed oil seed oil, exhibit significant deviations in the PV by NMR and by titration according to Wheeler. These differences may result from cross-reactions from the titration reagents with natural oil-compounds or additives. For example, black seed oil contains natural oxidizing ingredients such as thymoquinone, a pharmacologically active terpene with significant anti-oxidative properties, which shows a strong increasing effect of the analyzed PV. Furthermore, in olive oil a high content of several phenolic compounds decreases the PV titration results. These results show that natural compounds of the oil matrix can influence the titration results significantly (Skiera et al., 2012). Moreover, a low PV does not directly indicate a low oxidized lipid. During a further oxidation step primary oxidation products form secondary oxidation products such as aldehydes which are analyzed as the *p*-Anisidine Value (AV). The knowledge of the PV and AV provides a reliable way to determine the overall oxidation stage of lipids. The AV analysis is based on the chemical reaction with *p*-anisidine forming an intensively coloured Schiff base which is nonspecifically measured by UV at  $\lambda = 350$  nm (ISO 6885, 2006). The AV depends on the aldehyde type, whereby the number of double bonds leads to different response factors for alkanals, alkenals and alkadienals of 0.5, 6, and 30, respectively. Based on this knowledge, the classical AV determination is erroneous. With NMR spectroscopy the individual aldehydes can be identified and quantified as an absolute value. By setting the  $\alpha\text{-CH}_2$ -integral value to 2000 the integral value of aldehydes presents the aldehyde amount in mol-% (Fig. 19). A further advantage of NMR spectroscopy is the simultaneous detection of primary and secondary oxidation products. Thus, the NMR spectroscopy represents a powerful tool to monitor and investigate oxidation products in edible fats and oils.

### Adulteration Control

A series of 46 blends with a total weight of 300 mg was prepared from selected olive ( $n = 5$ ) and sunflower ( $n = 5$ ) oil samples. The amount of sunflower oil in these mixtures was 0%, 20%, 40%, 60%, 80% and 100% (w/w). In each mixture the samples from both origins were selected randomly in order to assure representativeness of multivariate regression models. Recorded NMR spectra pre-processed by bucketing were correlated with “ground truth” data of the blends composition using partial least squares regression (PLS) (Fig. 19).

Scatter plot of PLS scores for the first and the second PLS dimensions clearly demonstrated the discrimination of all spiking groups (Fig. 20). Fig. 21 showed the predicted-reference plot along with 95% prediction bands for sunflower oil content in blends obtained by PLS regression. Root mean square error of regression was equal to 1.1% w/w. Limit of detection (LOD) estimated using the slope and standard deviation of response of this curve was found to be 1.1%. Quantification of olive oil adulteration is possible starting from 3.5% w/w.

**Fig. 19**  $^1\text{H}$  NMR spectra of a high oxidized seed oil; details: aldehydes.

**Fig. 20** PLS scores on the first and the second PLS components for cross validation for olive-sunflower blends. Ellipsoids show 95% probability for each “spiking group” (defined as an average sunflower oil content in each group).

### Molecular Weight

Conventionally, molecular weights (MWs) of TAGs are determined with liquid or gas chromatography combined with mass spectrometry (Vorbeck et al., 1960). However, the MW can also be calculated with  $^1\text{H}$  NMR spectroscopy by taking the signals from the FAs and the glycerin backbone into account. Glycerol trioleate, Glycerol tristearate and Glycerol tridonadecanoate, whose molecular weights are known, have been analyzed with  $^1\text{H}$  NMR spectroscopy. After the quantification, the theoretical MW values have been compared with the NMR values (Fig. 22). A slope of 0.9937 and a correlation coefficient  $R^2$  of 0.9983 indicates that the NMR

**Fig. 21** Predicted-reference plot and 95% prediction bands (solid lines) obtained from spiking experiments.

**Fig. 22** Correlation of theoretical MW and with  $^1\text{H}$  NMR quantified MW.

spectroscopy is a versatile tool for the determination of molecular weights of vegetable oils. In the  $^1\text{H}$  NMR spectra the mean MW of lipids can be determined simultaneously to the analysis of several quality parameters such as free fatty acids, peroxides, aldehydes, saturation grade, fatty acid profile as well as secondary components such as phenols. All parameters are analyzed qualitatively and quantitatively in only one measuring step from one prepared sample, being ready in 3 min.

# Lipid-Derived Flavours and Off-Flavours in Food

Fereidoon Shahidi and Abreham Abad, Department of Biochemistry, Memorial University of Newfoundland, St. John's, NL, Canada

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Lipids, naturally present in food or added to food during processing, play an important role in nutrition as well as flavour and off-flavour development. Furthermore, lipid oxidation is a major cause of reducing the quality of food and its control is considered a challenge to the food industry. Generally, lipids present in food are more likely to undergo oxidative reactions resulting in the development of off-flavours, and loss of some bioactive compounds and liposoluble vitamins (Kolakowska and Bartosz, 2014; Souza and Bragagnolo, 2014; Akoh, 2017).

Generally, lipid autoxidation in food proceeds in two stages; the formation of hydroperoxides and their subsequent breakdown and production of odour-active volatile secondary lipid oxidation products (SLOP), such as alcohols, ketones, and aldehydes, among others. Polyunsaturated fatty acids (PUFA) are particularly prone to degradation due to their multiple methylene-interrupted *cis*-double bonds. Lipid oxidation is highly undesirable in food products because even low concentrations of SLOPs render distinct off-flavour to products (Jacobsen, 1999; Böttcher et al., 2015). Lipid oxidation has also generated much interest in the field of functional foods and in products that are frequently enriched with PUFA to improve their nutritional value, as in meat and meat products (Salcedo-Sandoval et al., 2013), milk and milk products (Let et al., 2003), and eggs (Petrović et al., 2012), among others. The biochemical or chemical degradation of lipids gives rise to a wide range of volatile compounds such as free fatty acids, their related esters, and lactones that are key components in the flavour of food and therefore, in the formation of aroma compounds (Wache et al., 2006). In addition, secondary products of lipid oxidation could react with peptides, proteins, and amino acids, contributing to protein oxidation that may result in loss of essential amino acids and also changes in the protein, in addition, leading to loss of functionality (Estévez, 2015; Estévez and Luna, 2016).

## Lipid Oxidation and Off-Flavour Development

The oxidation of unsaturated fatty acids is a complex phenomenon which occurs in the presence of oxygen, non-enzymatically or enzymatically. Lipid oxidation and formation of flavour-active components is catalyzed by heat, light, photosensitizers, oxygen, and transition metal ions (Mariutti and Bragagnolo, 2017). Non-enzymatic oxidation could occur via photooxidation or autoxidation. Photooxidation occurs in the presence of singlet oxygen ( $^1\text{O}_2$ ), while autoxidation occurs in the presence of triplet oxygen ( $^3\text{O}_2$ ). Enzymatic oxidation occurs by the action of lipoxygenase and the processes involved are different from non-enzymatic oxidation (Mariutti and Bragagnolo, 2017). The saturated fatty acids can enter the autoxidation process over higher temperatures during processing operations such as baking, boiling, and frying, among others. Meanwhile, only unsaturated fatty acids can be oxidised by atmospheric oxygen at ordinary temperatures (Resconi et al., 2013). The development of lipid oxidation could be followed by monitoring the primary products of fatty acid oxidation, for example, conjugated dienes and hydroperoxides, or the secondary oxidation products such as malondialdehyde (MDA), propanal, pentanal, and hexanal, among others. Usually, the thiobarbituric acid reactive substances (TBARS), reported as MDA equivalents is determined colorimetrically at 532 nm (Resconi et al., 2013).

## Autoxidation

The main mechanism of lipid oxidation in food is autoxidation which consists of the reaction of triplet oxygen with organic compounds. Triplet oxygen is a diradical species so one pair of its even number of electrons has parallel spins, and thus, it can easily react with radical species. Generally, direct reaction of oxygen with unsaturated fatty acids is not possible because their double bonds are in singlet spin state. Therefore, an initiator is necessary to remove an electron from the unsaturated lipid to generate a radical in order to facilitate the reaction between the oxygen and an unsaturated fatty acid. Lipid autoxidation is a chain reaction process induced by free radicals described by three steps of initiation, propagation, and termination. These steps have been thoroughly described by several researchers (Chaiyasit et al., 2007; Schaich et al., 2013; Shahidi and Zhong, 2010). Through the propagation stage, primary products of oxidation, namely lipid hydroperoxides, are produced. These products are unstable and break down to a number of secondary oxidation products such as ketones, aldehydes, hydrocarbons, alcohols, and volatile organic acids among others; some of which have undesirable odours with extremely low threshold values (Shahidi and Zhong, 2010). Table 1 summarizes the threshold values of relevant volatile compounds. Moreover, the products of lipid oxidation lead to loss of the nutritional value, texture, colour, and some functional properties of food (Shahidi, 2002).

**Table 1** Threshold values of compounds formed upon lipid oxidation

Compounds	Threshold value (ppm)
Hydrocarbons	90–2150
Alkenes	0.02–9
Vinyl alcohols	0.5–3
Alcohols, saturated	0.3–2.5
Alcohols, unsaturated	0.001–3
1-Alkenes	0.02–9
2-Alkenals	0.04–2.5
Furans	1–27
Alkenals	0.04–1
Aldehydes, saturated	0.014–1
Aldehydes, monounsaturated	0.04–2.5
Aldehydes, diunsaturated	0.002–0.6
trans,trans-2,4-Alkadienals	0.04–0.3
trans,cis-Alkadienals	0.002–0.006
Ketones, methyl	0.16–5.5
Ketones, vinyl	0.0002–0.007
Isolated alkadienals	0.002–0.3
Isolated cis-alkenals	0.0003–0.1

From Frankel (1985), Drumm and Spanier (1991), Shahidi (2002), and Min and Boff (2002).

### Photooxidation

The molecular oxygen in the ground state is in its triplet state ( $^3\text{O}_2$ ) which is a diradical, and could be activated by electronic excitation to a singlet state ( $^1\text{O}_2$ ). Singlet oxygen may be generated by ultraviolet light, or photosensitizers such as chlorophyll, riboflavin, and myoglobin, among others (Min and Boff, 2002). Singlet oxygen is more electrophilic than triplet oxygen, thus it is strongly reactive. For example, the reaction rate between singlet oxygen and linoleic acid is 1450 times higher than that with triplet oxygen (Min and Boff, 2002).

Singlet oxygen reacts easily with unsaturated fatty acids via cycloaddition and forms fatty acid hydroperoxides. The reaction occurs on the carbon atoms located between two double bond then cause change of position and then configuration of the double bond. Therefore, mono-, di- and triunsaturated fatty acids, respectively, oleic acid generates a mixture of two (9- and 10-hydroperoxides), linoleic acid generates a mixture of four (9-, 10-, 12- and 13-hydroperoxides), and linolenic acid generates a mixture of six hydroperoxides (9-, 10-, 12-, 13-, 15- and 16-hydroperoxides). Linolenic acid could form four conjugated and two non-conjugated hydroperoxides, while linoleic acid could form two conjugated and two non-conjugated hydroperoxides (Mariutti and Bragagnolo, 2015). The relative rates of oxidation for oleic, linoleic, and linolenic acids are shown in Table 2. The reaction rates of fatty acids upon photooxidation are faster than those during autoxidation.

### Enzymatic Oxidation

Enzymatic oxidation is based on the enzymatic activity of lipoxygenase (LOX). Lipoxygenase (LOX) is a globular protein soluble in water consisting of a single polypeptide chain with a molecular mass of 94–104 kDa in plants and 75–80 kDa in animals. It is capable of producing conjugated hydroperoxides through the oxidation of polyunsaturated fatty acids (Whitaker, 1972). And also, catalyzes the first reaction of so-called “way of lipoxygenase”. The way of lipoxygenase is of fundamental importance in the formation of all the volatile substances responsible for the aroma of vegetables and fruits that, in the case of olive oil, contributes markedly to the characterization as well as differentiation between different cultivars (Boe, 2012). A molecule of LOX contains, at the active site, one iron atom in high spin state  $\text{Fe}^{2+}$  that must be oxidized to  $\text{Fe}^{3+}$ , thus the oxidation reaction might proceed. This enzyme stereoselectively catalyzes the non-reversible oxidation of PUFA containing the group 1, 4-cis, cis-pentadiene

**Table 2** Relative rates of fatty acid oxidation

Fatty acid	Autoxidation	Photooxidation
Oleic (C18:1)	1	$30 \times 10^3$
Linoleic (C18:2)	50	$40 \times 10^3$
Linolenic (C18:3)	100	$70 \times 10^3$

Adopted from Min and Boff (2002).

( $-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$ , commonly called malonic system), and yields a stereospecific conjugated diene hydroperoxides fatty acid (Tappel, 1963; Galliard, 1989).

## Fatty Acid-Derived and Other Lipophilic Flavour Compounds

The majority of plant volatiles are produced from unsaturated and saturated fatty acids. Fatty acid-derived straight-chain alcohols, ketones, aldehydes, acids, lactones, and esters are found in the plant kingdom in high concentrations. These are formed by three distinct processes, lipoxygenase pathway,  $\beta$ -oxidation, and  $\alpha$ -oxidation (Schwab and Schreier, 2002). Generally, in plants, fatty acids are stored as triacylglycerols and thus enzymatic oxidative degradation of lipids occurs via the action of acyl hydrolase, and then liberating free fatty acids from acylglycerols. Furthermore, identification of a number of phosphatidylglycerols, and digalactosyldiacylglycerols demonstrates the possibility of direct oxidation of the fatty acid side chain in acylglycerols (Buseman et al., 2006; Schwab et al., 2008; El Hadi et al., 2013).

## Lipoxygenase

The pathway of chain oxidation, unsaturated and saturated volatile C6 and C9 aldehydes and alcohols are very important contributors to the characteristic flavours of vegetables, fruits, and green leaves. There are four enzymes involved in the biosynthetic pathway leading to their formation; these are hydroperoxide lyase (HPL), lipoxygenase (LOX), alcohol dehydrogenase (ADH), and 3Z, 2E enal isomerase (Matsui, 2006; Stumpe and Feussner, 2006) (Fig. 1). LOX is a non-heme, iron-containing dioxygenase which catalyzes the regio- and enantio-selective dioxygenation of the unsaturated fatty acids. Numerous plant lipoxygenases (LOX) have been characterized due to the essential components of oxylipin pathway, also converting fatty acids to hydroperoxides and finally flavour compounds like 2E-hexenal, 2E, 6Z-nonadienal, and 3Z-hexenal. Volatile compounds such as methyl jasmonate,

**Figure 1** Linolenic acid-derived flavour compounds. AAT, alcohol acyl CoA transferase; ADH, alcohol dehydrogenase; AER, alkenal oxidoreductase; AOC, allene oxide cyclase; AOS, allene oxide synthase; HPL, hydroperoxide lyase; JMT, jasmonate methyltransferase; LOX, lipoxygenase; OPR, 12-oxo-phytyldienoic acid reductase; and 3Z,2E-EI, 3Z,2E-enal isomerase. Adopted from [El Hadi et al. \(2013\)](#).

*cis*-3-hexenol, and *trans*-2-hexenal are derived from C18 unsaturated fatty acids including linolenic acid or linoleic acid that undergo dioxygenation in the reaction catalyzed by LOX. These enzymes can catalyze the oxygenation of polyenoic fatty acids at C9 or C13 positions yielding two groups of compounds, the 13-hydroperoxy and the 9-hydroperoxy derivatives of polyenoic fatty acids. These derivatives could be further metabolized by several enzymes such as allene oxide synthase (AOS) and hydroperoxide lyase (HPL) which represent two lipoxygenase pathways yielding volatile compounds. The 13-hydroxyperoxy linolenic acid is converted to 12, 13-epoxyoctadecatrienoic acid (Feussner and Wasternack, 2002). Several subsequent enzymatic reactions that lead to the formation of jasmonic acid can be converted to the volatile ester, methyl jasmonate, by enzyme jasmonic acid carboxymethyl transferase (Song et al., 2005). In the hydroperoxide lyase (HPL) branch of the LOX pathway, the oxidative cleavage of hydroperoxy fatty acids through the action of HPL leads to the formation of C6 or C9 volatile aldehydes such as 3-hexenal and 3, 6-nonadienal, respectively (Akacha et al., 2005; El Hadi et al., 2013).

The degradation of straight chain fatty acids by both  $\alpha$ - and  $\beta$ -oxidation is considered as a major process for the formation of flavour compounds in all organisms, however, specific pathways in plants are not yet fully understood. Baker et al. (2006) described various roles for this pathway in relation to the fatty acid as well as amino acid metabolism.  $\beta$ -Oxidation results in the successive removal of C2 units (acetyl, CoA) from the parent fatty acid (Goepfert and Poirier, 2007). Sanz et al. (1997) mentioned that  $\beta$ -oxidation of fatty acids is the primary biosynthetic process providing acyl coenzyme A (CoAs) and alcohols for ester formation by losing two carbons in every round of the  $\beta$ -oxidation cycle, the fatty acid acyl-CoA derivatives are converted to shorter chain acyl CoA which require flavinadenine dinucleotide (FAD). The two classical examples are pear and apple aromas of volatile formation through  $\beta$ -oxidation pathway (El Hadi et al., 2013).

### Volatiles Compounds From Lipid-Maillard Interaction

The Maillard reaction is considered as one of the main chemical reactions which takes place during cooking of red meat and poultry. This reaction occurs between reducing sugars and amino compounds and eventually results in a large number of compounds responsible for the flavour of any species of meat (Mottram, 1994a). During the first stages of the reaction, the Amadori products are formed via glycosylamine as a result of condensation of the carbonyl group of a reducing sugar with the amino compounds. Several sugar dehydration and degradation products like furfural and furanone derivatives, dicarbonyl compounds, and hydroxyketones are formed by rearranging and dehydration of the resultant products (Mottram, 1998; Calkins and Hodgen, 2007).

The Strecker degradation of amino acids by Maillard reaction-derived dicarbonyl compounds is a vitally associated reaction (Mottram, 1998; Jayasena et al., 2013). Maillard reaction-derived carbonyl compounds react with those compounds forming intermediates which are further involved in flavour-forming reactions. At the end, a large number of important classes of flavour compounds including pyrazines, furans, pyrroles, oxazoles, thiazoles, thiophenes and other heterocyclic compounds are formed (Melton, 1999). Shahidi (1989), Mottram and Madruga (1994) reported that sulphur-compounds derived from cysteine and ribose, and carbonyl compounds are principal contributors to the flavour of meat. However, ribose is considered as the most important flavour precursor in chicken meat (Meinert et al., 2009).

Mottram (1994b) and Whitfield (1992) reported that the interaction of lipid breakdown products with Maillard reaction leads to formation of several volatiles which are identified in meat (Fig. 2). Some thiazoles with C4 to C8 n-alkyl substituents in the 2-position as well as some other alkylthiazoles with much longer 2-alkyl substituents (C13 to C15) are reported in fried chicken and

wet-cured cooked hams	Alkenes; alkanes; aldehydes; alcohols; ketones; esters; pyrazines; chloride; terpenes; furans; amines; carboxylic acids; sulfur compounds; aromatic hydrocarbons	Ramarathnam et al., 1993, Leroy et al., 2009
dry-cured hams	2-heptanone; benzaldehyde; hexanal; limonene; hexanol; octanol; pentanol; butanol; propanone; 2-nonanone; 3-methylbutanal	Luna et al., 2006, Garcia-Gonzalez et al., 2008

heated chicken (Tang et al., 1983; Farmer and Mottram, 1994). The compound 2-octyl-4, 5-dimethylthiazole is found in chicken meat and it is also a product from interaction of lipids and Maillard reactions (Melton, 1999).

The formation of volatile compounds in different foods depend on their constituent components (Table 3). Thus flavour generation in bulk oil, oil emulsion, meat and poultry, fruits and vegetable, cereals, legumes as well as in processed foods such as coffee, roasted products by different means is dictated by a variety of factors. Some examples of different commodities and their flavour as affected by lipid constituents present are discussed in subsequent sections of this chapter.

### Flavour Compounds in Edible Oils

Unsaturated fatty acids that are oxidized by photooxidation, autoxidation or enzymatic oxidation form hydroperoxides that may decompose to low molecular weight compounds such as alcohols, ketones, hydrocarbons and aldehydes, as already mentioned (Chaiyasit et al., 2007). The decomposition of hydroperoxides (ROOH) generates volatile compounds as well as producing hydroxyl radical ( $\cdot\text{OH}$ ) and alkoxy radical ( $\text{RO}\cdot$ ), as the predominant pathway (Chaiyasit et al., 2007). Alkoxy radical ( $\text{RO}\cdot$ ) is more reactive than both peroxy radicals ( $\text{ROO}\cdot$ ) and alkyl radicals ( $\text{R}\cdot$ ) and could also react by different mechanisms: it could attack the unsaturated fatty acids or undergo  $\beta$ -cleavage. The radicals resulting from  $\beta$ -cleavage can react with several products to produce secondary products of oxidation. The main aldehydes formed by oxidation of linolenic acid are 2-butenal, propanal, 2-pentenal, 3-hexenal, 2-hexenal, 2-heptenal, 2,4-heptadienal, 2,6-nonadienal; 2,5 octadienal, and 2,4,7-decatrienal; of linoleic acid, hexanal, pentanal, heptanal, octanal, 2-octenal, 2-heptenal 3-nonenal, 2-nonenal, 2-decenal, 2,4-decadienal, and 2,4-nonadienal; and of oleic acid are octanal, heptanal, nonanal, decanal, 2- undecenal, and 2-decenal (Belitz et al., 2009).

The 4-hydroxyalkenals, one of the aldehyde classes formed during lipid oxidation, are of particular interest because these compounds are related to biological activities like chemotactic activity against neutrophils, enzyme inhibition, and inhibition of protein synthesis (Esterbauer et al., 1991). The 4-hydroxy-2-nonenal (HNE) is the main aldehyde that is formed during autoxidation of n-6 polyunsaturated fatty acids, but its mechanisms of degradation and formation is not yet completely elucidated (Esterbauer et al., 1991; Sakai et al., 2006). Mariutti and Bragagnolo (2015) have reported that the compounds of high molecular weight are responsible for changes in the viscosity and colour of the oxidized products, while compounds of low molecular weight are responsible for rancid flavour.

The oxidation of vegetable oil such as soybean oil results in the formation of hydroperoxides that degrade to form a different of volatile, short-chain secondary oxidation products (Ullrich and Grosch, 1988). Some of these volatile compounds negatively affect the quality of oil by producing undesirable off-flavours. Studies show volatile compounds in soybean oil are 2,4-hepta-dienal and 2-hexenal from linolenate hydroperoxides and hexenal, pentane 2,4-decadienal, and 2-heptenal from linoleate hydroperoxides (Selke and Frankel, 1987).

The aroma of olive oil for example is attributed to alcohols, aldehydes, ketones, hydrocarbons, esters, furans, and, maybe other unidentified volatile compounds. However, the studies reported that the major volatile compounds in most virgin olive oils in Europe are the C5 and the C6 volatile compounds. Hexanal, 1-hexanol and 3-methylbutanol, *trans*-2-hexenal are found (Aparicio et al., 1997; Kiritsakis, 1998; Angerosa, 2002). Research has shown odour thresholds and sensory descriptors of volatile compounds in olive oil (Table 4).

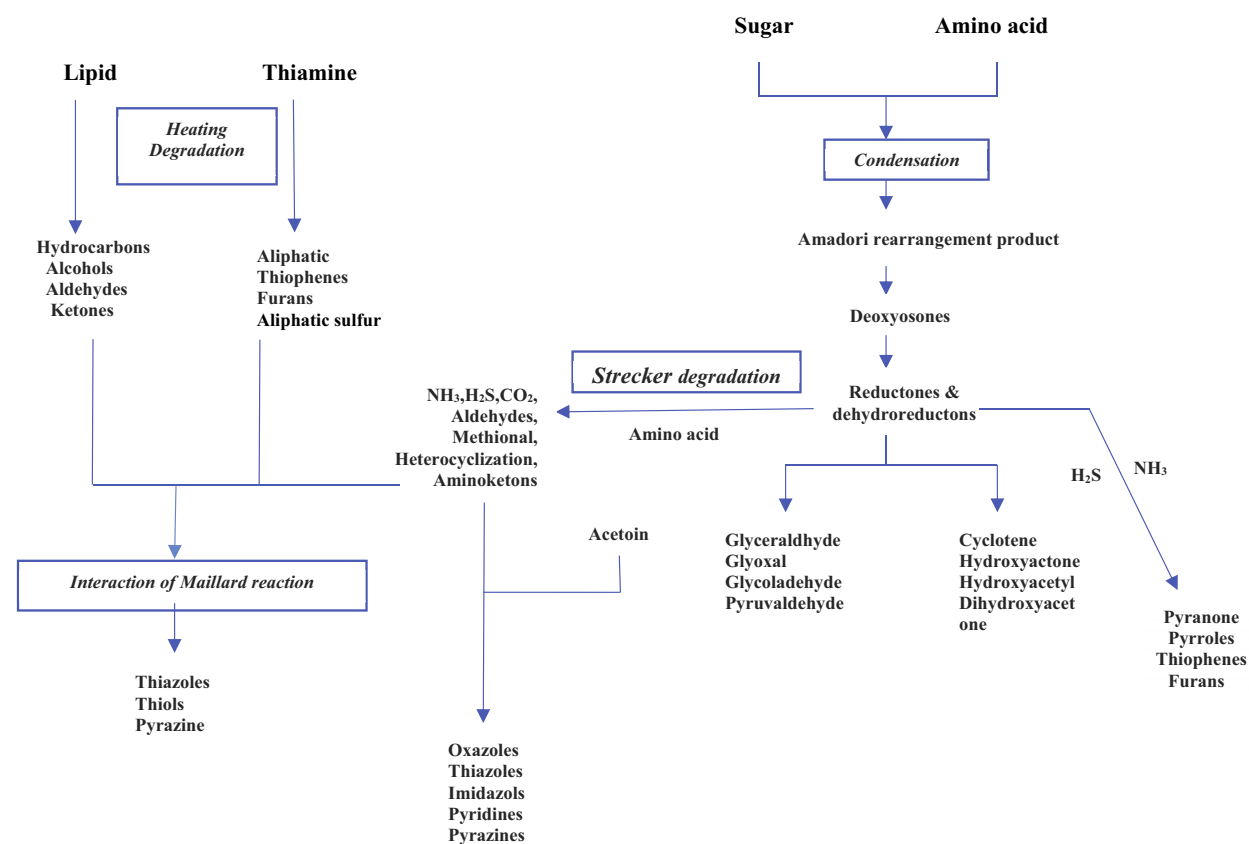

**Table 4** Odour thresholds and sensory descriptors of volatile compounds in olive oil

Volatile compounds	Odour threshold ( $\mu\text{g/kg oil}$ )	Sensory descriptor(aroma)	References
<b>Aldehydes</b>			
Acetaldehyde	0.22	Pungent, sweet	Reiners and Grosch (1998)
3-Methylbutanal	5.4	Malty	
Pentanal	240	Woody, bitter, oily	Morales et al. (2005)
Hexanal	75	Green-sweet

Ethyl propanoate	100	Fruit, strong	Morales et al. (2005)

### Flavour Compounds in Meat and Poultry

The development of the characteristic flavour of cooked meat is attributable to volatiles generated during heating as a result of processes such as lipid oxidation, Maillard reaction, interactions between lipid oxidation products and Maillard reaction products, and thermal degradation of thiamine, among others. **Fig. 3** Schematic illustration of volatile compounds generated by Maillard reaction between sugars and amino acids; heat degradation of lipid and thiamine (MacLeod, 1998).

Meat and meat products constitute an important source of dietary protein (Font-i-Furnols and Guerrero, 2014). The quality of these products as well as their attractiveness to consumers are, to a large extent, attributable to the palatability being a sum of gustatory and olfactory sensations. The flavour of raw meat is described as metallic, salty, and rare (bloody) with a bit of sweet aroma

**Figure 3** Schematic illustration of volatile compounds generated by Maillard reaction between sugars and amino acids; heat degradation of lipid and thiamine (Dashdorj et al., 2015; Kosowska et al., 2017).

(Soncin et al., 2007). Despite its weak flavour, meat is a rich source of compounds that serve as precursors of volatile compounds. Heat treatment initiates a series of reactions which result in the development of the characteristic flavour of meat, including lipid oxidation. Heat treatment of meat (lamb, pork, beef, and poultry) imparts non-species-specific meaty flavour, whereas warming up meat containing fat, particularly to a lesser extent triacylglycerols and phospholipids, causes development of a specific flavour of meat. Many volatile compounds are generated during thermal processing such as aldehydes, alcohols, ketones, hydrocarbons, carboxylic acids, furans, esters, lactones, pyrans, pyrazines, pyridines, phenols, pyrroles, thiophenes, thiazoles, oxazoles, thiazolines, and other sulphur or nitrogen compounds (Kosowska et al., 2017).

The species-specific flavour of meat is usually determined by mixtures of volatiles that in the case of heat-treated products includes hundreds of compounds. For instance, Mottram (1994c) had identified about 880 volatile compounds in cooked beef. The contribution of individual volatile compounds in developing the characteristic flavour, only a small part of this large number contributed to flavour development. Therefore, it is very important to distinguish aroma-active compounds from other odour inactive food constituents (Grosch, 1993). It is estimated that only 3% out of 10,000 identified volatile compounds are able of imparting odours to food products (Dunkel et al., 2014). Species specific flavour of meats are mainly influenced by the type of fats and fatty acids present in meat. Phospholipids are the major fraction of lipid that generates volatile compounds, and to a lesser extent by triacylglycerols (Meinert et al., 2007; Soncin et al., 2007). The distinct strong flavour of sheep meat (lamb or mutton) is due to the presence of volatile medium chain branched fatty acids. Brennad and Lindsay (1992) reported that 4-methyl- and 4-ethyl-octanoic acids that are present in the subcutaneous adipose tissue contribute to the species-related flavours in lamb upon hydrolysis.

The flavour of meat products is a result of several factors, the most important is the components and parameters of the production process. The main significance in finished product flavour development is ascribed to the kind of meat used as it affects the composition of volatile compounds. The major volatiles of cooked beef include nonanal, octanal (E,E)-2,4-decadienal, methional, methanethiol, 2-furfurylthiol, 2-methyl-3-furanthiol, 4-hydroxy-2,5-dimethyl-3-(2H)-furanone, and 3-mercapto-2-pentanone. These compounds also occur in chicken meat as well as cooked pork, however, their concentrations differ among species. The meaty-caramel odour noted in cooked beef is attributable to high concentration of compounds 4-hydroxy-2,5-dimethyl-3-(2H)-furanone, 2-methyl-3-furanthiol, and 2-furfurylthiol. For comparison, a lower concentration of 4-hydroxy-2,5-dimethyl-3-(2H)-furanone in pork results from significantly lower concentrations of its precursors, fructose 6-phosphate and glucose 6-phosphate. The concentration of carbonyl compounds with greasy odour notes, such as nonanal and hexanal is lower in pork than in beef (Belitz et al., 2009). The important volatile compounds of cooked poultry meat include hexanal, 2-furfurylthiol, 2(E)-nonenal, 2,4(E,E)-decadienal, 2,4(E,Z)-decadienal, and 2,4(E,E)-nonadienal (Kerler and Grosch, 1997). During oxidation stage of poultry fat,  $\gamma$ -dodecalactone and (E,E)-2,4-decadienal are formed from linoleic acid which are typical of the chicken meat flavour (Gasser and Grosch, 1991; Chen and Ho, 1998).

Ramarathnam et al. (1993) as well as Leroy et al. (2009) analyzed the wet-cured cooked ham and compared them with non-cured products. A significantly lower contents of carbonyl compounds were found in the cured products. They also found many volatile compounds originating from both the reactions in meat and from added spices or the applied smoke such as alkenes, alkanes, aldehydes, alcohols, ketones, aromatic hydrocarbons, esters, carboxylic acids, terpenes, sulphur compounds, pyrazines, chloride, furans, and amines. However, only a few of these compounds contributed to development of a typical character of a product. The main volatiles identified included terpenes (linalool, 1,8-cineole, L-carvone, menthol, cinnamaldehyde) which originated from seasonings, and also, 3-methylbutanoic acid and sulphur compounds formed upon Strecker degradation reaction (Toldra and Flores, 2007).

For the dry-cured ham, ketones alcohols, and aldehydes, had a significant effect on the characteristic flavour of the final products. The presence of 2-heptanone, benzaldehyde, hexanal, limonene, hexanol, 3-methylbutanal, octanol, pentanol, butanol, propenone, and 2-nonanone was also noted (Luna et al., 2006; Garcia-Gonzalez et al., 2008). There is an interesting group of meat products that includes raw-ripened sausages. For instance, about 51 key volatiles were identified in the Hungarian-type Salami sausage, which included amino acid degradation products (methional, phenylacetaldehyde and 3-methylbutanal), and fermentation products (acetic acid, acetaldehyde, butanoic acid, and 3-methylbutanoic acid) as well as short-chain fatty acids (Sollner and Schieberle, 2009).

The role of lipid-derived carbonyl compounds in chicken flavour has been studied by many researchers. The lean meat contains structural phospholipids and intramuscular triacylglycerols. Thus, both desirable and undesirable flavours could be generated in meat because of lipid oxidation. The reasonable thermal oxidative changes of lipids lead to generation of desirable flavour compounds as well as aromas in cooked meats (Shahidi, 2002). The flavour development of poultry meat is partly attributed to its lipids (Perez-Alvarez et al., 2010). Hundreds of volatile compounds are generated in cooked meat during lipid degradation; such compounds include aliphatic hydrocarbons, alcohols, aldehydes, ketones, carboxylic acids, esters, some aromatic hydrocarbons, in addition to oxygenated heterocyclic compounds like alkylfurans and lactones (Mottram, 1998; Jayasena et al., 2013). About forty-one out of one hundred ninety-three total compounds reported in the flavour of chicken (roasted chicken) are lipid-derived aldehydes (Shi and Ho, 1994). According to that study, 2,4-decadienal and hexanal are relatively high of aldehydes that identified in chicken flavour and known as primary oxidation products of linoleic acid (Shi and Ho, 1994).

Many studies have confirmed that phospholipids are more important in the development of aroma volatiles during the cooking of meat than triacylglycerols (Jayasena et al., 2013). This is attributed to the presence of higher proportion of unsaturated fatty acids, such as arachidonic acid (20:4) in phospholipids (Mottram and Edwards, 1983). The levels of unsaturated fatty acids in chicken are very high compared with red meat, hence they generate more unsaturated volatile aldehydes that are vital in specific aromas of

chicken (Noleau and Toulemonde, 1987). Moreover, the aroma of fat-fried food is due to 2,4-decadienal (Mottram, 1998). Thus, aliphatic aldehydes contribute to the fatty flavours of cooked chicken meat. Shahidi (2002) reported that low amounts of  $\alpha$ -tocopherol in chicken meat is a major reason for meat flavour deterioration and formation of the undesirable “warmed over flavour (WOF)” in chicken meat products. Lipid-derived compounds in meat volatiles have greater odour threshold values (2-methyl-3-furanthiol; 2-furfurylthiol; Bis (2-methyl-3-furyl) disulphide; 2,4,5-trimethylthiazole; 2,4-decadienal; 3-mercapto-2-pentanone; 2-formyl-5-methylthiophene) as opposed to nitrogen- and sulphur-containing heterocyclic compounds that make them less aroma significant. Heterocyclic compounds possess a significant effect on aroma because of their low odour threshold values (Jayasena et al., 2013).

## Flavour Compounds in Fruits and Vegetables

The volatile lipid-derived flavour of fruits depend on the cultivar, degree of maturity, geographic region, processing methods and parameters. In general, fruit of the same cultivar grown in different geographic regions produce different volatile compounds, as does fruit from different cultivars grown under the same environmental conditions (Sacchi et al., 1998; Angerosa et al., 1999; Ridolfi et al., 2002; Benincasa et al., 2003).

For vegetables, tomatoes as an example, include over 400 flavour volatiles identified, 10 of which contribute to the aroma of ripe tomato (Petro-Turza, 1986). These volatiles include beta-ionone (Z)-3-hexenal, 1-penten-3-one, hexanal (E)-2-hexenal (Z)-3-hexenol, 2- and 3-methyl-butanol, 6-methyl-5-heptene, and 2-isobutylthiazole. A majority of these volatiles are lipid derived and mainly from the lipoxygenase (LOX) pathway. Major tomato volatiles in peel and flesh could be broken down into three categories: lipid derived, carotenoid derived, and amino acid derived (Mirondo and Barringer, 2015). Usually, tomatoes are not peeled prior to being made to juice, and also it is unknown if the presence of peel during the crushing process impacts the volatile profile, viscosity, and colour of tomato products. However, tomato peels produce a bit higher levels of lipid-derived volatiles than the fleshy part through LOX activity (Ties and Barringer, 2012).

The LOX-derived volatiles include hexanol (E)-2-hexenol, and (Z)-3-hexenol, hexanal (E)-2-hexenal, and (Z)-3-hexenal, which are associated with a fresh green flavour note in tomatoes (Ties and Barringer, 2012). In high concentrations, the fresh green flavour note changes the sensory profile and intensity of tomato flavour (Hongsoongnern and Chambers, 2008). Usually cold break tomato juice (juice processed at a temperature below 70 °C) is higher in LOX-derived volatiles because of enhanced enzymatic activity that results in the increased production of these volatiles. Therefore, cold break tomato juice made with peel is more likely to produce higher levels of the green flavour than juice made without the peel, but hot break juice exhibits decreased levels of these volatiles due to the fact that enzymes are inactivated, which does not allow production of volatiles (Buttery et al., 1987).

## Flavour Compounds in Pulses and Legumes

Off-flavours could either be developed during harvesting, processing, and storage or inherent to the pulse (Sessa and Rackis, 1977). Off-flavours inherent to the pulse can only be removed, modified, or masked, however, they cannot be prevented other than by breeding new cultivars with less off-flavour, while the developed off-flavour could be limited by tuning the processing of the seeds. Table 5 provides an example of the most important compounds associated with off-flavours in peas and soybean, the latter being the most studied type of pulse (Roland et al., 2016).

The major cause for off-flavour development during harvesting, processing and storage is the oxidation of unsaturated fatty acids such as linoleic and linolenic acids (Sessa and Rackis, 1977). This oxidation can be non-enzymatic (Pattee et al., 1983) or enzymatic (Makower and Ward, 1950; Lee and Wagenknecht, 1958). Hexanal, n-pentylfuran, 3-cis-hexenal, 2(1-pentenyl) furan, and ethyl vinyl ketone are LOX-derived contributors to green, beany, and grassy flavours of peas and soy beans (Rackis et al., 1979). A cooked bean aroma has been reported for pinto bean paste. It has low raw beany and, nutty flavour, astringency, and bitterness (Song et al., 2009). Moreover, off-flavours can be formed by the effect of heat on amino acids and sugars, like Maillard reactions, thermal degradation of phenolic acids, thermal degradation of thiamine, and via oxidative and thermal degradation of carotenoids (MacLeod et al., 1988).

## Volatile Compounds in Processed Foods

In coffee, as an example, furans have long been considered as normal components of its flavour volatiles. For instance, about 6.5% of its volatile compounds were furans (Merritt et al., 1963). In roasted coffee, the number of volatile furans identified has increased with improvements in analytical techniques to about 800 reported in 1994 (Crews and Castle, 2007).

Fatty acids such as palmitoleic acid, oleic acid, linoleic acid and  $\alpha$ -linolenic acid are precursors for five to ten carbon aroma compounds. For example, 3-hexen-1-ol (leafy), 2-hexen-1-ol, and 2-hexenal (leafy) contribute greenish as well as fresh odors in tea infusions (Takeo and Tsushida, 1980). Formation of these volatile from the oxidation of tea lipids is associated with two main pathways. The first pathway, known as lipoxygenase-mediated lipid oxidation, contributes to the flavour of tea. The second

**Table 5** Main off-flavours and associated compound families causing off-flavour in soy and peas

Off-flavours	Peas	Soy	Compound
Volatile	Green	Beany	Aldehydes
	Beany	Fatty	Ketones
	Pea	Green	Alcohols
	Earthy	Grassy	Pyrazine
	Hay-like	Rancid	Others
	Leafy	Leafy	
	Metallic	Earthy

	Bitter	Bitter	Isoflavones
	Astringent	Astringent	Saponins
	Metallic	Metallic	Phenolic acids Peptides/amino acids

Sessa and Rackis 1977, Roland et al., 2016.

pathway is an oxidation reaction initiated by free radicals, such as autoxidation, photooxidation, and thermal oxidation. The rate of lipid oxidation increases with the degree of unsaturation of lipids. These two pathways have been thoroughly described by Ho et al. (2015). Moreover, Lipid degradation could also produce cyclic aroma compounds, for example, jasmine lactones, methyl jasmonate, and *cis*-jasmonate. These are fragrant volatiles initially identified from flowers of *Jasminum grandiflorum* as well as some green teas (Wang et al., 1996; Mosblech et al., 2009). Takeo and Tsushida (1980) reported the volatile aromas derived from lipid oxidation during the tea manufacturing process; hexanal, pentanal, jasmine, nonanal, *cis*-jasmonate, heptanal, 1-penten-3-ol (*E*)-2-hexenal (*Z*)-3-hexen-1-ol (*E,E*)-2,4-hexadienal (*E*)-2-hexen-1-ol, methyl jasmonate, and nerolidol.

## Conclusions

In order to have a food product with desirable flavour, it is important to understand how aroma compounds are derived, and the mechanisms by which flavour and off flavour compounds are generated. The formation of volatile compounds in different foods depend on their constituent components. Formation of volatile compounds is a multi-directional process as a result of some transformations linked with lipid oxidation, Maillard reaction, interactions between lipid oxidation products and Maillard reaction products, and thiamine degradation, among others.

### Glossary

**Antioxidant** A substance that, when present at low concentrations compared with those of an oxidizable substrate, significantly delays or prevents oxidation of that substrate.

**Bond-dissociation energy (BDE)** It is a measure of the strength of a chemical bond. The BDE for a species, AB, at room temperature is the reaction enthalpy of the bond homolysis reaction  $AB \rightarrow A + B$  and depends on the relative enthalpies of formation of reactant and product states. The BDE is the energy required to fragment the molecule AB in its ground state (i.e., the lowest energy electronic, vibrational, and rotational eigenstate) to ground state fragments A and B.

**Chain-breaking and retarder antioxidants** Chain-breaking antioxidants induce a lag phase during which the substrate is not substantially oxidized. Once the antioxidant disappears, the peroxidation rate rises sharply until it reaches the same rate as during uninhibited oxidation. Retarder antioxidants reduce the peroxidation rate without inducing a lag phase.

**Lipophilization** Grafting of a lipophilic moiety (fatty acid or fatty alcohol) on different substrates (e.g., phenolic compound, sugar, amino acid, protein), resulting in new molecules with modified hydrophilic/lipophilic balance.

**Phenolic compounds** Secondary metabolites widely found in plants, which form a part of the human diet. They include flavonoids (e.g., anthocyanins, flavonols, and flavanols) and nonflavonoids (phenolic acids such as benzoic acids and hydroxycinnamic acids, based on C1–C6 and C3–C6 skeletons, respectively; stilbenes; and derivatives).

**Deep eutectic solvent (DES)** A mix between a halide salt or another hydrogen bond acceptor and a hydrogen bond donor (HBD), resulting in a solvent with a room temperature melting point. The most common DESs are formed by choline chloride with cheap and safe HBD, the most popular ones being urea, ethylene glycol, and glycerol, but other alcohols, amino acids, carboxylic acids, and sugars have also been commonly used.

**Ionic liquids** Ion pairs that are liquid at ambient temperature. They consist in an association between an organic cation (such as an imidazolium or pyridinium) and a coordinating anion. Generally, cations are dissymmetric and large quaternary ammoniums or phosphoniums with various substitutions, whereas anions can be inorganic or organic.

### Nomenclature

BDE Bond-dissociation energy

CCL Critical chain length

DES Deep eutectic solvent

HLB Hydrophilic/lipophilic balance

ILs Ionic liquids

ROS Reactive oxygen species

## Introduction

Lipophilized antioxidants are amphiphilic molecules constituted of a lipid moiety covalently linked to a polar group possessing antioxidant properties, which when present at low concentrations compared with those of an oxidizable substrate, are able to delay or prevent oxidation of that substrate (Halliwell, 1990; Figueroa-Espinoza and Villeneuve, 2005). Antioxidants are employed to limit lipid oxidation of unsaturated fats and oils, the concomitant formation of toxic molecules, and degradation of organoleptic properties, to preserve the quality in food, cosmetics, and pharmaceutical products, which most of them exist as complex heterogeneous lipid dispersions. Meanwhile, because of some antioxidants' relatively low solubility in aprotic media, their application in oil-based products is limited. Hence, the importance of their functionalization by lipophilization can be performed chemically, enzymatically, or chemoenzymatically, through the covalent grafting of a lipid moiety onto the polar antioxidant. Depending on the structure of the latter, a multitude of lipophilized antioxidants can be synthesized; e.g., phenolic acids, flavonoids, tocopherols, and ascorbic acid. Lipophilized phenolic compounds, also called phenolipids, are antioxidants, which become surface-active molecules while preserving or even improving their physicochemical and biological properties over their parent phenolic compounds, which are known to possess antioxidant, antimicrobial, antiviral, antiinflammatory, and anticarcinogenic properties (Fung et al., 1985; Rice-Evans et al., 1997; Tanaka, 1997; Sergent et al., 2010; Yi-Hang et al., 2017).

The synthesis of lipophilized antioxidants is a strategy that allows to design powerful and custom-made surface-active antioxidants to protect heterogeneous systems (lipid dispersions such as emulsions, micelles or liposomes, or cultured cells) against oxidation and food and nonfood products against microorganism spoilage (Figuerola-Espinoza and Villeneuve, 2005; Laguerre et al., 2011; Suárez-Quiroz et al., 2013a,b; Suriyarak et al., 2013; Suriyarak et al., 2014; Durand et al., 2015; Decker et al., 2017; Durand et al., 2017b). This article focuses on lipophilized antioxidants derived from phenolic compounds, their physicochemical and biological activities, and their applications.

## Lipophilized Antioxidants in Nature

Alkyl esters of phenolic compounds are naturally present in plants, although long-chain esters are less common. For example, hexacosanyl and triacontanyl caffeates were isolated from the stem bark of *Pongamia glabra* Vent. (Leguminosae) (Saha et al., 1991), two esters of docosanol (n-docosanol-E-*p*-coumarate and caffeate) were isolated from *Myoschilos oblongum* (Santalaceae) roots (Piovano et al., 2003), tetradecyl ferulate was isolated from *Ocimum sanctum* L. (Lamiaceae) (Sonar et al., 2017), and methyl caffeate and a mixture of n-alkyl *p*-coumarates (C<sub>20</sub>, C<sub>22</sub>, C<sub>24</sub>) were isolated from the aerial parts and the roots, respectively, of *Artemisia assoana* Willk (Asteraceae; arid mountain regions of south Europe) (Martínez et al., 1987).

According to Snook et al. (1994), hexadecyl, octadecyl, and eicosyl *p*-coumarates could play a repellent role in the herbivore insect resistance of the sweet potato latex (*Ipomoea batatas* (L.) Lam.; Convolvulaceae) and contribute to the higher viscosity of the root latex compared with that of the vine latex. Bernards and Lewis (1992) identified nine alkyl ferulates in suberizing potato tuber tissue, after extraction from wounded tubers. C<sub>16</sub>–C<sub>28</sub> ferulates were identified, two being odd chain ferulates with C<sub>19</sub> and C<sub>21</sub> alkyl chains. Ferulate esters were at or near nondetectable levels in unwounded tubers, and their levels increased after 3–5 days following wounding, reaching a maximum after 11–15 days. Both C<sub>16</sub> and C<sub>18</sub> ferulates were more abundant than their longer-chain analogs, especially at 11 days after wounding. Ferulate accumulation was restricted to the wound periderm, suggesting that its formation is thus temporally and spatially correlated with suberin formation in the wound healing potato tubers playing a protecting role.

Gibbons et al. (1999) isolated a long-chain ester of caffeic acid (docosyl caffeate) from the halophytic plant *Halocnemum strobilaceum* (Pall.) M. Bieb. (Chenopodiaceae). Interestingly, these authors proposed that this kind of compounds may play a role in the stress management of halophytic plants by guaranteeing water retention within the plant cells: the alkyl chain would be anchored within the cell membrane and the hydrophilic portion would remain within the cell, thus retaining a hydration shell. Thus, phenolic lipophilized antioxidants in plants would play a protecting role against insects, microbial attack, or environmental stress.

## Lipophilization of Phenolic Compounds

Lipophilization of phenolic compounds to obtain phenolipids can be achieved chemically, enzymatically, or chemoenzymatically, by esterification, amidation, etherification, or transesterification. For example, phenolipids can be obtained by esterifying the carboxylic or a hydroxylic group of a phenolic compound with a fatty alcohol or a fatty acid, respectively (Figs. 1 and 2), or with a triacylglycerol or a phospholipid (López Giraldo et al., 2007). These reactions can be achieved in the presence of an organic solvent, in an excess of alcohol (playing both the role of solvent and reactant), or in microemulsions. Enzymatic lipophilization has been achieved by using enzymes of the carboxylic ester hydrolase family (lipases, tannin acyl hydrolases, feruloyl esterases, cutinases) (Figuerola-Espinoza and Villeneuve, 2005). More recently, to enzymatically lipophilize antioxidants, ionic liquids (ILs) and deep eutectic solvents (DESs) have been used as a green alternative medium to conventional organic solvents, while creating an efficient and low moisture reaction system where both phenolic compounds remain soluble and the enzyme remains active (Fig. 3) (Katsoura et al., 2009; Yang et al., 2012; Durand et al., 2013). The interest in using ILs or DESs lies in their particular physicochemical properties (e.g., low vapor pressure, high thermal stability, reduced toxicity, biodegradability, etc.).

Table 1 presents a nonexhaustive list of lipophilized antioxidants reported in literature. Examples of lipophilized flavonoids have been described and reviewed by Chebil et al. (2006). This article will focus more on lipophilized phenolic acids.

## Physicochemical and Biological Properties of Lipophilized Antioxidants

Lipophilized antioxidants exert antioxidant activity against lipid oxidation in heterogeneous systems and possess biological activities (antimicrobial, antiviral, antiinflammatory, anticarcinogenic, etc.), making them interesting multifunctional molecules for food and nonfood applications, as they are also surface actives and depending on the parent phenolic molecules, they can possess color properties.

The study of physicochemical and biological activities of a broad range of homologous series of lipophilized antioxidants in heterogeneous systems (e.g., dispersed lipids, microorganisms, cultured cells) showed that the relationship between the activity and hydrophobicity follows a parabolic-like trend or a nonlinear behavior named “cut-off effect,” the term that was first adopted

by Ferguson (1939). Balgavý and Devínský (1996) reviewed several hypotheses of the cut-off effect in biological activities of long-chain amphiphilic compounds and observed that the cut-off effect is a general phenomenon observed in various biological and toxic activities for almost all tested amphiphile homologous series. As a rule, the same substances display the cut-off effect in different biological activities. This cut-off effect for antioxidant activity also occurs in heterogeneous systems as lipid dispersions, cellular models, and microorganisms (Laguerre *et al.*, 2009). That means that the physicochemical or biological activities rise progressively with increasing alkyl chain length until a threshold or critical point, beyond which the activity collapses. Furthermore, for the same homologous series of phenolipids, the critical chain length may vary with the studied system, and the optimal chain length of the alkyl group varies with the nature of the parent antioxidant. An example of this is shown in Fig. 4: lipophilization

**Figure 4** Antioxidant capacity (in an emulsified system) and antifungal effect (at 1.5 mg/mL) against different *aspergilli* of 5-*O*-caffeoyl quinic acid and its esters, in function of their alkyl chain length. Adapted from Laguerre, M., Giraldo, L.J.L., Lecomte, J., et al., 2009. Chain length affects antioxidant properties of chlorogenate esters in emulsion: the cutoff theory behind the polar paradox. *J. Agric. Food Chem.* 57, 11335–11342; Suárez-Quiroz, M.M.L., Alonso Campos, A., Valerio Alfaro, G., et al., 2013a. Anti-*Aspergillus* activity of green coffee 5-*O*-caffeoyl quinic acid and its alkyl esters. *Microb. Pathog.* 61–62, 51–56.

improved the antioxidant (in O/W emulsion) and antifungal properties of 5-*O*-caffeoyl quinic acid (chlorogenic acid), which increased with the ester alkyl chain length, exhibiting a cut-off effect at 12 and 8 carbons, respectively (Laguerre et al., 2009; Suárez-Quiroz et al., 2013a). In the same O/W emulsion, rosmarinates exhibited a cut-off effect centered on an eight-carbon chain length (Laguerre et al., 2010). The partitioning behavior and location (aqueous, oil, and/or interfacial phase) of lipophilized antioxidants in emulsions govern their antioxidant efficiency.

The partition behavior of chlorogenic acid and its alkyl esters between the continuous phase and the discontinuous phase in the O/W emulsion showed that the concentration of chlorogenates into the aqueous phase decreases as the alkyl chain length increases, until a threshold was reached for the dodecyl chain. Short-chain chlorogenates would be in suspension and the long-chain ones may form micelles on the aqueous phase (Laguerre et al., 2009). C<sub>12</sub> chlorogenate's suitable surface activity allows it to be more fusogenic and to have a good affinity with the lipid–water interface close to the site of lipid oxidation.

More interestingly, this “cut-off” phenomenon was also observed in more complex systems such as living cells (human dermal fibroblasts) with a threshold for the C<sub>12</sub> chlorogenate that lowered the oxidative stress in cultured fibroblasts by decreasing the reactive oxygen species (ROS) located in the cytoplasm (Laguerre et al., 2011). These results suggest that the suitable esterified alkyl chain length confers to the parent molecule the highest affinity for a interfacial membrane (emulsion) or a biological membrane (microorganisms or fibroblasts). Similar behavior was observed when testing alkyl rosmarinates that showed a critical chain length at C<sub>8</sub> for their antioxidant activity in emulsified system (Laguerre et al., 2010), at C<sub>4</sub> for their antioxidant capacity in chitosan-coated liposomes (Panya et al., 2010), and at C<sub>10</sub> for their antioxidant activity in ROS-overexpressing fibroblasts, as these esters could cross cell membranes to enter into the fibroblasts to target mitochondria (a major site of ROS production) and act as ROS scavenger within the cell. C<sub>16</sub> and C<sub>18</sub> rosmarinates formed extracellular aggregates, whereas rosmarinic acid and C<sub>4</sub> rosmarinate distributed within the cytosol. These results showed that the in cellulo antioxidant activity of lipophilized antioxidants depends on their ability to cross the cell membrane and on their subcellular location. The antioxidant activity on ROS-overexpressing fibroblasts of a series of 1,2-diacylglycerol rosmarinates with different alkyl chain lengths from 5 to 18 carbons confirmed again the occurrence of a cut-off effect at C<sub>10</sub> (Durand et al., 2015).

The antioxidant and biological properties in heterogeneous system of lipophilized antioxidants are thus dictated by their reducing activity, the parent molecule toxicity, their hydrophobicity, and the position of the lipophilic group in the parent molecule. The hydrophilic/lipophilic balance of lipophilized antioxidants influences their partitioning in every phase constituting the dispersed system and their capacity to self-aggregate, e.g., to form micelles, alone and/or with other molecules present, e.g., in the continuous, discontinuous, or interface in an emulsion, or in membranes of microorganisms or cells.

The key to synthesize the optimal lipophilized antioxidant in a rational manner, to maximize its physicochemical and biological properties, would be to graft the proper lipophilic group (corresponding to critical chain length [CCL]) while maintaining intact the reactive moiety. This CCL would allow the lipophilized antioxidant to efficiently move toward the oxidation sites (e.g., the interface in an emulsion or a membrane for liposomes and cells), avoiding, if the grafted alkyl chain is too long, its self-aggregation in the continuous phase (e.g., forming micelles) or its internalization in the discontinuous one (e.g., into the lipid core of the oil droplet in emulsions and micelles). The length of the alkyl chain could also influence the mode of action of the lipophilized antioxidant: chain breaker or retarder (Grajeda-Iglesias et al., 2016). It was observed that C<sub>1</sub> to C<sub>8</sub> protocatechuates would have a chain-breaking

**Figure 5** Proposed scheme of the lipophilized antioxidants (LA) distribution in an oil-in-water emulsion. Adapted from Grajeda-Iglesias, C., Salas, E., Barouh, N., et al., 2016. Antioxidant activity of protocatechuates evaluated by DPPH, ORAC, and CAT methods. *Food Chem.* 194, 749–757.

behavior and  $C_{10}$  to  $C_{16}$  protocatechuates a retarder one in an oil-in-water microemulsion antioxidant test (Laguerre et al., 2008). An illustration of how lipophilized antioxidants could distribute in an oil-in-water emulsion is presented in Fig. 5. This system is not static as an interparticle transfer exists for both oxidants and lipophilized antioxidants in oil-in-water emulsions. The molecules can get transferred by three mechanisms: diffusion, collision–exchange–separation, and micelle-assisted transfer (Laguerre et al., 2017). According to the alkyl chain length, lipophilized antioxidants can distribute between the water phase, the interface (as they are surface actives (Yuji et al., 2007)), and the oil drop, as individual molecules or as aggregates, depending on their solubility. They can form micelles or comicelles with other molecules present in the corresponding phase. They can also move from one phase to another, depending on their own mobility and solubility, either alone (short and medium alkyl chain) or transported by micelles (formed by amphiphilic molecules present in the system: added emulsifier and/or medium and long alkyl chain lipophilized antioxidants). The existence of micelles formed by an excess of emulsifier and/or long alkyl chain lipophilized antioxidants in the continuous phase of an oil-in-water emulsion is possible, and the transfer of these molecules from the oil droplet to the continuous phase by an excess of emulsifier has been proposed (Panya et al., 2012). We could also imagine that lipoperoxyl radicals, being slightly more polar than triglycerides, could approach the interface and then migrate into the aqueous phase transported by the surfactant micelles, formed by the excess of emulsifier and/or lipophilized antioxidants, and thus be stabilized forming “mixed” micelles or comicelles. In addition, it is also possible that lipophilized antioxidants in surfactant micelles could inactivate aqueous phase free radicals that originate from hydrogen peroxide or surfactant peroxides (Kubo et al., 2002c).

In conclusion, lipophilization would be a double-edge sword; if the grafted aliphatic chain is too short or too long, the resulting antioxidant activity will not be optimal (Laguerre et al., 2013). The factors to take into account to predict antioxidant capacity in homogeneous and/or heterogeneous systems of lipophilized antioxidants are as follows:

- To maintain the reactive moiety of parent antioxidants by grafting the nonreactive lipophilic moiety in the proper position.
- The presence of an *o*-dihydroxy group (catechol) in the structure of the parent molecule and/or the occurrence in the parent molecule of any structure that extends the conjugation of phenolic hydroxyls, i.e., enlarging the unpaired electron delocalization area and lowering the bond-dissociation energy, making the parent antioxidant more reactive.
- The intrinsic chemical reactivity of lipophilized antioxidant toward free radicals.
- The lipophilized antioxidant surface activity (hence hydrophobicity).
- The lipophilized antioxidant mobility to easily diffuse to the site of action and to properly position in heterogeneous systems; e.g., compartmentalized systems such as emulsions, membranes, or living cells.

## Biological Properties of Lipophilized Antioxidants

Some examples of biological properties of lipophilized antioxidants are shown in Table 2.

Phenolic compounds' antimicrobial and antiviral activities can be improved by lipophilization (Kubo et al., 2004; Suárez-Quiroz et al., 2013a,b; Suriyarak et al., 2013; Durand et al., 2017b). Grafting a lipophilic moiety to a phenolic compound allows the bioactive hydrophilic molecule to penetrate the lipid barrier that it encounters in various systems (microbial, living cells, etc.).

As for antioxidant activities, biological activities of long-chain surface-active substances also show a nonlinear dependence on the chain length or cut-off effect. For example, the antimicrobial cut-off effect of gallates has been largely studied (Kubo, 1999; Fujita and Kubo, 2002; Kubo et al., 2002a,b,c). The antibacterial activity of alkyl gallates against a Gram-positive bacterium (*Bacillus subtilis*) was observed to be a parabolic function of their lipophilicity and presented a cut-off effect with an alkyl chain of 9 and 10 carbons (Kubo et al., 2004). In Gram-positive bacteria, various enzymes from the electron transport chain (ETC) are embedded in the cytoplasmic membrane, which possesses an inner and outer hydrophilic surface and a hydrophobic interior. Alkyl gallates would penetrate the membrane lipid bilayer portion, thus inhibiting the ETC by interfering with the redox reactions. In most of Gram-negative bacteria, gallates would not reach the ETC in the cytoplasmic membrane because they would be incorporated into the Gram-negative outer membrane (lipopolysaccharide layer) (Kubo et al., 2002a). This is in accordance with the results of Suárez-Quiroz et al. (2013b) who observed that dodecyl chlorogenates were active against some Gram-positive bacteria (*Bacillus cereus*, *Clostridium sporogenes*, and *Listeria innocua*) but inactive against three Gram-negative ones (*Escherichia coli*, *Pseudomonas fluorescens*, and *Salmonella enterica*). Long-chain alcohols possess a more important antimicrobial activity on Gram-positive bacteria, yeasts, and molds, than against Gram-negative bacteria (Kubo et al., 1995). The presence on Gram-negative bacteria of an outer lipopolysaccharide layer could entrap hydrophobic antibacterial agents, delaying their adverse effect on the electron transport chain.

In contrast, the antifungal activity of alkyl gallates (C<sub>3</sub>–C<sub>13</sub>) and protocatechuates (C<sub>3</sub>–C<sub>14</sub>) would be due to their ability to act as nonionic surfactants disrupting the membrane in yeasts, such as *Saccharomyces cerevisiae* (Kubo et al., 2002c; Nihei et al., 2004). They observed a cut-off effect with the nonyl esters. The pyrogallol moiety of alkyl gallates would adsorb onto the surface of *S. cerevisiae* by forming an intermolecular hydrogen bond with the hydrophilic portion of the membrane surface, and the alkyl chain would create a disorder in the fluid bilayer of the membrane by disrupting specific target proteins such as cell-surface receptors or signal transduction proteins.

The antiviral activity versus AIDS' virus HIV-1 of ferulic acid and its esters was studied by Sonar et al. (2017). These authors observed that the esterification of ferulic acid with a long alkyl chain (C<sub>10</sub> to C<sub>18</sub> and C<sub>18:1</sub>) is essential for the inhibition of RNase H function, as neither ferulic acid nor methyl ferulate were efficient. C<sub>14</sub> and C<sub>18:1</sub> ferulates were the most actives. Furthermore, molecular modeling studies together with Yonetani-Theorell analysis demonstrated that N-oleylcaffeamide is able to bind to both the allosteric sites: one close to the nonnucleoside reverse transcriptase inhibitor (NNRTI)-binding pocket and the other close to ribonuclease H (RNase H) catalytic site, thus inhibiting viral replication.

Lipophilized antioxidants could also be used as antiinflammatory drugs. For this, it is important to determine their toxicity profile and mechanism of action. For example, Pereira et al. (2017) evaluated the cytotoxicity of C<sub>8</sub> to C<sub>16</sub> protocatechuates against cancer and noncancer cell lines and on the macrophages cell line RAW 264.7, which are among the most widely used in vitro models for the study of antiinflammatory drugs. It was found that these lipophilized antioxidants are selectively toxic to macrophages. The most toxic protocatechuates against cancer cells and macrophage cell line were the C<sub>10</sub>–C<sub>14</sub> and the C<sub>8</sub>–C<sub>14</sub>, respectively. These last provoked the nuclear morphological changes on macrophages (shrunk nuclei, and chromatin condensation and fragmentation), loss of mitochondrial membrane potential, and increase in intracellular ROS. This toxicity would be a consequence of their higher partition coefficient and thus their higher accumulation in cells. C<sub>8</sub> protocatechuate was the most toxic compound, toxicity started to decrease with C<sub>10</sub>, and mild toxicity was found up to C<sub>14</sub>. Furthermore, C<sub>10</sub> and C<sub>12</sub> esters were the only ones that, at the higher

tested concentrations, provoked loss of membrane integrity. These results are in line with those from Durand et al. (2017a) who investigated, via small angle X-ray scattering approaches in model membrane liposomes, the interaction and location within the lipid bilayer of a homologous series of rosmarinates; C<sub>8</sub> rosmarinate shows the highest affinity for the membrane, whereas C<sub>10</sub> rosmarinate constitutes a critical chain length from which the penetration depth decreased. These interesting results show that lipophilized antioxidants can be used as antiinflammatory drugs.

## Conclusion

Lipophilized antioxidants are amphiphilic molecules possessing a myriad of interesting physicochemical and biological properties, including antioxidant (in food and nonfood products and in cells), emulsifying, antimicrobial, antiviral, anticarcinogenic, and antiinflammatory properties. The ability of these bioactive molecules to cross or to interfere with lipid interfaces or membranes depends at once on the structure of their polar head and of their lipophilic tail. Finding the optimal lipophilic moiety chain length to lipophilized antioxidants is crucial to maximize their physicochemical properties and overall biological effects, and it has to consider both the parent molecule structure and the nature of the heterogeneous system where it will be applied, may this last be a cell or organism or a food or nonfood product.

### Glossary

**Aging** A process of holding carcasses or a part of it at refrigeration temperatures for improving sensorial characteristics, particularly tenderness.

**Antioxidant** A synthetic or natural molecule that inhibits the oxidation of other molecules.

**Electrical stimulation** A practice whereby an electric current is transmitted through the carcass immediately after slaughter to avoid cold shortening.

**Haem or heme** A cofactor consisting of an  $\text{Fe}^{2+}$  ion contained in the center of a porphyrin.

**Myoglobin** An oxygen-binding protein found in muscle tissue of vertebrates, which serves as a local oxygen reservoir.

**Oxidation** This is the loss of electrons or hydrogen or gain of oxygen and an increase in oxidation state by an atom, molecule, or ion.

**Reduction** This is the gain of electrons or hydrogen or loss of oxygen and a decrease in oxidation state by an atom, molecule, or ion.

**Rigor** Stiffening of postmortem muscles due to irreversible binding of myosin to actin after exhaustion of ATP reserves.

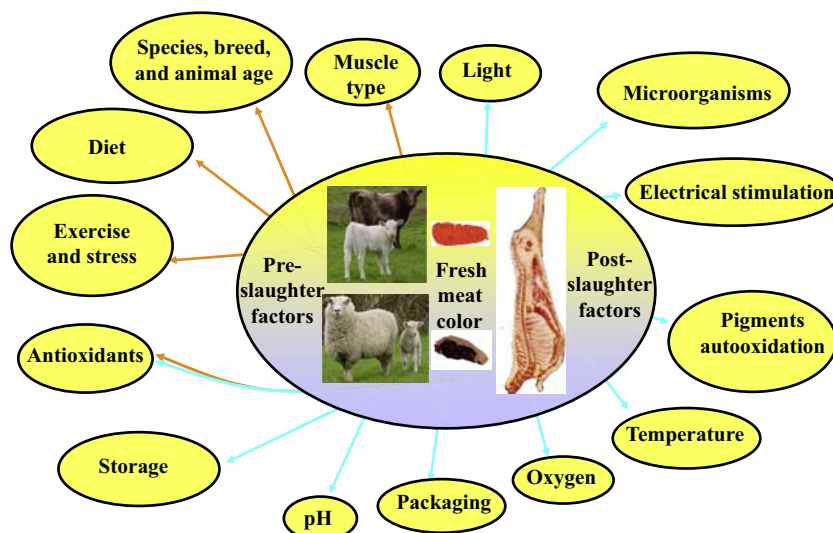

**Water-holding capacity** An ability of postmortem muscle to retain its water when some external force or pressure is applied to it.

### Introduction

The color of meat at any time after the animal has been slaughtered is a combination of the composition of the muscle of origin, the process where that muscle turns into meat and the conditions under which that meat is stored. Meat color is largely a result of the amount and state of the oxygen-binding protein, myoglobin (Mb), and the inevitable oxidation of the iron within it over time. As color is an important quality characteristic and a key determinant of shelf life, there have been a number of technologies developed to slow the oxidation process.

### Myoglobin in Muscle

Variation in meat color is dependent on many animal factors (species, breed, sex, age, diet, and activity) and the muscle type (Fig. 1). These affect both the amount of Mb (the native pigment, also known as deoxymyoglobin) and whether it is oxymyoglobin (OxyMb), deoxymyoglobin, or metmyoglobin (MetMb). The increase in MetMb over time is the primary cause of deterioration in muscle color.

**Figure 1** Factors affecting the color of fresh meat.

## Autoxidation of Meat Pigments

The general understanding of MetMb accumulation is that the net amount of MetMb formed is the result of its formation by the autoxidation of OxyMb and Mb and its reduction by MetMb reducing activity (Bekhit and Faustman, 2005; Bekhit et al., 2013). Mb autoxidation has a half-life of hours under in vivo pH, ionic strength, and temperature conditions (Livingston et al., 1986). The binding of O<sub>2</sub> triggers a globin conformational adjustment so that the orientation of the proximal imidazole, which is in contact with heme, changes to enhance the  $\pi$  orbital overlap with the iron (Giddings, 1977). At a physiological pH (7.2), the Hb association/dissociation rate is too low to produce any detectable autoxidation, but at normal pH (5.8) of meat the autoxidation rate is significant (Adams, 1976). Gotoh and Shikama (1974) estimated that the autoxidation half-life of bovine OxyMb at pH 5 was 2.8 h at 25°C and 5 days at 0°C. OxyMb has a high resonant structure that makes it more stable to oxidation than deoxymyoglobin (Giddings, 1974).

Renner et al. (1992) reported that the autoxidation of purified OxyMb separated from LD and PM muscles over a wide pH range (5–9), temperature (20–50°C), and ionic strengths (0–500 mM) was dependent on the postmortem time and muscle type. The autoxidation rates for the muscles were not different when the OxyMb was extracted at 2 h postmortem but at 192 h postmortem the autoxidation of the PM OxyMb was higher than that from the LD muscle.

Heme pigments may be more active as catalysts when iron is in the ferric state (Greene and Price, 1975). Inherent differences in MetMb accumulation (rates of autoxidation) have been claimed to be the primary factor for the differences in color stability between different muscles (O’Keeffe and Hood, 1982). On the other hand, Ledward et al. (1977) and Ledward (1985) reported that the rate of autoxidation between a range of muscles was similar and that the MetMb reducing system was the most important factor regulating the color. Increased oxidation of Mb postmortem in the absence of antioxidant and low reducing activity is the main cause of discoloration (Bekhit et al., 2007, 2013).

## Muscle Type

The biochemical and physiological characteristics, as well as the visual appearance of muscle, reflect the properties of the fiber types within a muscle (Karlsson et al., 1999). On the basis of histochemical staining or molecular techniques, Harper (1999) divided muscle fibers into three broad categories: glycolytic (fast-twitch B), slow oxidative (slow-twitch), and intermediate (oxidative–glycolytic, fast-twitch A). Muscle fiber types contain different concentrations of Mb, oxidative and glycolytic enzymes, and different contractile proteins (Klont et al., 1998). The slow oxidative (slow-twitch) fibers, which are typically red, have high concentrations of mitochondria, Mb, and blood vessels, but the fiber diameter is small. The fast oxidative–glycolytic (fast-twitch A) muscles are pink, having intermediate concentrations of mitochondria, Mb, and blood vessel supply. The fast glycolytic (fast-twitch B) fibers are white, having low concentrations of mitochondria, Mb, and fewer blood vessels. Different muscle fibers have different amounts of MetMb reducing activities (Echevarne et al., 1990; Reddy and Carpenter, 1991). The proportions of fiber types within a muscle vary with the action of the muscle. Animal muscles used for locomotion appear darker in color because they usually contain higher concentrations of Mb than support muscles, e.g., 12 mg/g wet tissue in extensor carpi radialis compared to 6 mg/g wet tissue in LD (Cross et al., 1986). Muscles containing high Mb concentrations appear darker than those with less Mb. Differences in OCR and Mb autoxidation rate with muscle types can explain variation in color stability between different muscles (Renner and Labas, 1987). Renner (1984) reported that the catabolism of NAD differs according to the muscle type. Madhavi and Carpenter (1993) found that LD was more color stable than PM. They also reported that the LD muscle had a higher MetMb reducing activity, high NAD content, and low OCR compared to the PM muscle.

## Muscle to Meat

Meat color is also affected by the rate of decline in temperature and pH postmortem and the ultimate pH of the meat. During this postmortem period, the balance between prooxidative and antioxidative factors favors oxidation (Morrissey et al., 1998; Bekhit et al., 2007).

## The Rate of pH Fall

The conversion of muscle to meat involves anaerobic glycolysis to lactic acid to maintain ATP levels (O’Halloran et al., 1997). The rate of glycolysis and the resulting pH decline is affected by animal species, preslaughter stress (Warriss, 2000), and postmortem temperature (Tornberg et al., 2000). Abnormal rates of pH fall may reduce the quality of the meat produced and can play a role in determining the color stability of meat by modifying the perceived color independently of MetMb formation (Ledward, 1985). A rapid pH fall, while the carcass temperature is high, can result in a low ultimate pH (>5.5) and a lighter meat appearance due to decreased water-holding capacity and increased unbound water. This is seen in pale soft exudate (PSE) pork. A slow rate of pH fall, while the carcass temperature is high, results in a higher ultimate pH (>5.8) and darker meat color in beef and lamb and dark firm dry (DFD) pork.

The unusual pH and water-holding capacity of PSE and DFD meat produce abnormal colors in fresh meat (Faustman and Cassens, 1990a; Ledward, 1992). They also display different color stabilities during retail display of pork with PSE, the least stable, and DFD, the most stable. The poor stability of PSE meat is probably due to increased Mb autoxidation and the decreased MetMb reduction with the lower pH (Owen and Lawrie, 1975).

The rate of change of temperature and pH of the muscle during postmortem glycolysis can also influence the color of fresh meat independent of MetMb formation (Ledward, 1985). The oxygen consumption rate (OCR) in rapidly chilled meat is likely to be higher than in slowly chilled meat and may be responsible for the formation of the higher contents of MetMb during storage (Atkinson and Follett, 1973). Higher OCR is found in high pH meat and contributes to the dark color associated with such meat (Ledward, 1985).

## Electrical Stimulation

Electrical stimulation is used in the meat industry to avoid the incidence of cold shortening that causes meat toughness. The temperature–pH profiles are very important factors to consider when electrical stimulation (ES) is applied to carcasses to improve the tenderness of meat. For example, during ES, the pH of meat falls approximately 0.35 units per min (Lawrie, 1998), which represents a 100- to 150-fold increase over the normal rate. The importance of ES on meat color originates from its effect on the pH–temperature relationship and, depending on the ES intensity, it can also affect the muscle tissue structure.

Electrical stimulation per se has generally been associated with improvement of the fresh meat appearance by imparting a lighter bright red color on the meat surface (Savell et al., 1978; Tang and Henrickson, 1980; Eikelenboom et al., 1985; Smith, 1985; Unruh et al., 1986). Moore and Young (1991) found that the color stability of ES chilled lamb during display was better than that of non-ES lamb. However, the advantage disappeared after 2 weeks aging in a vacuum pack at  $-1.5^{\circ}\text{C}$ . In contrast, Powell et al. (1996) reported that consumers did not perceive differences in the rate of discoloration between ES and non-ES SM steaks. However, significant consumer preferences were found for ES compared to non-ES meat that were associated with pH differences (5.08–6.0) and between meat aged for 5 days and 33 days.

Mareko (2000) studied the effect of mild ES (75 V, 15 Hz, 20 s) versus intense ES (75 V, 15 Hz, 40 s) on the quality of LD muscles of beef carcasses. Mild ES meat exhibited significantly higher  $a^*$  (redness, CIE- $L^*a^*b^*$  system) than intense ES. Both  $a^*$  and  $b^*$  values increased after 7 days of vacuum packing at  $2^{\circ}\text{C}$  with significant higher values in mild ES compared to intense ES. A lighter color of meat was produced from low voltage ES compared to non-ES carcasses (Hildrum et al., 2000).

Unwanted and negative effects of ES on color have also been reported (Petch and Gilbert, 1997). Ledward et al. (1986) reported a reduction in the color stability of deep muscles such as SM, while surface muscle such as LD was unaffected. The greater color stability of LD was related to its exterior position on the carcass, which allowed it to cool rapidly. Studies by Ledward (1985) and Ledward et al. (1986) pointed out that the negative effect of ES on the color stability of beef muscle was more pronounced in meat, which has been aged compared to fresh meat. Others did not report any effect of ES on the color of beef SM muscle (Sammel et al., 2002). While Renere and Bonhomme (1991) found a positive effect for ES and hot boning on lamb LD muscle, Jeremiah et al. (1997) found no effect of ES and hot boning on the color or color stability of lamb muscles (LD and SM).

## Rigor Temperature

Color and color stability has been reported to be affected by the temperature at which the muscle enter rigor (Ledward, 1985). This is relevant to meat processing, particularly those that use ES and hot boning. Although those muscles, which entered rigor at higher temperatures as a result of ES, were less stable, there is evidence of significant improvements in color parameters (chroma and  $L^*$ ) if rigor occurred at the extreme temperatures of  $30\text{--}35^{\circ}\text{C}$  has been reported (Ledward, 1985; Farouk and Swan, 1998; Young et al., 1999; Geesink et al., 2000). However, the effect was lost with vacuum packaging and aging (Farouk and Swan, 1998; Geesink et al., 2000).

## Ultimate pH

The ultimate pH ( $\text{pH}_u$ ) is an important general indicator of meat quality and a specific indicator of meat color. A significant correlation between beef color and  $\text{pH}_u$  has been reported (Purchas et al., 1999). The  $\text{pH}_u$  was found to correlate with  $a^*$  and  $b^*$  components of color but not with  $L^*$  in beef (Warner, 1989).  $\text{pH}_u$  for normal meat ranges from 5.4 to 5.8 (Faustman and Cassens, 1990a,b). At lower and higher pH values, abnormal meat conditions and color can be found. It is generally regarded that meat with a low pH discolors more rapidly than meat with a high  $\text{pH}_u$  (Ledward, 1985; Zhu and Brewer, 1998). For example, it has been reported that beef with  $\text{pH}_u$  of 5.6 was less color stable than beef with a  $\text{pH}_u$  higher than 5.80 (Ledward et al., 1986).

Renner (1999) proposed that the poor stability at low pH was caused by an increased rate of Mb autooxidation, while the enzymatic reduction was severely reduced. In addition to the acceleration of the Mb autooxidation rate at a low pH (Gotoh and Shikama, 1974), the nonenzymatic MetMb reduction was decreased especially as the pH reached less than pH 6.0 (Zhu and Brewer, 2003).

Possible mechanisms for a low pH accelerating the oxidation of Mb or OxyMb to MetMb and causing meat discoloration are as follows:

- Denaturation of the globin protein moiety that protects the heme groups. This causes the disassociation of O<sub>2</sub> from the heme, as well as the oxidation of the iron molecule (Cross et al., 1986).
- The low stability of OxyMb at low pH. For example, the half-life of beef OxyMb at 0°C was 71 times higher at pH 9.0 than OxyMb at pH 5.0. At 25°C, the half-life of OxyMb was 60 times higher at pH 9.0 than at pH 5.0 (Gotoh and Shikama, 1974).
- Acceleration of the protonation of bound O<sub>2</sub> and the formation of reactive oxygen species (ROS) that are potent prooxidants (Livingston and Brown, 1981).
- Iron-catalyzed oxidation that has been reported to be pH-sensitive and the most active under acidic conditions (Lee and Hendricks, 1997).

High pH<sub>u</sub> increases the water-holding capacity, and OCR (Ledward, 1985) causing dark color due to swelling of the fibers results in closer spacing of the fibrils leading to less light scattering and, as a consequence, the meat is more translucent. Under such conditions, the light penetrates deeper into the meat and hence, the Mb absorbs the light stronger, causing the darker color of the meat. The increased water-holding capacity and a more closed myofibril structure resist deep O<sub>2</sub> diffusion that, in addition to the high OCR, makes deoxymyoglobin the dominating pigment. Hence, this meat has a dark purple color (Warner, 1989).

The rate of OxyMb formation at pH 8 can be three to four times that at pH 5–7 (Schwimmer, 1981). Lowering the pH from 7.4 to 5.7 during the muscle to meat conversion process tends to denature some of the active reducing enzymes and cause a decrease in OCR (Schwimmer, 1981). In support of this view, Asghar et al. (1990) found that the presence of mitochondria and microsomes in sarcoplasmic extracts increased OxyMb and decreased MetMb at high pH, but at a low pH their presence had little effect.

## Storage Conditions

After the muscle has turned into meat, the carcass is processed into individual cuts of meat and often stored under chilled conditions. During this when meat is first exposed to air the color changes from the purple of deoxymyoglobin to the bright cherry-red color of oxymyoglobin, a process known as blooming. After this time the color deteriorates mainly as a result of oxidative processes.

## Oxygen

The brightness and saturation of a developed red color depends on the depth of the zone in which O<sub>2</sub> can penetrate into the tissue and oxygenate the Mb. Oxygen penetration increases linearly with time after meat is cut and is influenced by animal species and muscle type (MacDougall and Taylor, 1975). The depth of the O<sub>2</sub> penetration into the meat tissue is determined by (1) the rate of O<sub>2</sub> diffusion into the tissue, (2) OCR of the tissue, and (3) the pressure of the O<sub>2</sub> at the surface (O’Keeffe and Hood, 1982). At low O<sub>2</sub> levels, off-colors develop in meat. This effect can be observed in a freshly cut cross-section of an aged beef steak. The pigment at the surface, where O<sub>2</sub> is readily available, is OxyMb (bright red) resulting from the mass action effect of O<sub>2</sub>, which has diffused into this region. As the amount of available O<sub>2</sub> diminishes, available Mb is converted into MetMb. This is manifested as thin brown layer a few millimeter below the original surface. As the O<sub>2</sub> is exhausted in this region, no O<sub>2</sub> is available to migrate to the next region, center of the slice, so that this region (the center) imparts the purplish color of Mb. The formation of MetMb is optimal when the O<sub>2</sub> partial pressure is 6 mm Hg (at 0°C) or 7.5 mm Hg (at 7°C) (Ledward, 1970).

The OCR decreases with time postmortem due to the depletion of substrates and coenzymes and degradation of enzymes involved in mitochondrial respiration (DeVore and Solberg, 1974). The OCR of LD muscle was decreased to 30% of its initial value after 2 days of postmortem and to 15% after 10 days of postmortem (O’Keeffe and Hood, 1982). This can lead to higher O<sub>2</sub> penetration (Feldhusen et al., 1995) and faster blooming on exposure to air. Thus, many researchers believe that OCR is the main factor controlling the color stability (Echevarne et al., 1990; Lanari and Cassens, 1991). Inhibiting mitochondrial respiration by the addition of rotenone or lowering the pH of prerigor beef muscle homogenates produced a bright red color (Cornforth and Egbert, 1985), which supports the hypothesis. Dark color associated with prerigor meat is due to the active mitochondria that consume O<sub>2</sub> and maintain Mb in their deoxygenated form (purple color).

## Storage Atmosphere

Modifying the atmosphere surrounding meat can considerably influence the storage life (meat color) of fresh meat. Modified atmosphere packaging (MAP) in combination with optimum temperature control and processing hygiene is the most effective means of extending the storage life of fresh chilled meat and maintaining the product quality and safety (Jeyamkondan et al., 2000; Mancini et al., 2009). MAP commonly utilizes different amounts of CO<sub>2</sub>, O<sub>2</sub>, and N<sub>2</sub>.

Vacuum packaging can be regarded as a special case of MAP, since creating anoxic conditions modifies the package atmosphere. It is well known that the color of fresh meat deteriorates with storage time and that vacuum packaging improves the color of raw meat on exposure to air. However, any improvements in the color are short lived and the rate of change in color of meat previously vacuum packed is higher than nonvacuum-packed meat.

When O<sub>2</sub> is included in the MAP gas mixture the Mb is maintained in the oxygenated form. It has been reported that packages containing high concentrations of O<sub>2</sub> (80% O<sub>2</sub> and 20% CO<sub>2</sub>) can improve the storage life of beef by 2 weeks while maintaining acceptable red color at 1.5°C (Gill and Jones, 1994).

The use of CO<sub>2</sub> has the advantage that its inhibitory effect increases with decreasing meat temperature (Jay, 1992). It has been shown that a combination of high CO<sub>2</sub> MAP (100%) and low temperature (−1.5°C) can improve the shelf life of meat products (Gill and Jones, 1992). However, at that high CO<sub>2</sub> percent the color is purple and the consumers may not accept it unless they have been educated. CO<sub>2</sub> is bacteriostatic, but the exact mechanism of microbial inhibition is not known (Jeyamkondan et al., 2000). Nitrogen is usually used as an inert filling gas.

## Temperature

The influence of temperature on meat color deterioration is well known. An increase from 0 to 5°C doubles the rate of discoloration (Taylor, 1981), and the degree of discoloration after 96 h storage at 10°C caused two to five times the discoloration of storage at 0°C depending on the muscle (Hood, 1975). The Q<sub>10</sub> (the temperature coefficient) for OxyMb oxidation is 1.25–2.5 times that of chemical or enzymatic reactions (Faustman and Cassens, 1990a). High temperatures favor greater scavenging of O<sub>2</sub> by residual respiratory enzymes, which leads to low O<sub>2</sub> tension and facilitates Mb autooxidation. Lipid oxidation also increases with elevated temperatures, which contributes to the nonenzymatic Mb oxidation (Renner, 1999).

The impact of storage temperature is dependent on the packaging and muscle type. For example, when beef meat is stored in air, the increased rate of discoloration by a high storage temperature was proportionately the same for all muscles (PM, GM, and SM) or higher for muscles (SM) with more color stability (Ledward, 1985; O’Keeffe and Hood, 1980-1981a,b). When the meat was stored in an O<sub>2</sub> free atmosphere, the increase in storage temperature resulted in a higher discoloration rate in a muscle (PM) with intrinsically less color stability (O’Keeffe and Hood, 1980-1981a,b).

Increased temperature accelerates Mb and OxyMb oxidations resulting in increased MetMb formation in meat through the following mechanisms:

- Increased oxidative processes by increasing the rate of prooxidant reactions and accelerated lipid oxidation (Faustman and Cassens, 1990a).
- Decreased oxygen solubility that favors the dissociation of O<sub>2</sub> from OxyMb. The less stable deoxymyoglobin has a greater tendency toward oxidation (Giddings, 1977; O’Keeffe and Hood, 1982).
- Increased OCR (Urbain and Wilson, 1958; cited from O’Keeffe and Hood, 1982) that results in a corresponding decrease in the depth of the O<sub>2</sub> penetration.
- Increased microbial growth.

## Lipid—Heme Reciprocal Autoxidation

The relationship between lipid oxidation and muscle pigments has been substantiated by many studies (Faustman et al., 1989, 1992). Heme pigments in meat tissue catalyze the oxidation of muscle tissue lipids and result in a rancid odor and flavor. Free radicals produced in oxidizing lipids can oxidize and decompose the heme pigments (Bekhit et al., 2013). These two reactions appear to be interdependent in that inhibition of either reaction will result in inhibition of the other (Greene and Price, 1975). A time lapse has been observed between initiation of pigment oxidation and initiation of lipid oxidation, which suggests that conversion of Mb to MetMb is necessary to accelerate lipid oxidation catalysis (Koizumi et al., 1973).

The development of a MetMb layer under the surface of meat depends on the partial O<sub>2</sub> pressure and therefore one may expect that a high O<sub>2</sub> pressure should stabilize the color since MetMb formation requires a low O<sub>2</sub> pressure. According to Wang (1962), the rate of OxyMb oxidation is slower than the corresponding process for free heme by a factor of about 10<sup>8</sup>. Hence, maintaining the Mb in the oxygenated form reduces the autoxidation rates dramatically. However, high O<sub>2</sub> pressure increases the rate of lipid oxidation and may counteract the beneficial effects on color gained by that treatment.

The ferric forms of Hb and Mb were reported to be very active catalysts of lipid oxidation (Kaschnitz and Hatefi, 1975). Likewise, the activity of OxyMb as a catalyst was reported to be similar to that of MetMb, especially at lower concentration ratios of heme pigments to unsaturated lipid (Koizumi and Nonaka, 1975). Greene and Price (1975) concluded that heme pigments may be more active catalysts of lipid oxidation when ferric and that nonheme iron may be more active catalyst in the ferrous state. Ferrous nonheme acts as a prooxidant in cooked meat, whereas MetMb exhibits little or no prooxidant activity (Love and Pearson, 1975). Thus, iron (free and protein bound), heme, and nonheme (oxidized or reduced) have the ability to oxidize unsaturated fatty acids in meat (Gandemer, 1998).

## Effect of Antioxidants

Oxidative processes contribute to the deterioration in the color of displayed fresh retail meat (Decker et al., 1995). Synthetic antioxidants, such as butylhydroxytoluene (E 321) and butylhydroxyanisole (E 320), are currently permitted as food additives. These antioxidants, however, have limited applications because of their low water solubility and low penetration of intact muscles (Lee et al., 1998). Their safety is also in question (Kansci et al., 1997).

Vitamin C is regarded as a safe antioxidant and has been under investigation in many meat systems. However, the ability of vitamin C to maintain the color or improve the color stability of raw meat depends on the method of incorporation into meat. Dipping or spraying meat with 2.5% or 5% ascorbate solution inhibited the formation of MetMb but impaired the blooming (Hood, 1975; Harbers et al., 1981). Preslaughter injection of ascorbate improved the color stability and the shelf life of PM, GM, and SM but not LD (Hood, 1975), whereas jugular infusion of preslaughter extended the shelf life of PM, GM, and LD (Schaefer et al., 1995).

Vitamin E is able to delay the oxidative process and to improve fresh meat color. Dietary supplementation with vitamin E improved beef color (Lanari et al., 1993; O'Grady et al., 2001a; Mitsumoto et al., 1995). Steaks from cattle supplemented with dietary vitamin E were preferred over controls during display by 91% of surveyed Japanese (n = 10941) (Sanders et al., 1997). Vitamin E affected the length of the MetMb induction period (Sanders et al., 1997) and diminished the adverse effect of temperature abuse (Chan et al., 1995). That effect was dependent on dose (the higher the vitamin E supplement the longer the induction period) and muscle type (LD had longer induction period than the color labile GM). Faustman et al. (1989) and Arnold et al. (1993) reported that 3–3.5 mg vitamin E/kg muscle was needed depending on the muscle. In contrast, other researchers found that vitamin E delayed lipid oxidation but had no effect on color stability in turkey muscles (Mercier et al., 1998) or beef (Yang et al., 2002) and did not change the antioxidant enzymes, catalase, superoxide dismutase, and glutathione reductase (Renner et al., 1999). The role of vitamin E has been reviewed by Liu et al. (1995), Morrissey et al. (1994), and Faustman et al. (1998).

Vitamin B3 (niacin) is another antioxidant, which has shown promising results in increasing the color stability of fresh meat. Depending on the muscle type, niacin supplements can produce a significantly more intense red color than controls for up to 12 days of storage (Naruse et al., 1998). The decrease of NAD nucleosidase and the consequent preservation of NAD may be the direct effect of niacin addition and hence result in the maintenance of meat color (Schwimmer, 1981).

Organic selenium supplements do not affect the susceptibility of beef meat to oxidative processes (O'Grady et al., 2001b). Chan and Decker (1994) suggested that the better stability of white muscle fibers against oxidative processes could be due to the higher concentrations of anserine and carnosine in these muscles compared to red muscles. However, Bekhit et al. (2003, 2004) found carnosine to promote Mb oxidation at normal meat pH (5.5–5.7).

Renner (1999) and Renner et al. (1996, 1999) found that the antioxidant enzyme activities in oxidative (red) muscles were higher than in glycolytic (white) muscles, but it did not appear to offer increased protection against free radicals or improve its color stability. Furthermore, the supplementation with vitamin E did not affect the activity of antioxidant enzymes (Renner et al., 1999).

## Light

Photooxidation normally refers to modification or destruction of amino residues especially the histidyl imidazole; the phenylalanyl and tyrosyl rings; the heterocyclic tryptophyl ring system; and the methionyl and cysteinyl sulfurs (Foote, 1968; Giddings, 1977). Incident light in display cabinets can contribute to meat discoloration and is a major problem in frozen meat. Its impact depends on the wavelength and intensity of the light, temperature, O<sub>2</sub> pressure, meat pH, storage time, and the presence of transition metal ions (Hunt et al., 1975; Owen et al., 1976; Satterlee and Hansmeyer, 1974). Photocatalysis, either indirectly through riboflavin associated compounds or directly through photosensitization of heme or changes in the amino acid in Mb, has been reported (Lynch et al., 1976; Griddings, 1977).

A predisplay dark storage period of 30 days of meat supplemented with vitamin E delayed MetMb accumulation in meat subsequent displayed due to a reduction in the OxyMb autooxidation rate (Lanari et al., 1994). There is now sufficient evidence verifying that meat kept in the dark has better color stability (Taylor, 1981).

MacDougall and Powell (1997) studied the effects of display temperature and light properties on the color stability of fresh and aged meat. They concluded that meat temperature in the display case was the most important factor. If the temperature was low then the illumination level was the factor dictating the case life. The type of light can affect meat color, but illumination level is the most important factor. There are intrinsic differences between muscles (LD and PM) and within muscles (outside and inner side of the SM), which can affect color stability as they respond differently to light.

High rate of discoloration of meat cuts displayed under illumination was due to the heat generated from the light bulbs (Greer and Jeremiah, 1980, 1981) and UV light (Anderson et al., 1989). The energy gained from light can induce the formation of excited ROS, which cause pigment autooxidation (Schwimmer, 1981). Berthelsen and Skibsted (1987) stated that light is the most important factor in frozen meat discoloration. It is worth noting that singlet O<sub>2</sub> has been implicated for Hb oxidation in light (Possani et al., 1970). Since Mb and Hb share a lot of characteristics, Mb may equally be affected by light.

## Microorganisms

Bacterial activity is another factor contributing to pigment changes in raw meat (Faustman et al., 1990). Psychrotrophic bacteria, such as *Pseudomonas* and *Brochothrix thermosphacta*, utilize  $O_2$  act as a prooxidant in low population numbers ( $10^4$  CFU/g) and reduce MetMb at high populations ( $10^8$  CFU/g) (Faustman and Cassens, 1989).

Depending on the conditions of meat packaging, meat discoloration will vary according to the availability of  $O_2$ . Aerobic bacteria in  $O_2$  permeable packages have a high  $O_2$  requirement during the logarithmic phase of growth that leads to low  $O_2$  tension at the surface and, consequently, discoloration. *Pseudomonas geniculata*, *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, and *Achromobacter faciens* are examples of aerobic bacteria that can cause meat discoloration (Robach and Costilow, 1962). As aerobic bacteria increase in number, the surface of the meat changes from red OxyMb to brown MetMb and then to purple reduced Mb (Cross et al., 1986). Also, Cross et al. (1986) explained the purple color imparted in raw meat by high counts of bacteria that create an anaerobic environment due to blocking the  $O_2$  from entering the meat. This enhanced the reduction of MetMb by the MetMb-reducing system and, consequently, prevented the oxygenation of the newly formed Mb.

Bacteria may also cause greening discoloration. For example, in vacuum packed meat that has pH > 6.0, bacteria such as *Pseudomonas mephitica* and *Alteromonas putrefaciens* can produce hydrogen sulfide that contributes to the formation of the green-colored sulfmyoglobin (Cross et al., 1986). However, on opening the vacuum package, the green color will be converted to oxysulfmyoglobin, which is red, but the meat will have the odor of rotten eggs.

Although bacteria, in general, cause color problems, Arihara et al. (1993) have found that certain species convert MetMb to OxyMb.

## Conclusions

Color of fresh meat and its stability can vary widely among species and cuts from the same animal due to differences in anatomical, physiological function and biochemical processes of the muscles where the meat is obtained from. The color and shelf life are the result of the initial muscle, the changes as the muscle goes into rigor, and how the meat is stored and displayed. Different systems that try to delay oxidative processes (cooling, vacuum and modified packaging, addition of antioxidants) appear to be successful in improving color stability and shelf life. The success of these strategies, however, is not universally successful and should be considered on for individual meat cuts.

### Glossary

**Aging** The process where meat held at refrigerated temperatures becomes more tender as a result of proteolysis.

**Blooming** The oxygenation process responsible for the formation of oxymyoglobin following exposure to air or high concentrations of oxygen.

**CIE LAB or L\* a\* b\*** Representation of colour measurements system recommended by an International Commission on Illumination known as Commission International de l'Eclairage (CIE).

**Colour** Colour is an appearance property attributable to the spectral distribution of light. *Colour is made up of varying proportions of the three additive primary colours red, green and blue.*

**Discoloration** Formation of colours other than the colour desired by consumers.

**Metmyoglobin** Oxidised form of myoglobin.

**Myoglobin** A globular cytoplasmic protein found in muscle that binds oxygen on a haem. It is the main pigment responsible for meat colour.

**Oxidation** The state where atoms in an element lose electrons as a result of reaction and an increase in the valency of the element is correspondingly achieved.

**Oxymyoglobin** The oxygenated form of myoglobin.

### Introduction

Consumers judge the quality of meat at the point of sale on colour, visible fat content and odour (Bickerstaffe, 1996). Colour is perhaps the most important sensory attribute of a food because if the colour is objectionable for the consumer, the food will not be purchased and/or eaten, and consequently, all other sensory attributes lose significance. The consumer often uses colour as an indicator of the freshness and quality of meat (Hood and Riordan, 1973). For example, if the colour of beef is not bright cherry-red, the meat is usually considered undesirable or even spoiled. Fig. 1 shows the discolouration in a plant and in meat. While, discolouration in plant materials is taken as indication for loss of freshness, as in meat, it is also associated with loss of nutrients and other important sensory attributes, which is not considered with old meat. The change in fresh meat colour is a reflection of the net balance between oxidative, antioxidative and reducing systems in meat. Discolouration of fresh meat indicates dominance of oxidative processes that can have great consequences on the digestion and bioavailability of nutrients, but this is yet to be considered in meat science.

The colours associated with good meat quality depend on the type of meat. For Chicken, turkey, veal and pork are considered white meats and a pink-greyish colour is considered to be normal. Fresh lamb and beef products are red meats and a bright red colour is usually desired (Schwimmer, 1981). The colour of meat ultimately depends on the amount and state of pigments in meat, namely, myoglobin, haemoglobin and cytochromes. Myoglobin is the primary pigment associated with meat since most of the haemoglobin is discharged during bleeding after exsanguination. As such, the level of meat discolouration and colour formed are also influenced with the amount of myoglobin present. For example in meat that is rich in myoglobin such as venison, beef and lamb the discoloured meat is brown while in meat that contains small amounts of myoglobin the discoloured meat is grey.

### Meat Pigments and Colour Development

Myoglobin (Mb) is an intracellular protein found in red skeletal muscle and heart. It binds oxygen (O<sub>2</sub>) reversibly and enhances O<sub>2</sub> consumption especially under conditions of low O<sub>2</sub> availability (Bailey et al., 1990) by facilitating the diffusion of O<sub>2</sub> from the extracellular space to the mitochondria (Wittenberg and Wittenberg, 2003). Myoglobin consists of a single polypeptide protein, globin, and a prosthetic group, haem. The haem has a centrally located iron atom with six coordination sites. Four coordination sites are in the plane of, and bound to, the N atoms of four flat porphyrin rings, while the other two coordination sites lie perpendicular to this structure. One of the perpendicular coordination sites is connected to an N atom of the globin protein molecule and the other site is open and available for binding a variety of ligands (Cornforth and Jayasingh, 2004). Each molecule of Mb contains a single iron atom, which may bind to one molecule of O<sub>2</sub> when the iron is in the ferrous state (Mb-Fe<sup>2+</sup>). Mb-Fe<sup>2+</sup> undergoes spontaneous oxidation *in vitro* to the ferric state (Mb-Fe<sup>3+</sup>) known as MetMb, which cannot bind O<sub>2</sub>. The type of molecule attached to the sixth bond and the oxidation state of the iron atom (ferrous or ferric) determines the colour of the

**Figure 1** A representation of oxidative change in plant (A) and meat (B) samples.

meat. Myoglobin is commonly found in three forms; oxymyoglobin (OxyMb), deoxymyoglobin and MetMb. The relative proportions of the various forms of Mb determine the colour of fresh meat. When the animal is alive, the majority of Mb is in the oxygenated form (the sixth coordination site is occupied with  $O_2$  molecule).

Freshly cut meat is purple in colour due to the presence of myoglobin in its native form (deoxymyoglobin). Upon exposure to air, myoglobin is oxygenated to the bright red oxymyoglobin. During storage, myoglobin (Mb), and oxymyoglobin (OxyMb) are oxidised to the brown metmyoglobin (MetMb). The accumulation of MetMb at the meat surface is the major factor leading to the discolouration of fresh meat. Apart from the colour change with oxygenation and oxidation, changes in the haem moiety of Mb of meat can give a variety of discolouration as shown in [Table 1](#). Alterations of the haem structure can cause the greening

**Table 1** Meat discolouration as a result of changes in haem iron state and Mb derivatives

Pigment	Colour	State of iron		Remarks
Myoglobin	Purple	$Fe^{2+}$	$H_2O$	Native protein/reduced form
Oxymyoglobin	Bright Red	$Fe^{2+}$	$O_2$	Oxygenated form
Metmyoglobin	Brown	$Fe^{3+}$	$H_2O$	Oxidised form
Carboxymyoglobin	Bright Red	$Fe^{2+}$	CO	Treated with CO
Nitrosomyoglobin	Bright Red (pink)	$(Fe-NO)^{2+}$		Treated with NO or nitrite
Nitrosometmyoglobin	Green	$Fe^{3+}$	NO	Excess nitrite
Metmyoglobin nitrite	Reddish brown	$Fe^{3+}$	NO	Metmyoglobin with excess nitrite
Globin myohaemichromogen	Dark brown	$Fe^{3+}$	$H_2O$	Cooked meat
Nitric oxide myohaemochromogen	Bright red (pink)	$Fe^{2+}$	NO	Cooked cured
Choleglobin	Green	$Fe^{2+}$ or $Fe^{3+}$	$H_2O$	Interaction with $H_2O_2$
Sulfmyoglobin	Green	$Fe^{3+}$	HS	Interaction with $H_2S$
Oxysulfmyoglobin	Red	$Fe^{3+}$	O-HS	
Nitriheamin	Green	$Fe^{3+}$	NO	Excess nitrite

discolouration of raw meat. There are two derivatives of Mb that may be responsible for the green discolouration, choleglobin and sulfmyoglobin (Faustman and Cassens, 1990a); although other compounds that cause meat green colour were reported (Table 1; Lawrie, 1985). Choleglobin is formed by a reaction between Mb, OxyMb or MetMb with hydrogen peroxide which can be produced by bacteria or the interaction of ascorbic acid with the O<sub>2</sub> molecule of OxyMb or from endogenous muscle reactions (Faustman and Cassens, 1990b). Sulfmyoglobin is formed by hydrogen sulfide and O<sub>2</sub> reacting with reduced Mb (Lawrie, 1985). A relevant pigment in fresh meat is carboxymyoglobin that is formed by inclusion of carbon monoxide (CO) in meat package at level <0.4% to form a bright cherry-red colour that is more stable than oxymyoglobin. The affinity of CO for binding with deoxymyoglobin is stronger than O<sub>2</sub>, but both OxyMb and CarboxyMb are vulnerable to be oxidised via lipid oxidation reactions in the same way (Joseph et al., 2009). Premature browning during cooking is a safety problem with fresh meat treated with CO as consumers use browning as indication of cooking of meat and this can occur at low temperatures in meat treated with CO, giving rise to risk of exposure to viable microorganisms.

## Haemprotein Interactions

Myoglobin and haemoglobin in their native physiological state have the characteristic of being oxygenated (oxygenated form which is bright red in colour) and maintaining the iron atom in the ferrous state. They are capable of reversible oxygenation, where the OxyMb and oxyhaemoglobin (OxyHb) release the O<sub>2</sub> molecule and change to the deoxygenated form, which is purple in colour. At low O<sub>2</sub> partial pressure tension and during aging, Mb and OxyMb are oxidised to MetMb which is brown in colour. MetMb can be reduced enzymatically by MetMb reductase to Mb, subject to the availability of cofactors and substrates, which in turn can be oxygenated to OxyMb (Bekhit and Faustman, 2005; Bekhit et al., 2007). However, in harsh environments (high temperature and UV ray), the globin moiety is denatured which leaves the iron atom unprotected. This leads to a spontaneous oxidation of the iron atom to the ferric state and the occupation of the sixth coordination site with H<sub>2</sub>O.

The ligand attachment is influenced by accessibility to the iron ion and the protein shape, which is determined by its amino acid sequence. Amino acid substitution in Mb from different marine species has resulted in different myoglobin-oxygen affinities and disassociation rates (Carver et al., 1992; Marcinek et al., 2001; Stewart et al., 2004). Suman and Joseph (2013) found the molecular mass of myoglobin from several commercial red and white meat sources ranged between 16,824 and 17,380 Da, reflecting differences in Mb sequences. They also reported high Mb homology of 88.2–98.7 among red meat species (cattle, buffalo, sheep, goat and pig), and lower values (68.6–74.5) when comparing Mb from birds with red meat species.

## Myoglobin Content

The Mb content in meat varies with species, breed, individual animals, age, diet and muscle type. The highest Mb contents in commercial meats can be found horse meat and venison, but the exact values vary in literature depending on the study. Yasui (1956–1957) reported the average Mb contents in fresh pork, horse, sheep and cattle meats to be 1.9, 4.5, 2.1 and 3.3 mg/g fresh weight for *deltoideus*, 0.78, 4.4, 1.1, and 4.0 for *longissimus dorsi*, and 0.9, 3.3.2, 0.4 and 2.6 for *semitendinosus*, respectively. They found very high variation in Mb content among animals from the same species. McKenna et al. (2005) found Mb content in 19 beef muscles varies from 3.6 to 5.62 mg/g fresh weight. Wide range of Mb contents has been reported for different pork cuts that is likely to be due to breed and diet. For example, Topel et al. (1966) reported a range of 2.9–6.4 mg/g in various pig muscles, whereas Kim et al. (2010) found a range of 1.2–2.1 mg/g.

Among game meats, Zebra meat was reported to contain the highest Mb content (7.2 mg/g) (Onyango et al., 1998).

## Colour Models

A colour model is a three dimensional orthogonal coordinate representation of colour. The purpose of a colour model is to allow convenient specification of colours. Several different colour models have been proposed to model the characteristics of a colour. All the colour models use three components to describe a colour. The use of one colour model over another depends on the nature of the problem.

Some of the models used to describe colour are; RGB model (red, green, blue), CMY (cyan, magenta, yellow), YIQ (luminance, inphase, quadrature) and intensity-chromaticity colour spaces (HSB, hue, saturation, brightness; HSI, hue, saturation, intensity; HSV, hue, saturation, value; HSL, hue, saturation, lightness; HVC, hue, value, chroma). The later model colour space represents colour as human tends to perceive and are widely used in food literature. Thus colour measurements utilizing only these models will be reported in this section. The major systems depicting colour are the CIE system, Munsell system and Hunter Lab system.

## Colour Measurement Systems

Colour is an appearance property attributable to the spectral distribution of light. The colour that we perceive is the result of three components; a source of illumination, an object to interact with the light which comes from this source and a human eye to observe the resulted effects. Thus understanding colour requires a consideration of all three components, which brings together concepts arising from three natural sciences disciplines, chemistry, physics and biology. In addition, the determination of colour as seen by the human eye depends on a physical stimulus in the eye followed by an interpretation by the brain. Thus the phenomenon of colour is said to be psychophysical (Kramer and Twigg, 1970).

The colour of muscle foods is critically appraised by consumers and often is their basis for product selection or rejection (Hunt et al., 1994). Colour measurements, whether for fundamental research or product development, description or specification, must be done as carefully as other analytical methods. The colour of fresh meat is most commonly evaluated by visual assessment or direct measurement using a colorimeter or reflectance spectrophotometer.

## Visual Colour Evaluation

While subjective (visual) assessment of meat colour reflect the actual perception of colour by panellists, which will vary within the population, it can be an inaccurate and imprecise method since a number of variables are associated with colour detection (human judgments may not be repeatable from day to day and are influenced by personal preference, lighting, visual deficiencies of the eye, the psychological status and appearance factors other than colour). Various scoring scales have been utilized for panel evaluations (these have been reported in detail in AMSA (2012)). There are two potential types of panels used in subjective colour evaluation, trained or consumer panels. Sensory studies recommend 8–12 for trained panel and 120 panellists for the consumer panel. The information received from these panels is different. Trained panels are used to evaluate colour attributes and colour stability with high precision and minimum biases, whereas consumers' panels are used to evaluate acceptance of and satisfaction with meat samples and possibly willingness to pay. The scales are mainly descriptive and imply averaging the colour over the entire meat surface area or worst-point score for a single or cumulative discoloured area. This is an important structure for evaluation of meat colour since the discolouration process during storage is not uniform and irregular discolouration patches can form sporadically on the surface of meat leading to two-tone colour. This characteristic change of meat can have drastic effect on meat quality as the tolerance of discolouration can vary greatly among consumers depending on the individuals familiarity and knowledge of meat (farmers prefer discoloured meat as they know it has been aged longer and likely to be more tender than a fresh meat cut) as well as the consumer nationality (Japanese consumers are very interested in bright red colour than Egyptian for example).

Another visual way of colour evaluation is the use of colour cards or colour standards (such as the Japanese colour standards).

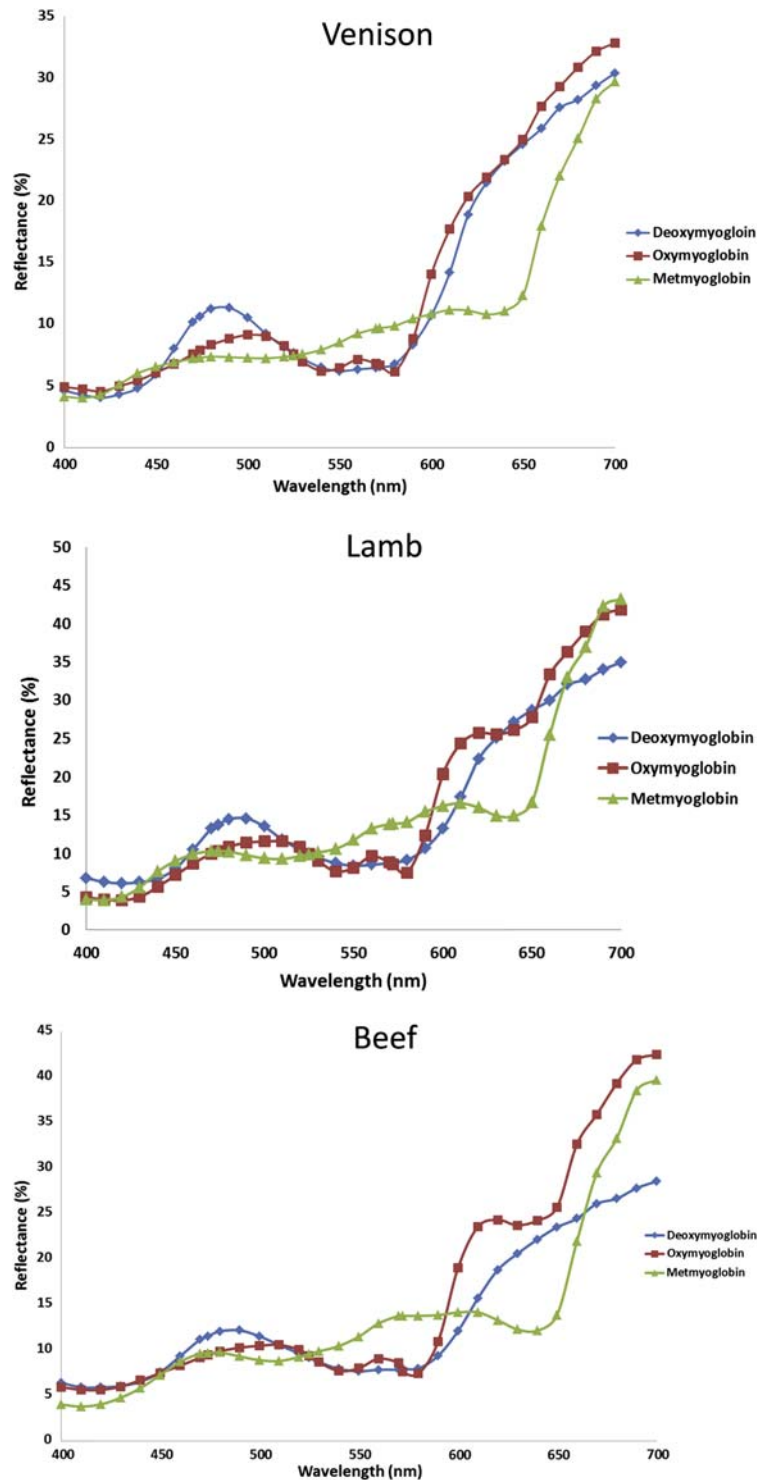

## Instrumental Colour Evaluation

The measurement of colour using instruments that have been standardised for the light source and the detection of colour differences, results in a more accurate evaluation of meat colour. The most widely used instruments for colour measurements are colorimeters and spectrophotometers.

Colorimeters determine the proportions of the primary additive lights that match the colour reflected or transmitted by the sample. Tristimulus colorimeters employ filters to stimulate the response to the human eye. White light from a standard CIE source is shone on the sample. Light reflected at 45° is measured by a photocell after it passes through an X, Y or Z filter.

Spectrophotometers differ from the measurements determined by colorimeters. Reflectance spectrophotometers measure the amount of light reflected by a surface as a function of wavelength to produce a reflectance spectrum (Fig. 2). The reflectance spectrum of a sample can be used, in conjunction with the CIE standard observer function and the relative spectral energy distribution of an illuminant, to calculate the CIE XYZ tristimulus values for that sample under that illuminant. A spectrophotometer illuminates the sample with white light and then calculates the amount of light that is reflected by the sample at each wavelength interval. Typically data are measured for 31 wavelength intervals starting at 400, 410, 420, ..., 700 nm. This is achieved by passing the reflected light through a monochromating device that splits the light into separate wavelength intervals. The instrument is calibrated using white and black tiles whose reflectance at each wavelength is known compared to a perfect diffuse reflecting surface. The reflectance of a sample is either expressed between 0 and 1 (as a fraction) or between 0 and 100 (as a percentage). The reflectance values obtained are relative values and, therefore independent of the quality and quantity of the light used to illuminate the sample. Slight differences in the reflectance of meat from different species (Fig. 2) can exist, but the impact of these differences on estimation of Mb derivatives is not established.

Both systems produce data in the form  $L^*a^*b^*$ , where  $L^*$  indicates lightness and it has a scale of 0–100, 100 = white, 0 = black, and lighter colours will have higher  $L^*$  value,  $a^*$  measures redness when value is positive and indicate green colour if the value is negative, and  $b^*$  measures yellowness  $b^*$  values is positive and indicate blue colour when the value is negative. Using  $a^*$  and  $b^*$  values, the actual colour (Hue angle) can be calculated using the equation  $\text{Hue angle} = \tan^{-1} b^*/a^*$ , where the shifting of the angle

**Figure 2** Reflectance spectra for 100% myoglobin, 100% oxymyoglobin and 100% metmyoglobin in venison, lamb and beef.

from the red colour region to higher angles indicate browning and discolouration. The Chroma “Saturation index” can be calculated using the following equation  $C = (a^2 + b^2)^{1/2}$  and larger C values means the colour is more intense.

Spectrophotometers provide a rapid, non-invasive method of determining the percentage of Mb, OxyMb and MetMb on the surface of the meat. Several equations have been derived based on the reflectance (%) values transformation into K/S values using Kubelka–Munk equation  $[(1-R)^2/2R]$  to take into consideration the variation due to light scatter. To determine the three forms of Mb, 3 references for 100% Mb, OxyMb and MetMb are generated either chemically or physiologically as described in [AMSA \(2012\)](#) and the following equations are used;

$$\% \text{ OxyMb} = \frac{\frac{\frac{K}{S} 610}{\frac{K}{S} 525} \text{ for 100\% MetMb} - \frac{\frac{K}{S} 610}{\frac{K}{S} 525} \text{ for sample}}{\frac{\frac{K}{S} 610}{\frac{K}{S} 525} \text{ for 100\% MetMb} - \frac{\frac{K}{S} 610}{\frac{K}{S} 525} \text{ for 100\% OxyMb}} \times 100$$

$$\% \text{ MetMb} = \frac{\frac{\frac{K}{S} 572}{\frac{K}{S} 525} \text{ for 100\% Mb} - \frac{\frac{K}{S} 572}{\frac{K}{S} 525} \text{ for sample}}{\frac{\frac{K}{S} 572}{\frac{K}{S} 525} \text{ for 100\% Mb} - \frac{\frac{K}{S} 572}{\frac{K}{S} 525} \text{ for 100\% MetMb}} \times 100$$

$$\% \text{ Mb} = \frac{\frac{\frac{K}{S} 474}{\frac{K}{S} 525} \text{ for 100\% OxyMb} - \frac{\frac{K}{S} 474}{\frac{K}{S} 525} \text{ for sample}}{\frac{\frac{K}{S} 474}{\frac{K}{S} 525} \text{ for 100\% OxyMb} - \frac{\frac{K}{S} 474}{\frac{K}{S} 525} \text{ for 100\% Mb}} \times 100$$

## Rapid Systems for Online Colour Measurements

New technologies are promising the ability to measure meat colour during meat processing with the possibility of feedback to producers. Measuring  $L^*a^*b^*$  values from RGB digital images (León et al., 2006) with high accuracy provides the potential of online measurement for rapid evaluation of meat colour as a tool for quality control. Similarly the use of NIR to measure colour and other quality attributes and composition (Mitsumoto et al., 1991; Hildrum et al., 1994; Forrest et al., 2000; Geesink et al., 2003) provides a great opportunity for a comprehensive and non-invasive evaluation of meat. Video image scanning and analysis (VISA) systems (Stanford et al., 1998; Hopkins et al., 2004) can also provide opportunities for evaluation of yield, colour and other important quality attributes that enable fast grading and evaluation of overall quality of meat.

## Conclusions

The colour of meat is very important as it can directly affect the marketing of meat. While consumers use colour as indicator of freshness and discoloured meat is likely to be discriminated against, this is more likely to be based on safety concerns rather than impact on nutrition and digestive consequences of consuming oxidised material that can propagate oxidative processes during digestion. Myoglobin, OxyM and MetMb are the main pigments controlling fresh meat. Several methods are available for the evaluation of meat colour. These methods have advantages and disadvantages in terms of ease to use in different locations (e.g. processing plants and research labs), research questions (subjective or objectives methods) and how fast the answer is required versus cost. Colour measurements can be a useful tool to improve breeding and on farm management system to address any low shelf life fresh meat products.

## Glossary

**Alkylglycerol** ether lipids have an alkyl chain linked to the *sn*-1 position of the glycerol backbone by an ether bond.

**Peroxisome** a single-membrane-bounded organelle that contains hundred enzymes involved in essential lipid metabolisms including plasmalogen synthesis.

**Peroxisome biogenesis disorders** fatal human recessive disorders caused by defects of matrix protein import and/or impairment of membrane assembly.

**PEX** gene encoding a protein essential for biogenesis of peroxisome.

**Plasmalogen** ethanolamine-containing alkenyl ether glycerophospholipid.

**RCDP** a rare genetic disease in children who manifest impairment in the synthesis of plasmalogens due to the dysfunction or defect in peroxisomal localization of enzymes responsible for plasmalogen synthesis.

## Nomenclature

**ADAPS** alkyl-dihydroxyacetonephosphate synthase

**ADHAPR** acyl/alkyl-DHAP reductase

**AG** alkylglycerol

**CHO** Chinese hamster ovary

**DHAPAT** dihydroxyacetonephosphate acyltransferase

**ER** endoplasmic reticulum

**Far1** fatty acyl-CoA reductase 1

**PBDs** peroxisome biogenesis disorders

**PE** phosphatidylethanolamine

**PlsCho** choline-plasmalogen

**POPC** palmitoyl-oleyl-phosphatidylcholine

**RBC** red blood cell

**RCDP** rhizomelic chondrodysplasia punctata

**ROS** reactive oxygen species

## Introduction

Plasmalogens belong to the class of ether glycerophospholipids characterized by the presence of vinyl-ether bond at the *sn*-1 position of the glycerol backbone. Ethanolamine plasmalogens (hereafter referred as plasmalogens) are major constituents of biological membranes where plasmalogens constitute approximately 5%–20% of the phospholipids in most mammalian cell membranes (Braverman and Moser, 2012), implying that plasmalogens are major phospholipid component of cellular membranes. The presence of vinyl-ether bond makes plasmalogens susceptible to reactive oxygen species (ROS) in cultured cell (Zoeller et al., 1999). However, recent studies reconsider the protective function of plasmalogens as a scavenger of ROS because the increased oxidative stress is not detectable in plasmalogen-deficient mouse and *Caenorhabditis elegans* (Brodde et al., 2012; Drechsler et al., 2016).

By taking into account the relatively higher amount of plasmalogens in the cell membranes, plasmalogens are also thought to potentially effect on the biophysical properties of cell membranes including thickness, rigidity, lateral phase separation, and fusion (Rog and Koivuniemi, 2016; Koivuniemi, 2017). A study on molecular dynamics in simulations of lipid membranes composed of plasmalogens and palmitoyl-oleyl-phosphatidylcholine (POPC) bilayers shows that plasmalogens form more compressed, thicker, and rigid lipid bilayers as compared with bilayers composed of phosphatidylethanolamine (PE) and POPC, which is likely due to a highly ordered state of *sn*-1 chain and a closer packing of the *sn*-1 and *sn*-2 chains in plasmalogens (Rog and Koivuniemi, 2016). However, how plasmalogens effect the biophysical properties of cell membranes containing different lipid species remains unknown. Plasmalogens are enriched in lipid rafts (Pike et al., 2002; Honsho et al., 2008), a cholesterol- and sphingomyelin-enriched domain of the plasma membrane, and myelin, a specialized membrane to insulate axon, in both of which plasmalogens

are mostly located in the inner leaflet (Fellmann et al., 1993; Kirschner and Ganzer, 1982; Honsho et al., 2017). In addition, it has been shown that plasmalogens are abundant in vesicles containing raft-like lipid composition, such as extracellular vesicles (Simbari et al., 2016), and envelope of viruses including HIV and influenza virus (Brugger et al., 2006; Gerl et al., 2012). Based on these observations together with the finding that fluorescence anisotropy showing a lower-order parameters in fibroblasts from patients defective in plasmalogen synthesis such as those with rhizomelic chondrodysplasia punctata (RCDP) and peroxisome biogenesis disorders (PBDs), as compared to those in a healthy control (Hermetter et al., 1989), it seems plausible that vinyl-ether linkage of plasmalogen increases the rigidity of cellular membranes. Moreover, the complete lack of plasmalogens has been reported in several organs of patients defective in peroxisome biogenesis (Heymans et al., 1983) and decline of plasmalogen content in several neurological disorders including Alzheimer's disease, Niemann-Pick type C disease (Ginsberg et al., 1995; Schedin et al., 1997), autism (Yu et al., 2013), and Down syndrome (Murphy et al., 2000), and even during normal aging (Farooqui and Horrocks, 2001; Nagan and Zoeller, 2001; Maeba et al., 2007). However, precise mechanisms concerning how dysregulation of plasmalogen homeostasis impairs cellular functions remain unknown. The finding of the feedback regulation of plasmalogen biosynthesis (Honsho et al., 2010, 2013) infers that regulation of plasmalogen synthesis is important for the accomplishment of the functions of plasmalogens in cellular membranes.

### Physiological Consequence of Plasmalogen Biosynthesis in the Homeostasis of Plasmalogens

The level of plasmalogens in mutant cells defective in plasmalogen synthesis is lower than 10% of that in wild-type cells (Honsho et al., 2008; De Vet et al., 1999; Nagan et al., 1997, 1998). In addition, such a striking reduction of plasmalogen level is also found in several organs including brain, heart, and kidney from patients with PBDs (Heymans et al., 1983). Similarly, severe decline of plasmalogens is reported in several tissues of mouse defective in *PEX7* (Brites et al., 2011), an essential cytosolic receptor for the peroxisomal import of the peroxisome targeting signal type 2-containing matrix proteins such as alkyl-dihydroxyacetonephosphate synthase (ADAPS) (Fig. 1) (Braverman et al., 1997; Motley et al., 1997; Purdue et al., 1997). Together, these studies strongly suggest

**Fig. 1** Biosynthetic pathway of plasmalogens and its regulation. Plasmalogen synthesis is initiated in peroxisomes, in which dihydroxyacetonephosphate acyltransferase (DHAPAT) and alkyl-DHAP synthase (ADAPS) sequentially catalyze the generation of alkyl-DHAP by replacing the acyl chain of acyl-DHAP with a long chain alcohol. Fatty acyl-CoA reductase1 (Far1), a peroxisomal C-tail anchored protein, is the enzyme responsible for the synthesis of long chain alcohols. Alkyl/acyl-DHAP reductase (ADHAPR) reduces alkyl-DHAP to yield 1-alkyl-*sn*-glycero-3-phosphate (G3P), followed by synthesizing 1-alkenyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (GPE), plasmalogen, via the remaining four steps in the endoplasmic reticulum. Plasmalogens are transported to the post-Golgi compartments including endosomes and plasma membranes in a manner dependent on ATP, but not vesicular transport (Honsho et al., 2008), followed by localizing in the inner leaflet of plasma membrane. Plasmalogens can be synthesized from alkylglycerol through its phosphorylation (Watschinger and Werner, 2013) by bypassing the first three steps of plasmalogen synthesis in peroxisome (dashed arrow). The biosynthesis of plasmalogen is regulated in a manner dependent on total cellular level of plasmalogens through a mechanism comprising three steps: sensing plasmalogens in the inner leaflet of plasma membrane, transferring the signal indicating the cellular level of plasmalogens, and modulating the Far1 level on peroxisome.

that *de novo* synthesis of plasmalogens plays a pivotal role in the homeostasis of plasmalogens in cells and tissues. Nevertheless, feeding alkylglycerol (AG), a precursor of plasmalogens, and administration of plasmalogens would be attractive approaches to elevating plasmalogens in animals.

### Potential Approaches to the Elevation of Plasmalogens by Feeding Alkylglycerol or Administration of Plasmalogens

AG restores the impaired synthesis of plasmalogen in plasmalogen-deficient cells by bypassing the first three steps of plasmalogen synthesis (Fig. 1) (Honsho et al., 2008; Nagan and Zoeller, 2001; Nagan et al., 1997; Zoeller et al., 1988). Administration of AG, such as 1-*O*-octadecyl-*sn*-glycerol, to *PEX7*-knockout mouse elevates the level of plasmalogen containing C18:0 fatty alcohol in peripheral tissues to the levels of AG-fed wild-type mice (Brites et al., 2011). Moreover, restoration of plasmalogen levels significantly slows down the progression of the pathology in several organs and improves nerve conduction in peripheral nerves (Brites et al., 2011). Similarly, feeding 1-*O*-heptadecyl-*sn*-glycerol, an uncommon ether lipid, to young rats shows its incorporation to a high extent into plasmalogens of several tissues (Brites et al., 2011; Das et al., 1992; Das and Hajra, 1988). However, total level of plasmalogens in the peripheral tissues in rats fed with 1-*O*-heptadecyl-*sn*-glycerol is not elevated, perhaps due to the concurrent reduction of endogenous plasmalogens harboring C16:0, C18:0, and C18:1 fatty alcohols (Brites et al., 2011; Das et al., 1992). Therefore, plasmalogens in peripheral tissues can be synthesized from AG, giving rise to an elevation of the level of plasmalogens derived from the fed AG by reducing the level of endogenously synthesized plasmalogens. Such alternation of plasmalogen species in organs may contribute potential hazardous effects on metabolism (Zhang et al., 2013).

Plasmalogens are not found in plants (Felde and Spiteller, 1994), whereas considerable amount of plasmalogens are present in mammalian meat, fish, and marine invertebrates (Blank et al., 1992; Yamashita et al., 2016). Interestingly, similar total plasmalogen levels are found in red blood cell (RBC) from humans on western diets or vegan diets (Moser et al., 2011). Therefore, it is tempting to speculate that dietary plasmalogens less contribute the level of plasmalogens in RBC, although oral administration of plasmalogens through foods containing high concentration of plasmalogens increased plasmalogen levels in rat RBC (Mawatari et al., 2012; Yamashita et al., 2017).

Plasmalogen level in brain is severely reduced in *PEX7*-knockout mouse (Brites et al., 2003, 2011) and mice each with brain specific deficiency of *PEX5* (Krysko et al., 2007) and *PEX13* (Müller et al., 2011), essential genes for the biogenesis of peroxisome (Fujiki et al., 2014). Moreover, plasmalogen level in brain of *PEX7*-knockout mouse is not increased by feeding AG despite the elevation of plasmalogen in peripheral tissues (Brites et al., 2011). These studies suggest that plasmalogens required for the function of brain are more likely supplied by locally synthesized plasmalogens in brain rather than the transport of peripherally synthesized plasmalogens by crossing blood brain barrier. Therefore, it is crucial to understand the mechanism underlying the regulation of plasmalogen synthesis, a system highly contributing to the homeostatic regulation of quality and quantity of plasmalogens in brain as well as peripheral tissues.

In the following sections, we will summarize the pathway of plasmalogen synthesis and the mechanism addressing how synthesis of plasmalogens is regulated.

### Biosynthesis of Plasmalogens in Mammalian Cells

Biosynthesis of plasmalogen is initiated in peroxisomes (Fig. 1). The initial enzyme, dihydroxyacetonephosphate acyltransferase (DHAPAT) catalyzes the generation of acyl-DHAP. At the second step, ADAPS replaces the acyl chain of acyl-DHAP with a long chain fatty alcohol. This fatty alcohol is synthesized by fatty acyl-CoA reductase 1 (Far1), the enzyme responsible for the reduction of fatty acyl-CoA to generate C16:0, C18:0, and C18:1 fatty alcohols (Honsho et al., 2010, 2013; Cheng and Russell, 2004). Alkyl-DHAP is further reduced by acyl/alkyl-DHAP reductase (ADHAPR) and plasmalogen is synthesized via the remaining four steps in the endoplasmic reticulum (ER). The biosynthetic pathway of plasmalogen was comprehensively reviewed by several groups of investigators (Braverman and Moser, 2012; Nagan and Zoeller, 2001; Wanders and Waterham, 2006; Malheiro et al., 2015).

### Regulation of Plasmalogen Synthesis in Cells

The elevated activity of Far1, not DHAPAT, ADAPS, and ADHAPR in plasmalogen-deficient cells (De Vet et al., 1999; Nagan et al., 1998; Rizzo et al., 1993; James et al., 1990; Thai et al., 2001) suggests that Far1 is a potential rate-limiting enzyme in plasmalogen synthesis. Indeed, the elevated activity of Far1 in plasmalogen-deficient cells is reduced to normal by restoring cellular level of plasmalogens, concomitant with the reduced level of Far1 without lowering the transcription of *FAR1* (Honsho et al., 2010). In addition, elevation of plasmalogen levels reduces the expression of Far1 in several cultured cell lines (Honsho et al., 2010, 2013). Collectively, these results strongly suggest that synthesis of plasmalogen is regulated by modulating the Far1 level in a manner dependent on total cellular level of plasmalogens (Honsho et al., 2010, 2013), not hexadecanol, the product of Far1

(Bishop and Hajra, 1981). Molecular mechanisms underlying plasmalogen-mediated degradation of Far1 on peroxisomes remain unknown. Far1 is degraded upon restoring of plasmalogens even in *PEX1*-deficient Chinese hamster ovary (CHO) cells defective in the transport of peroxisomal matrix proteins (Honsho et al., 2010), suggesting that peroxisomal matrix proteinases such as trypsin domain-containing 1 (Tysnd1) (Kurochkin et al., 2007; Okumoto et al., 2011) and peroxisomal Lon protease (PsLon) (Okumoto et al., 2011) are less likely involved in the plasmalogen-mediated degradation of Far1. It is tempting to speculate that peroxisomal membrane proteins such as ATPase family AAA domain-containing protein 1 (ATAD1) localized in mitochondria and peroxisomes (Chen et al., 2014; Liu et al., 2016), might be involved in the degradation of Far1.

Plasmalogen sensing is also a crucial step for the regulation of plasmalogen synthesis. Plasmalogen sensing in peroxisomes is less likely because plasmalogens are under the detectable level in peroxisomes (Honsho et al., 2008; Yang et al., 2003; Kuerschner et al., 2005). Recent studies by monitoring the protein level of Far1 suggest that plasmalogens localized in the inner leaflet of plasma membranes are most likely sensed (Honsho et al., 2017). In the plasma membranes, plasmalogens are mostly localized in the inner leaflet (Fellmann et al., 1993; Kirschner and Ganter, 1982; Honsho et al., 2017). This asymmetric distribution of plasmalogens is mediated by flippase belonging to the P4 subfamily of P-type ATPases (P4-ATPases). Eliminating the expression of *CDC50A* encoding a  $\beta$ -subunit of P4-ATPases essential for exiting of most of P4-ATPases from the ER by forming a hetero-oligomer (Lopez-Marques et al., 2014; Van der Velden et al., 2010; Bryde et al., 2010) dislocates plasmalogens to the outer leaflet of plasma membranes (Honsho et al., 2017) and stabilizes Far1 without altering total cellular level of plasmalogens (Honsho et al., 2017). Similarly, Far1 is stabilized in the presence of nystatin (Honsho et al., 2017) by inducing distortion of the structure and function of cholesterol-rich membrane domain thorough sequestering cholesterol (Ros-Baró et al., 2001). In contrast, degradation of Far1 is accelerated by inhibiting endocytosis with two distinct inhibitors, dynasore and myristyl trimethyl ammonium bromide (MitMAB) of dynamin, a GTPase required for membrane scission during endocytosis, and by knockdown of flotillin1, a protein enriched in lipid rafts of the plasma membrane (Glebov et al., 2006; Bickel et al., 1997) without changing the total cellular level of plasmalogens (Honsho et al., 2017). Importantly, the amount of plasmalogens in the Triton X-100-insoluble fraction obtained from flotillin1-knocked down HeLa cells is augmented, perhaps due to the inhibition of the endocytosis of plasmalogens. Collectively, these studies suggest that plasmalogens enriched in the plasma membrane is most likely sensed, followed by accelerating degradation of Far1. Therefore, biosynthesis of plasmalogen is spatiotemporally regulated by sensing plasmalogens in the inner leaflet of plasma membranes, followed by transferring a signal emerged from the sensing of plasmalogen level to peroxisomes and modulating the Far1 level (Fig. 1).

## Regulation of Plasmalogen Synthesis in Organs

Regulation of plasmalogen synthesis in tissues has not been addressed. The finding that total plasmalogen level in rat remains unchanged even by reducing the level of endogenous plasmalogens harboring C16:0, C18:0, and C18:1 fatty alcohols after administration of 1-*O*-heptadecyl-*sn*-glycerol suggests that synthesis of plasmalogens in peripheral tissues is likely downregulated by sensing the elevated level of plasmalogens containing C17:0 fatty alcohol (Das et al., 1992), perhaps via the reduction of Far1 protein. Conversely, Far1 protein level is increased in kidney derived from plasmalogen-deficient mouse as compared to that in wild-type mouse (Wiese et al., 2012), suggesting that plasmalogen synthesis is regulated by modulating the Far1 level in kidney as well, similar to the mechanism found in cultured cells (Honsho et al., 2010).

In humans and mouse, the isozymes, Far1 and Far2, sharing 59% identity and 78% similarity were differentially expressed. Far1 shows a broad distribution in several organs and acts on fatty acids that vary in their size and saturation, whereas Far2 is highly expressed in eyelid of mouse and has narrow substrate specificity (Cheng and Russell, 2004). Unlike Far1, Far2 is not degraded upon restoring the plasmalogen level in plasmalogen-deficient CHO mutant and MCF7 cells (Honsho et al., 2013). Moreover, the severely reduced level of plasmalogens in red blood cells from *FAR1*-defective patients further supports that fatty alcohols required for the synthesis of plasmalogens are mainly provided by Far1 (Buchert et al., 2014). Collectively, Far2 seems to possess more specialized function rather than the reduction of acyl-CoA for the synthesis of plasmalogens.

Choline-plasmalogen (PlsCho), another type of plasmalogen, is highly abundant in heart and muscle where approximately 50% of plasmalogens are PlsCho (Braverman and Moser, 2012). PlsCho is thought to be synthesized from hydrolysis of plasmalogens and a following modification of the resultant alkenylglycerol with phosphocholine catalyzed by choline phosphotransferase (Braverman and Moser, 2012; Nagan and Zoeller, 2001; Brites et al., 2004; Lee, 1998). Regulatory mechanism of PlsCho synthesis remains unknown. Feeding 1-*O*-octadecyl-*sn*-glycerol to wild-type mouse increases the total plasmalogen level in heart with a reduced level of plasmalogens containing C16:0 fatty alcohol. However, reduction of PlsCho containing C16:0 fatty alcohol is not evident despite of the elevation of PlsCho containing C18:0 fatty alcohol (Rasmiena et al., 2015). Given these data, synthesis of plasmalogens and PlsCho is most likely regulated by a mutually distinct mechanism in heart.

## Acknowledgments

We thank M. Ishii for preparing Figure and the other members of our laboratory for discussions. This work was supported in part by grants from the Ministry of Education, Culture, Sports, Science and Technology of Japan, Grants in-aid for Scientific Research, MEXT KAKENHI Grant Number JP26116007 (to Y.F.) and the Japan Society for the Promotion of Science Grants-in-aid for Scientific Research, Japan Society for the Promotion of Science KAKENHI grants JP26440102 and JP17K07337 (to M.H.), and JP24247038, JP25112518, JP25116717, JP15K14511, JP15K21743, and

JP17H03675 (to Y.F.) as well as grants from the Takeda Science Foundation, the Naito Foundation, the Japan Foundation for Applied Enzymology, and the Novartis Foundation (Japan) for the Promotion of Science (to Y.F.).

# Biochemical Reactions During Fresh Meat Storage

José A Beltrán, Pedro Roncalés, and Marc Bellés, Universidad de Zaragoza, Zaragoza, Spain

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Calpain** calcium-dependent protease involved in proteolytic degradation of myofibrillar proteins during meat maturation.

**Free radical** molecule which possesses an unpaired electron and is extremely reactive, being capable of attack other molecules thereby generating many more free radicals.

**Phenolic compound** compound with a structure containing an aromatic ring bearing one or more hydroxyl groups.

**Superchilling** refrigeration at temperatures comprised between freezing and chilling, usually between  $-0.5$  and  $-2.8$  °C.

**Vacuum skin packaging** vacuum package that achieves a tight disposition of the film on meat surface, reducing the formation of pockets and consequently, decreasing residual  $O_2$ .

## Nomenclature

ROS Reactive oxygen species

PUFA Polyunsaturated fatty acid

SFA Saturated fatty acid

MAP Modified atmosphere packaging

VP Vacuum packaging

VSP Vacuum skin packaging

AP Active packaging

GRAS Generally Recognised As Safe

TBARS Thiobarbituric acid reactive substances (mg malondialdehyde/kg of meat)

## Introduction

Meat consists entirely of skeletal muscle of animals. Animal death occurs at slaughter; nevertheless, muscles remain alive. All muscle cell constituents and structures, basically proteins, lipids and enzymes, are still functional, so that biochemical reactions may further proceed. Those reactions are no more subjected to hormonal or nervous regulation nor to any extracellular supply, thus they are regulated solely by intracellular factors such as substrate concentration. After rigor mortis onset, due to ATP depletion, carbohydrate metabolism and lactic acid formation, the environment becomes acid, reaching a pH within the range 5.5–5.8. From this time onwards, two type of reactions may chiefly occur: enzymatic degradation of proteins and oxidative reactions focusing on lipids. It must not be overlooked that, besides these, other degradative reactions linked to microbial growth may also occur, mainly at late stages of meat storage but depending on environmental conditions.

## Proteolytic Changes

Protein myofibrillar structures are known to be responsible for muscle function, i.e. contraction and relaxation. Myofibrils no longer work after rigor mortis onset, since they need ATP to fueling the process, though they still render a stable complex structure which results in a tough fibrous texture as meat is chewed. Consumers consider toughness the most negative sensory property of meat, so it is highly negatively evaluated at this post mortem stage (Koochmaraie and Geesink, 2006; Huff-Lonergan et al., 2010).

A number of muscle proteases may be active under the conditions prevailing in meat early post mortem. As meat ageing proceeds they target the myofibrillar proteins leading to structure disruption and finally to meat tenderization. As a consequence, meat becomes progressively less chewy with ageing time, i.e. its sensory valuation steadily increases throughout storage (Koochmaraie and Geesink, 2006). Table 1 summarizes some comprehensive data on the proteases present in muscle tissue, including factors which affect their activity.

Conditions prevailing in meat must be considered in order to come to a conclusion on whether they may be active throughout meat storage. Regarding tissue location, only calpains and the proteasome are available for proteolytic action within the cytosol and the myofibrils (Goll et al., 2003; Houbak et al., 2008); cathepsins must be released from the lysosomes and caspases from apoptosomes, which appears to be unlikely, at least in early phases of meat storage (Sancho et al., 1997; Underwood et al.,

**Table 1** Proteases present in muscle tissue and factors which affect their activity

Protease	Location	Optimum pH	Regulating factors
Calpains $\mu$ -calpain $m$ -calpain calpain 3	Cytosol	7,0–7,5	Calcium ( $\mu\text{mol-mmol}$ ) Calpastatin (specific inhibitor) Phospholipids
Cathepsins	Lysosomes	4,0–6,0	Release from lysosomes Temperature Inhibitors
Proteasome	Cytosol	7,5–8,0	Ubiquitin ATP
Caspases	Apoptosomes	6,5–7,5	Apoptosis Cellular death

2008). Despite the optimum pH of the former seems to be far from that existing in meat after rigor mortis onset, they are known to show a significant activity at a pH of 5,5–6,0 (Ceña et al., 1992; Goll et al., 2003). Concerning the proteasome, a complex regulation which involves the ubiquitin system based on the energy provided by ATP is needed for activity (Lamare et al., 2002; Houbak et al., 2008). Therefore, only calpains appear to be actually available to afford to accomplish the proteolytic degradation of myofibrillar proteins (Roncalés et al., 1995; Koohmaraie and Geesink, 2006).

Calpains need calcium for its activation though very low concentrations ( $\mu\text{molar}$ ) of this cation are sufficient, which are indeed existing in meat at that level. Furthermore, the  $m$ -calpain and calpain-3 forms act as a reservoir since they may transform into  $\mu$ -calpain as this latter inactivates itself after exerting its proteolytic action (Goll et al., 2003; Huff-Lonergan et al., 2010). A further concern on calpain activity raised when the existence of its specific inhibitor calpastatin was reported; nevertheless, it has been demonstrated that calpain may overcome calpastatin inhibition under normal conditions of meat storage (Goll et al., 2003; Koohmaraie and Geesink, 2006). Besides this, the presence of phospholipids is known to enhance calpain activation. In summary, the cysteine-protease calpain is likely to be the sole responsible for myofibrillar proteins degradation throughout meat storage and therefore for meat tenderization, though at a low rate due to low pH and temperature (Ceña et al., 1992; Goll et al., 2003; Huff-Lonergan et al., 2010).

Not all the myofibrillar proteins are targeted by calpain, in fact only a few of them appear to be hydrolyzed by this endoprotease, mainly the giant protein titin, desmin, nebulin and  $\alpha$ -actinin (Koohmaraie and Geesink, 2006; Huff-Lonergan et al., 2010). These are essential components of some crucial myofibril structures, respectively, elastic filaments, transversal filaments, N filaments and Z lines. It is noteworthy to highlight that the most abundant myofibrillar proteins myosin and actin, essential components of thick and thin filaments, respectively, are not affected by calpain action (Sancho et al., 1997; Huff-Lonergan et al., 2010). Electrophoretic patterns of meat throughout storage closely fit with this outlook and demonstrate the unique involvement of calpain on meat aging (Roncalés et al., 1995; Koohmaraie and Geesink, 2006). It must be also emphasized that collagen, the main protein of the tough connective tissue of muscle, is neither hydrolyzed by calpain (Purslow, 2005).

Hydrolysis of those target proteins onto large polypeptides causes the cleavage of critical ultrastructural filaments and lines and this leads to myofibril disruption and progressive breakup. Ultimately, the result is that meat exerts a lower resistance to mastication and therefore becomes more tender (Goll et al., 2003; Koohmaraie and Geesink, 2006). However, as collagen is not degraded, tenderization occurs within the limits of the connective tissue contents and characteristics of any particular meat cut.

Fig. 1 depicts the changes occurring along meat aging related to meat texture. Perceived (measurable) toughness reaches a maximum at rigor mortis onset and decreases thereafter in a hyperbolic manner tending asymptotically to the lower limit, which is determined by the collagen content (Purslow, 2005). This process may go on for weeks depending on meat characteristics and environmental conditions. This is of course a schematic approach to how tenderisation proceeds though it reflects the actual behavior of meat texture, which steadily passes from tough to increasingly tender.

**Figure 1** Changes of texture and volatile nitrogen compounds occurring throughout meat aging.

According to this view meat might be aged as long as possible in order to reach the most tender texture. But a limit for aging arises from the increasing amount of volatile nitrogen molecules, which results in odor enhancement and finally in putrid smell. Those compounds are produced by microbial metabolism, so that their concentration depends on microbe counts. In fact, a significant upsurge of the nitrogen compounds concentration is closely related to the phase of microbial exponential growth (Casaburi et al., 2015). As a consequence, any factor delaying microbial growth, such as low temperature, low pH, oxygen absence or inhibitors presence, will result in an extended aging period.

## Oxidation During Meat Storage

Oxidation is a biochemical process involving a transfer of oxygen atoms, hydrogen atoms or electrons between two coupled compounds maintaining a net chemical charge. In the biological systems the donor is called pro-oxidant and the acceptor antioxidant. Antioxidant defences, which protect the body against oxidative damage *in vivo*, are rapidly depleted after slaughter, thus leaving meat exposed to oxidation during storage (Morrissey et al., 1998).

### Lipid Oxidation

Lipid oxidation consists of the oxidative degradation of lipids through complex linked reactions which result in a wide range of compounds that involve a lessening of nutritional and sensory value of meat and even may compromise its safety.

#### Mechanism of Action

Lipids can be oxidized by enzymatic or non-enzymatic reactions; however, autoxidation is the main mechanism of lipid oxidation in fresh meat. It starts at the phospholipid membrane of cell followed by a free-radical chain reaction commonly divided into three major steps: initiation, propagation and termination (Cheng, 2016). Fig. 2 shows the main reactions involved in lipid oxidation.

An initiator such as light, transition metals or oxygen reactive substances (ROS) is required to spring the process. Initiation starts by the attack of any reactive substance to abstract a highly reactive hydrogen atom from a fatty acid, thereby generating a lipid radical. The higher reactivity of hydrogen atoms of a methylene group bound to 2 carbon-carbon double bonds make them more prone to become oxidized (Blanksby and Ellison, 2003). The latter lipid radical reacts with oxygen to form a peroxy radical ( $\text{ROO}\cdot$ ), which in a subsequent reaction attacks a new unsaturated fatty acid and thus arising two different compounds: a new alkyl radical ( $\text{R}\cdot$ ) and a hydroperoxide ( $\text{ROOH}$ ). At this stage, a cascade of chain reactions spreads, in which each new molecule boosts the reaction speed (Min and Ahn, 2005). The reaction of a radical with a fatty acid substrate always generates another radical, thereby the oxidation process continues. The termination step takes place when two radicals are combined between them forming non-reactive compounds. Commonly, termination starts when there are enough radical species for favoring the contact of two radicals (Min and Ahn, 2005).

#### Effect of Lipid Oxidation on Meat Quality

Hydroperoxides are tasteless and odorless compounds with no impact on meat sensory attributes. Nonetheless, they are highly unstable and tend to disintegrate in hundreds of secondary lipid oxidation-by-products that concern severe changes in meat quality. In the presence of nonheme iron ( $\text{Fe}^{2+}$ ) there is a breakdown of hydroperoxides which generates hydroxyl ( $\cdot\text{OH}$ ) and alkoxy ( $\text{RO}\cdot$ ) radicals, followed by the scission of the fatty-acid chain next to the alkoxy radical. Thereby, a huge variety of volatile and non-volatile compounds are generated, which are responsible of oxidation-related modifications of meat sensory properties. The

**Figure 2** Overview of lipid autoxidation steps.

kind of compounds produced depends on both the alkyl chain of the hydroperoxide and the position where cleavage occurs (Papuc et al., 2017; Resconi et al., 2013).

Nutritionists recommend increasing the consumption of polyunsaturated fatty acids (PUFA) instead of saturated fatty acids (SFA). On the other hand, a high ratio of n-6:n-3 PUFA is also a risk factor in cancer and coronary heart disease (Enser et al., 2001). Unfortunately, both PUFA and especially n-3 PUFA are more prone to oxidation and tend to degrade during meat storage, hence decreasing meat nutritional value (Álvarez et al., 2009; Bellés et al., 2018). Furthermore, lipid-derived free radicals and hydroperoxides give rise to the conversion of amino acids into Strecker aldehydes,  $\alpha$ -keto acids, and amines, thus reducing their bioavailability (Hidalgo and Zamora, 2016). Otherwise, lipid autooxidation also exacerbates the depletion of valuable micronutrients such as vitamins A, C, E and flavonoids.

Lipids contribute both to desirable and undesirable meat flavors during storage. In fact, the characteristic flavor of the different meat species depends on its particular fatty acid profile. On the other hand, the oxidation of lipids during storage results in hundreds of volatile compounds directly responsible of the unpleasant odor and flavor of oxidized meat. Among all of them, aldehydes are generally believed to be the chief contributors to rancidity, since they are abundant in oxidized meat and possess low olfaction thresholds. Other oxidation-by-products like ketones, alcohols and furans may play a significant role in rancidity too (Resconi et al., 2013). The accumulation of unpleasant odors and flavors arisen from lipid autooxidation can overpower meat desirable flavors, thus resulting in a decrease of meat quality. Moreover, some studies suggested that secondary by-products of lipid peroxidation, which are bioavailable, would be likely to have cytotoxic and genotoxic properties and might be related to inflammatory diseases, cancer, atherosclerosis etc (Vieira et al., 2017).

## Protein Oxidation

Proteins become oxidized by different chemical pathways. ROS can attack directly multiple side-chain and backbone sites of a protein, thereby exerting modifications in its conformation structure. On the other hand, products of lipid oxidation, mainly secondary compounds, can interact with the amino acid residues of proteins modifying their structure and function. Furthermore, both lipid and protein oxidation can exacerbate each other (Zhang et al., 2013).

The oxidation of a protein may lead to increased side-chain hydrophilicity, side-chain and backbone fragmentation, aggregation and altered conformation. All these modifications would compromise its proper function thereby resulting in meat modifications such as reduced water holding capacity, discoloration, toughness and increased lipid oxidation (Zhang et al., 2013).

## Factors Affecting Meat Oxidation

### Meat Composition

Oxidative stability is a balance between meat antioxidants and pro-oxidants, the rate of oxidative reactions in meat matrix is actually highly related with the availability and abundance of several compounds as well as the interaction among them. The content of fat in muscle is critical to its stability against oxidation: the more fat, the faster development of oxidation through display (Estévez et al., 2005; Park et al., 2008). Unsaturated fatty acids are particularly prone to oxidation. A higher content of PUFA in muscle may favor the initiation step, thus increasing the susceptibility of meat to oxidize. In this regard, non-ruminant meat presents an intense lipid autooxidation because of its PUFA/SFA ratio. Similarly, several studies evidenced that meat enrichment with PUFA and particularly n-3 PUFA exacerbated lipid oxidation due to their greater tendency to be oxidized during storage (Wood et al., 1999; Díaz et al., 2011). Otherwise, red meat is rich in heme and nonheme iron which may catalyse heme protein-mediated lipid oxidation (Rhee and Ziprin, 1987).

Grass feeding favors the deposition of natural antioxidants in muscle thereby increasing the antioxidant defences of meat after slaughter. As a consequence, meat from grass fed animals shows more stability against oxidation than that providing from concentrate fed (Mercier et al., 2004). Differences among muscles are also related with the proportion of different muscle fibers. Muscles with greater relative proportions of type I muscle fibers have a higher content of myoglobin and oxygen consumption rate, hence enhancing myoglobin oxidation and consequently discoloration (Jeong et al., 2009).

### pH

It is generally accepted that low pH environments enhance both lipid and protein oxidation. At low pH, heme protein is exposed to external environments which compromise its stability. On the other hand, a lower pH environment exacerbates the protonation of bound oxygen and stimulates the formation of superoxide anion (Yin and Faustman, 1993).

### Atmosphere Composition

Oxygen plays a key role in promoting meat oxidation, increasing its rate with the concentration of oxygen in the surrounding atmosphere. In fact, oxidative processes usually involve reactive oxygen species. Carbon dioxide may act as pro-oxidant in concentrations above 30%, owing to the decrease of meat pH. Carbon monoxide (CO) is not likely to affect lipid oxidation but it has been very effective in preventing myoglobin from oxidation by promoting the formation of carboxymyoglobin. In contrast, nitrogen (N<sub>2</sub>) and argon (Ar) do not seem to be involved in oxidative processes (Martínez et al., 2005; Bellés et al., 2017a).

### Light

Light may initiate lipid and myoglobin oxidation. It can excite either unsaturated fatty acids or oxygen thereby favoring the formation of hydroperoxides. Photo-oxidation depends both on the wavelength and the intensity of light. White fluorescent lighting is more oxidizer than incandescent lighting while the incorporation of UV-light filters may significantly protect meat from photo-oxidation during display (Whang and Peng, 1988; Martínez et al., 2007). On the other hand, new light emitting diode (LED) seems to reduce discoloration but it may slightly enhance lipid oxidation (Cooper et al., 2016; Steele et al., 2016).

### Temperature

Both protein and lipid oxidation reactions are not completely inhibited at chilling temperatures but progress at a reduced rate. Temperature has been described to be the main factor for protecting meat from discoloration and lipid oxidation during display (Jakobsen and Bertelsen, 2000; Yin and Faustman, 1993). The effect of temperature against oxidation is still more pronounced at freezing temperatures, at which lipid oxidation is almost inhibited (Bellés et al., 2018). Nevertheless, there is a range between refrigeration and freezing in which a decrease of temperature may exacerbate oxidative processes. At superchilling temperatures (usually between  $-0.5$  and  $-2.8$  °C) meat could suffer mechanical damages which result in the release of pro-oxidant compounds, thereby increasing meat oxidation (Bellés et al., 2017b).

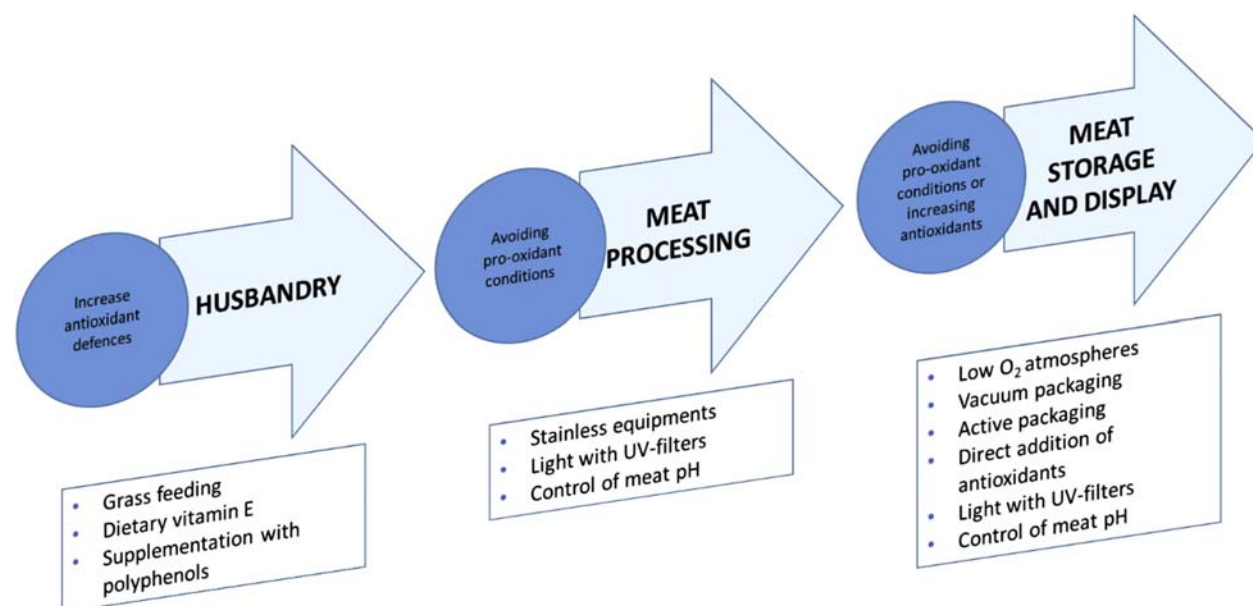

## Strategies to Inhibit Oxidative Reactions

Fig. 3 summarises the most common strategies used for reducing meat oxidation from farm to fork.

### Packaging

With the development of vacuum packaging (VP) and modified atmosphere packaging (MAP), meat industry started modifying the atmosphere surrounding the meat in order to change the atmospheric composition for a more profitable mixture of gases. Red meat is commonly packed in oxygen-enriched atmospheres (70%–80% O<sub>2</sub>) with the aim of producing optimum color by promoting oxymyoglobin formation. However, high proportions of oxygen in the package headspace have been described to favor lipid and ultimately protein oxidation leading to rancidity development, PUFA degradation and protein oxidation. In fact, oxidation is one of the main causes of deterioration of aerobic packaged meat (Bellés et al., 2017a). In contrast, the removal of oxygen from the package provides an anoxic atmosphere which minimize oxidative reactions. Despite low amounts of oxygen are enough to promote oxidation, vacuum skin packaging (VSP) seems to be able to avoid the formation of wrinkles which minimize residual oxygen in the package thus improving the antioxidant effect of traditional vacuum packaging (Bellés et al., 2017b). Table 2 presents some atmospheres commonly used for meat preservation.

The development of active packaging (AP) represents a new concept in meat packaging. Packaging becomes active when it plays some desirable role in food preservation besides providing an inert barrier to external conditions. AP incorporates additives (loose within the pack, attached to the inside of packaging materials or incorporated within the packaging materials) with preservative properties that enhance primary functions of the package (Hutton, 2003). Some interesting mechanisms such as scavengers of oxygen and ROS or emitting of natural antioxidants have shown interesting effects on inhibiting meat oxidation.

### Herb Extracts and Essential Oils

Synthetic compounds have been commonly used in food industry to make a profit of their powerful antioxidant properties (Moure et al., 2001). Nevertheless, increasing demand of cleaner foods have immersed chemical additives in the eye of the storm. In contrast to synthetic additives, natural antioxidants are included in the Generally Recognised As Safe (GRAS) list of the American Food and Drug Administration. Essential oils and herb extracts contain substances with antioxidant and inhibitory effects against numerous pathogenic and spoilage bacteria. As can be seen in Table 3, potential sources of antioxidant compounds have been searched in different plant materials such as fruits, leaves, oilseeds, cereal crops, spices and herbs.

Polyphenols are the plant compounds with antioxidant activity mostly used for meat preservation. Phenolic compounds have an aromatic ring attached to one or more hydroxyl groups and their structure range from a simple molecule to a complex high-molecular weight polymer. The antioxidant activity of phenolic compounds, which depends on the structure, consists of their ability to scavenge free radicals, donate hydrogen atoms or electron, or chelate metal cations (Balasundram et al., 2006). Natural antioxidants have been employed for meat preservation obtaining a significant delay of lipid oxidation, discoloration as well as microbial growth, thus extending meat shelf life.

### Nutritional Strategies

The improvement of the balance between muscle pro-oxidants and antioxidants *in vivo* leads to an increase of antioxidants defences of meat after slaughter. A positive balance may be achieved by including supranutritional doses of natural antioxidant in animals feed, thereby favoring their depot accumulation in muscle cells.

Vitamin E is the main fat soluble antioxidant in mammalian cells, preventing oxidative reactions at the start site by a potent chain-breaking antioxidant. Vitamin E compounds possess a hydroxylic group which is able to transfer a hydrogen atom to a peroxy radical, which becomes a lipid hydroperoxide, while vitamin E becomes a low activity radical, the  $\alpha$ -tocopheroxyl radical. This radical, which does not take part in propagation reactions, can be reduced to tocopherol by other antioxidants like vitamin C, showing again antioxidant activity (Fennema et al., 2004). Tocopherols can inactivate different kinds of high reactive molecules such as singlet oxygen, alkoxyl radicals, peroxyxynitrite, nitrogen dioxide, ozone and superoxide. A large number of studies have observed that the administration of supranutritional doses of vitamin E before slaughter favors the deposition of tocopherol in the muscle increasing the stability of meat against oxidation (Bellés et al., 2017d, 2018; Muela et al., 2014; Jose et al., 2016).

Otherwise, feeding with plants rich in phenolic compounds or the supplementation with purified phenolic compounds and essential oils may improve the antioxidant status of meat (Vasta and Luciano, 2011).

### Glossary

**Caramelization** Caramelization is the degradation of sugar in the absence of an amino group where the initial sugar enolization proceeds with a series of dehydration, fragmentation and oxidation followed by polymerization of reaction intermediates and reactants. Caramelization usually occurs in the range of temperatures from 120 to 200 °C.

**Lipid oxidation** Lipid oxidation is a major deterioration reaction during degradation leading to the loss of nutrients, alteration of colors and generation of off-flavors.

**Maillard reaction** Maillard reaction is a term used to describe the reaction of proteins with sugars under application of heat.

**Melanoidins** Melanoidins are polymerized and colored products resulting from the advanced stages of the Maillard reaction. Melanoidins can be formed in wide variety of food products during domestic and industrial food processing.

**Strecker degradation** Strecker degradation is the conversion of  $\alpha$ -dicarbonyls into  $\alpha$ -aminocarbonyls. The reaction involves the formation of a Schiff base of an  $\alpha$ -dicarbonyl with an amino acid. Following the rearrangement, decarboxylation and hydrolysis, an  $\alpha$ -aminocarbonyl and the Strecker aldehyde are formed.

### Introduction

The majority of food items consumed daily are subjected to heat treatment to develop certain organoleptic characteristics. The main reasons for these changes in taste, flavor, texture, and color involve nonenzymatic browning reactions (Kanzler et al., 2017). With increased consumption of processed foods globally, food processors are becoming more interested in understanding the ways in which browning reactions can be controlled to better achieve more functional and healthful foods.

There are three general types of nonenzymatic, so-called “browning,” reactions recognized in food technology. The most common reaction, the carbonyl-amine reaction, was named after its discoverer French biochemist Louis Camille Maillard, who was the first to report that aqueous solutions consisting of amino acids and reducing sugars turn progressively brown during heating (Maillard, 1912). It includes the reactions of aldehydes, ketones, and reducing sugars with amines, amino acids, peptides or proteins (Hodge, 1953). The Maillard reaction occurs effectively at temperatures  $>50^{\circ}\text{C}$  and is favored at pH 4–7 (Kroh, 1994). A second reaction type, called “caramelization,” occurs when polyhydroxycarbonyl compounds, including sugars and polyhydroxycarboxylic acids, are heated above their melting points ( $>120^{\circ}\text{C}$ ) under acidic (pH 3) or alkaline (pH 9) conditions in absence of nitrogen-containing compounds. This type of browning usually requires more energy than the Maillard reaction to get started. The Maillard reaction and caramelization are independent of the presence of oxygen (Hodge, 1953). On the other hand, another type of browning important to the food processor is the group of oxidative reactions. Here, for example, ascorbic acid and polyphenols are converted into di- or polycarbonyl compounds that can then participate in the Maillard reaction itself. With enzymatic oxidation, such as polyphenoloxidase oxidation of dietary polyphenols, a catechol structure is formed, *o*-quinone, representing a source of carbonyls in the Maillard reaction. Secondary reactions of the *o*-quinones include the Strecker degradation of amino acids to form flavor-important volatile aldehydes (Rizzi, 2006). Ascorbic acid can also react with proteins (Meucci et al., 1991; Pischetsrieder et al., 1995). It is well-established that ascorbic acid can be oxidized to dehydroascorbic acid, which is then hydrolyzed irreversibly to 2,3-diketogluconic acid. The latter undergoes amine-catalyzed degradation following both the  $\beta$ -dicarbonyl fragmentation and the oxidative  $\alpha$ -dicarbonyl cleavage routes (Smuda and Glomb, 2013). The oxidation of lipids also produces carbonyl compounds, which readily react with free amino groups to produce browning (Gillatt and Rossell, 1992). For instance, the decomposition of lipid hydroperoxides generates aldehydes and ketones which then catalyze browning. All types of browning are caused by the formation of unsaturated, colored polymers of varying composition. Since compounds that produce browning usually contain carbonyl groups, polyhydroxy compounds and sugars in which the carbonyl function is blocked do not give rise to browning (Hodge, 1953).

## The Pathways of Browning Reactions

### The Major Steps in the Development of the Maillard Reaction

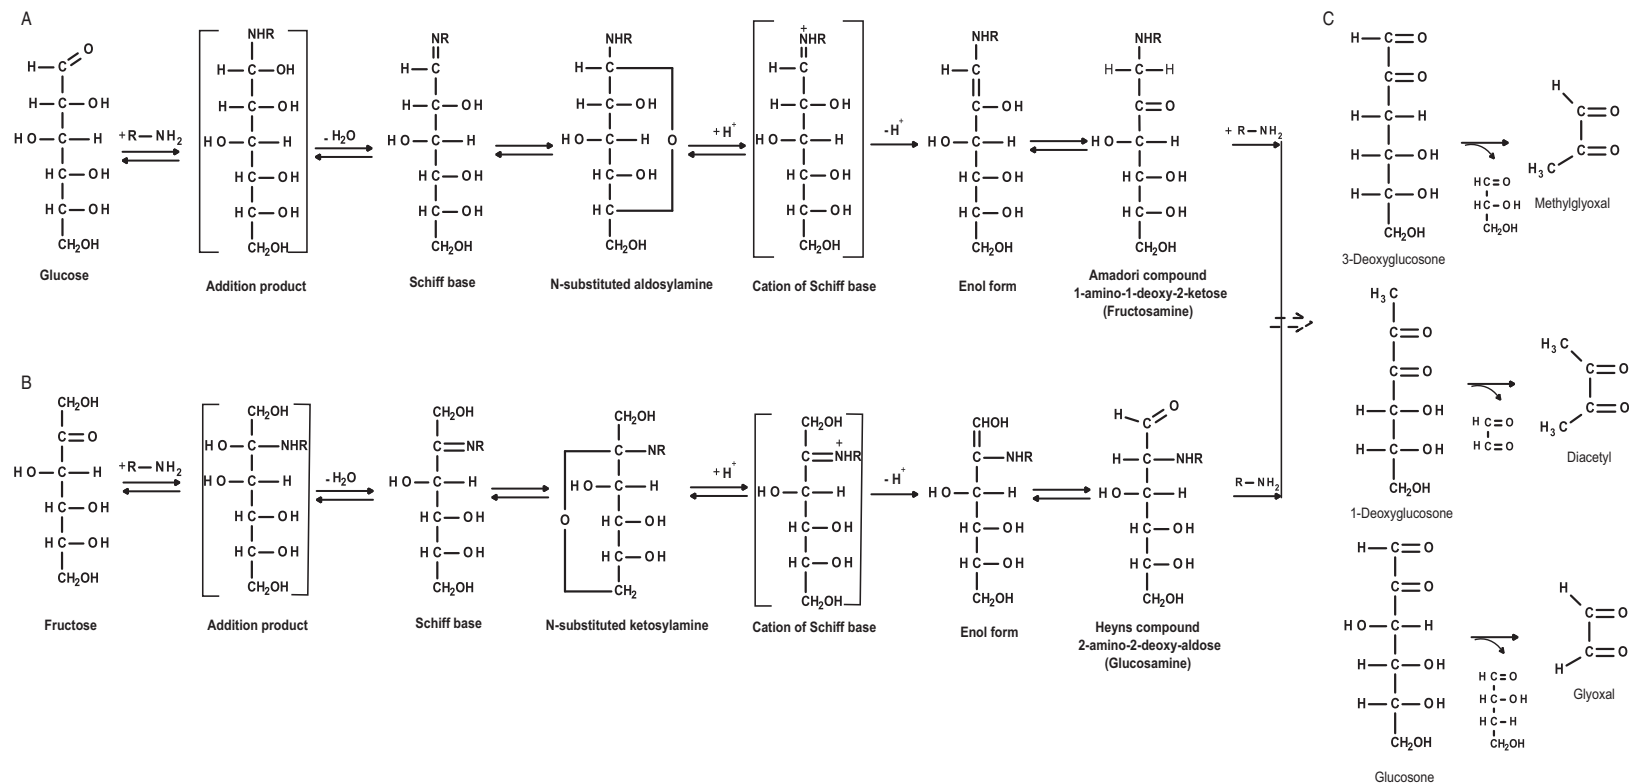

Maillard reaction is a sequence of reactions, starting with the formation of covalent bond between the amine groups and carbonyl compounds. In 1953 John E. Hodge proposed the reaction to be divided into “early,” “advanced” and “final” stages, where each step is dependent on the reaction conditions and distinguished by the characteristic reaction product (Silván et al., 2011; Hellwig and Henle, 2014). The main participants of the Maillard reaction are biomolecules with free amine groups including proteins, nucleotides and some phospholipids. Amines have several properties that are responsible for their reactivity, where major is their ability to act as nucleophiles by possessing a lone pair of electrons on the nitrogen atom. The properties of the carbonyl group are primarily those of the carbon-oxygen double bond. Its reactivity is mainly due to the difference in electronegativity between carbon and oxygen, leading to a dipolar resonance form (Feeney et al., 1975).

The initial stage of the Maillard reaction involves the condensation of a carbonyl group, for instance from a reducing sugar such as glucose or fructose, with a free amino group, typically the  $\epsilon$ -amino group of a lysine residues within proteins, to form an addition product. The addition product dehydrates to form the unstable imine known as a Schiff base, that spontaneously cyclizes to form a more stable *N*-glycosylamine (Fig. 1). Glycosylamines are hydrolyzable and the free amino acid and sugar are usually re-generated and therefore nutritionally available (Dills, 1993). *N*-glycosylamine from aldose sugars further rearranges to 1-amino-1-deoxy-2-fructose (ketoamine), which is known as the Amadori product (Fig. 1A) after the Italian scientist Mario Amadori. Derivatives from amino acids and ketoses (ketosylamines), similarly to the Amadori rearrangement, undergo the Heyns rearrangement (Fig. 1B) (Davidek and Davidek, 2003) named after Kurt Heyns, a chemist at the Chemical Institute of the University of Hamburg (Hellwig and Henle, 2014), who reported the formation of D-glucosamine in the reaction of fructose with ammonia (Heyns and Koch, 1952). Typically, no major color changes are observed at this stage of reaction (Damodaran, 2008), yet the nutritional value can be reduced due to irreversible modification of lysine, arginine, tryptophan, and isoleucine residues (Dworschak and Carpenter, 1980). Ketoses are more reactive in the sugar degradation reaction than their aldose isomers (Brands and van Boekel, 2001).

Intermediate stage of the Maillard reaction is more complicated in its pathways, reactants and products. It often shown as separate modules or pathways, however a myriad of possible interactions between unstable intermediates from variety of the pathways needs to be taken into account (Hoskin and Dimick, 1995). In any case, this stage involves the degradation of Amadori and Heyns rearrangement products to deoxydicarbonyl sugars (deoxyosones), which is pH-dependent (Fig. 1C). These deoxyosones contain two vicinal carbonyl groups and are therefore also named  $\alpha$ -dicarbonyl compounds. At lower pH, 1,2-enolization occurs resulting in formation of 3-deoxyglucosone, whereas neutral and alkaline pHs favor 2,3-enolization generating 1-deoxyglucosone. The other important  $\alpha$ -dicarbonyl compounds include methylglyoxal, glyoxal and diacetyl (Henle et al., 1996). The enolization pathways and formation of  $\alpha$ -dicarbonyls from Amadori and Heyns compounds is described in details by Davidek et al. (2002) and Hrynets et al. (2015), respectively.

Following cyclization and elimination of water, 3-deoxyglucosone forms hydroxymethylfurfural (HMF), whereas 1-deoxyglucosone produces isomaltol, maltol and furanones (Fig. 2A). These compounds are important aroma compounds which also have antioxidative properties (Coghe et al., 2004).

**Figure 1** The early stage of the Maillard reaction leading to the formation of (A) Amadori or (B) Heyns compounds; (C) Structures of the major deoxyosones produced from Amadori and Heyns rearrangement products. Apart from cyclization Strecker degradation can occur in which α-dicarbonyls act as oxidizing agents to start decarboxylation of amino acids which is usually followed by hydrolysis of the resulting imine to produce free ammonia or a primary amine (α-aminoketone) and an aldehyde, known as a Strecker aldehyde (Fig. 2B) (Yaylayan, 2003). A comprehensive review on the pathways of the Strecker degradation is published by Yaylayan (2003). The Strecker degradation is an important for the generation of flavor-active compounds during the Maillard reaction. Strecker aldehydes of certain amino acids, in particular leucine, phenylalanine, or methionine, belong to key aroma components of many fresh and processed foods. They are important for flavor development in bread, coffee, cocoa, roasted meat, and dark beer (Vanderhaegen et al., 2006); however, can be perceived as off-flavors in ultrahigh-temperature (UHT) processed milk (Jansson et al., 2014a,b).

Alpha-dicarbonyls, glyoxal and methylglyoxal in particular, readily react with both lysyl and arginyl residues yielding advanced glycation end-products (AGEs) (Fig. 2C). Among the AGEs formed, N<sup>ε</sup>-carboxymethyllysine (CML), N<sup>ε</sup>-carboxyethyllysine (CEL), pyrrolidine, methylglyoxal–lysine dimer (MOLD), glyoxal–lysine dimers (GOLD) are the major lysine-related products. Glyoxal-derived hydroimidazolone (Glarg), carboxymethylarginine (CMA), methylglyoxal-derived hydroimidazolones (MG-H1, MG-H2 and MG-H3) and carboxyethylarginine (CEA) are arginine-related AGEs (Frolov et al., 2014; Gruber and Hofmann, 2005). For a thorough review on different AGEs formed refer to Arena et al. (2014).

Further rearrangements occur later in the final stage, including cyclization, dehydration, retroaldolization, isomerizations, rearrangements and condensation of low molecular weight Maillard reaction products (MRPs). This results in the formation of a large group of high molecular weight, brown-colored and nitrogen-containing polymerized products, known collectively as melanoidins (Henle et al., 1996; Fogliano and Morales, 2011). These products are mainly responsible for specific color and typical appearance of processed foods (Mesias and Delgado-Andrade, 2017). Though, the definite structure of variety of melanoidins unidentified due to the variety of the reactants and reaction conditions, several mechanisms of their formation were proposed, described as (1) cross-linking of low-molecular weight colored substances to free amino groups of lysine or arginine of protein (Hofmann, 1998); (2) furan or pyrrole unit which upon polycondensation form repeating units of melanoidins (Heyns and Hauber, 1970; Tressl et al., 1998); (3) a skeleton made up from proteins cross-linked by MR reaction products (i.e. melanoproteins) (Hofmann et al., 1999). For more detailed review on the structural properties, the mechanisms of formation and biological activity of melanoidins refer to Wang et al. (2011). Additional information about the biological activity of melanoidins and melanoproteins in the gastro-

intestinal can be found in review from Tagliazucchi and Bellesia (2015). For the strategies to control the Maillard reaction in foods refer to the review of Lund and Ray (2017).

### The Chemistry of Caramelization Reaction

Caramelization is a complex process in which sugar reaction products condense and form brown no-nitrogen containing polymers. The reaction can occur under both acidic and alkaline conditions. Under acidic conditions the dehydration is promoted and yield furfural derivatives. Under alkaline conditions, isomerization and fragmentation are favored, although it can occur to some extent in weakly acidic solutions (Kroh, 1994). In aqueous alkaline medium monosaccharides undergo both reversible and irreversible transformations. The reversible reactions include (1) ionization, to give an equilibrium of neutral and ionized monosaccharides; (2) mutarotation, to give an equilibrium of the different cyclic hemiacetal structures of monosaccharides, and (3) enolization, causing the transformation of interconvertible monosaccharides. The isomerization via the enolization is accompanied by (4) irreversible transformation of the monosaccharides into carboxylic acids, generally known as the alkaline degradation reaction (De Bruin, 1986) (Fig. 3).

Alpha-dicarbonyl compounds are key intermediates which can form not only during the Maillard reaction, but also from sugar itself. Dehydration of hexose sugars produces mainly 1-deoxyglucosone, 3-deoxyglucosone, and 3,4-dideoxyglucosone, whereas oxidation of hexoses produces glucosone (Fig. 3). Fragmentation of these  $\alpha$ -dicarbonyl compounds produces shorter chain glyoxal, methylglyoxal, and diacetyl. Removal of three molecules of water from a hexose sugar forms 5-hydroxymethyl-2-furfural (De Bruin, 1986) (Fig. 3). Alpha-dicarbonyl compounds not only lead to the formation of caramel color but give rise to the important volatile products which are typical of caramel flavor (Kroh, 1994). Further reactions include intramolecular cyclization and dehydration giving rise to variety of heterocyclic compounds of furan and pyran types (Kroh, 1994). For instance hydroxymethylfurfural (HMF) (Fig. 3) contributes to desired taste, aroma and color of caramel and its amount is used as a quality indicator for certain foods (i.e. caramel products, dried fruits, coffee, honey) since it is related to the heat load applied during processing of carbohydrate-rich foods (Zappala et al., 2005). These heterocyclic compounds further undergo a series of polymerization reactions.

**Figure 3** Selected degradation mechanisms of glucose and fructose showing the formation of  $\alpha$ -dicarbonyl compounds, hydroxymethylfurfural and carboxylic acids. Adapted from Kocadağlı, T., Gökmen, V., 2016. Effect of sodium chloride on  $\alpha$ -dicarbonyl compound and 5-hydroxymethyl-2-furfural formations from glucose under caramelization conditions: a multiresponse kinetic modeling approach. J. Agric. Food Chem. 64, 6333–6342. Copyright 2016 American Chemical Society.

Browning of reducing mono- and disaccharides typically occurs more rapidly, as compared to glycosidically bound carbohydrates, since oligomers first have to be converted into more reactive, lower molecular weight intermediates (Kramhöller et al., 1993). Fructose and xylose solutions brown much more rapidly than those of maltose, glucose, lactose or sucrose (Buera et al., 1987). For instance, the initial reaction of hydrothermolysis of short-chain glucan like maltotriose generates maltose and D-glucose. Further rearrangements include the production of 1,6-anhydro- $\beta$ -D-glucose. Increase in degree of polymerization ( $>3$ ) of carbohydrates changes the kinetic of thermolysis for oligomeric glucans. If maltotriose degrades in part the same way as maltose and D-glucose, increase in polymerization degree to 4–5 residues result in degradation behavior comparable to that of polymeric glucans (Kroh et al., 1996). Kroh et al. (1996) showed that the thermolysis/hydrothermolysis of maltodextrins and soluble starch is initiated by the scission of a glycosidic linkages leading to the formation of D-glucose and 1,4-linked maltooligosaccharides, which act as reaction intermediates. These further undergo hydrothermolysis, transglycosylation, dehydration, and isomerization. As a result of these reactions non-volatile degradation products with sugar structure such as monomeric sugars (D-glucose), anhydrosaccharides, fructose containing sugars and short chain, partly branched, maltodextrins are formed. Consequently two parallel processes are taking place in the overall thermolysis, such as the simultaneous degradation of the oligo- or polymeric carbohydrate and new formation of oligomeric carbohydrate structures (Schulz et al., 2007). In some foods the caramelization and the Maillard reaction occur simultaneously and the reaction products of caramelization are at the same time starting material for the Maillard reaction resulting in a production of volatile (flavor) and non-volatile (pigments) compounds. For more details on the mechanisms of caramelization and resulting products refer to the Kroh (1994) and Kroh et al. (1996). The Maillard reaction of dextrins and starch was investigated by Kramhöller et al. (1993).

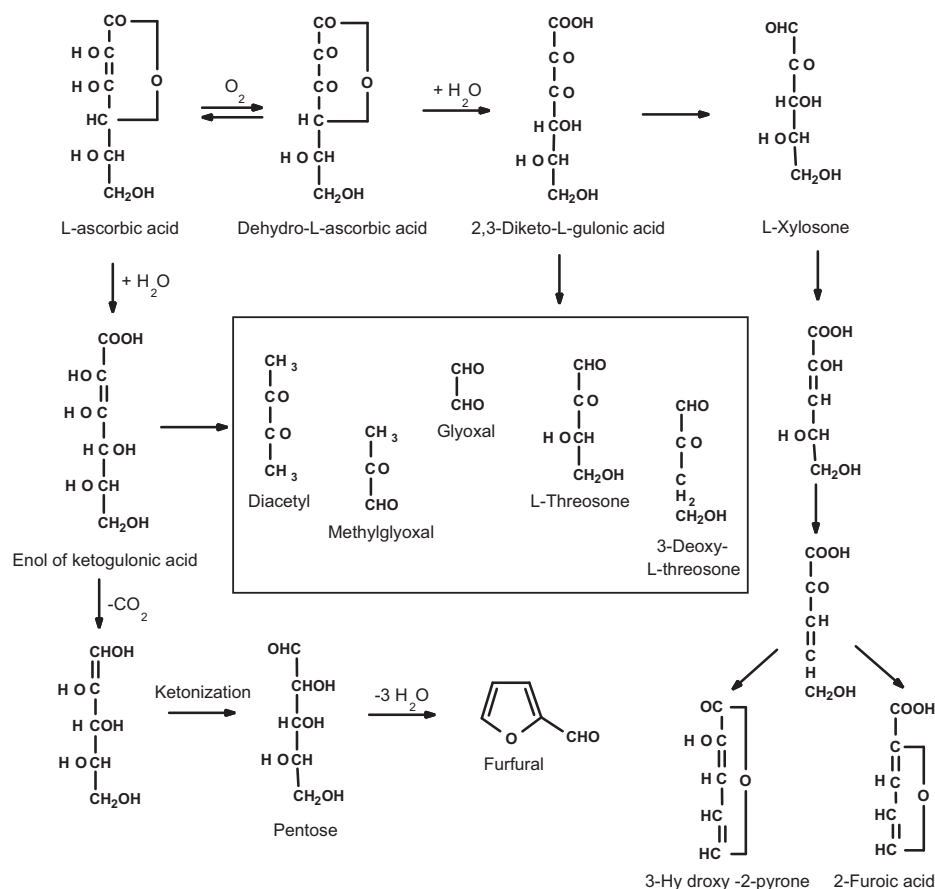

### Browning of Ascorbic Acid

L-ascorbic acid (further referred to as ascorbic acid) is a well-known natural antioxidant, so-called vitamin C, which occurs naturally in many food materials, especially citrus fruits and green vegetables. Physiologically this compound is attributed to the class of essential vitamins. Chemically, ascorbic acid belongs to the family of carbohydrates, classified as a sugar acid ( $\gamma$ -lactone) and an enediol (Schulz et al., 2007; Vernin et al., 1997). Ascorbic acid is widely utilized as food additive, cosmetic ingredient and pharmaceutical agent. Its degradation is among the common mechanisms of nonenzymatic browning during storage and processing of foods. Upon common practices in food processing, including heat, oxygen, and exposure to transition metals of ascorbic acid-containing foods, it behaves similarly to reducing sugars in the Maillard reaction (Vernin et al., 1997). Its degradation products react with amino acids, peptides, and lipids (or their degradation products) and give rise to a large number of aromatic and polymeric products via nonenzymatic browning reactions.

Several of the mechanisms of nonenzymatic browning of ascorbic acid are summarized in Fig. 4. Decomposition of ascorbic acid is rapid in an alkaline medium and is much slower at a pH less than 7 and in the absence of metal catalysts. The oxidation of ascorbic acid starts with the formation of the intermediates dehydroascorbic acid and diketogulonic acid. The latter can form L-xylosone and further degrade to various five-carbon compounds (Kimoto et al., 1993; Sawamura et al., 1994; Yuan and Chen, 1998) including 2-furoic acid and 3-hydroxy-2-pyrone. Ascorbic acid can also be readily converted into pentoses, which upon dehydration form cyclic products (i.e. furfural). Important intermediates,  $\alpha$ -dicarbonyls, are also generated in the course of the nonenzymatic browning initiated by thermal treatment of ascorbic acid, including glyoxal, methylglyoxal, diacetyl, 3-deoxy-L-pentosone, and L-threosone (Schulz et al., 2007). The carbonyl compounds resulting from decomposition of ascorbic acid can subsequently react with amines in the Maillard reaction. For more information on degradation of ascorbic acid refer to Schulz et al. (2007), Vernin et al. (1997), Kimoto et al. (1993), Sawamura et al. (1994), Yuan and Chen (1998), and Nursten (2005a).

### Interplay Between Lipid Oxidation and Nonenzymatic Browning

The role of lipids in the nonenzymatic browning reactions is their ability to be oxidized. Lipids in food can be oxidized by both enzymatic and nonenzymatic reactions, however autoxidation is the central reaction involved in the oxidative deterioration (Zamora and Hidalgo, 2005). Lipid autoxidation involves free radical mechanisms, with hydroperoxides being the initial products. Since hydroperoxides are relatively unstable, they further degrade in the second step of lipid oxidation generating volatile and nonvolatile monomers. For instance, glyoxal and methylglyoxal are formed not only during the Maillard and caramelization reactions, but also are the products of lipid peroxidation (i.e. polyunsaturated fatty acids (PUFA)) (Negre-Salvayre et al., 2008). Among the reactive carbonyl compounds, 4-hydroxynonenal (4-HNE), 4-hydroxyhexenal (4-HHE), 4-oxo-2-nonenal (ONE), malondialdehyde (MDA) and acrolein are the most characteristic products of lipid peroxidation (Fig. 5A). MDA is one of the most common aldehydes, resulting from peroxidation of arachidonic, eicosapentaenoic and docosahexaenoic acid (Esterbauer et al., 1991). MDA determination by thiobarbituric acid-reactive substances (TBARS) assay is one of the most frequent assays in lipid peroxidation studies (Uchida, 2003). These compounds can further react resulting in the generation of colored polymers by aldol condensations and/or carbonyl-amine polymerization (Zamora and Hidalgo, 2005). 4-HNE can react with histidine (His), cysteine (Cys) or lysine (Lys) residues of proteins (Fig. 5B). Upon reaction with lysine, HNE forms multiple products, including the HNE-lysine Michael adduct, pyrrole-type adduct, and fluorescent cross-linking type adduct (3-hydroxy-3-imino-1,2-dihydropyrrole) (Fig. 5C) (Uchida, 2003). MDA also reacts with Lys residues by forming Schiff bases (Esterbauer, 1993).

**Figure 4** General scheme of ascorbic acid degradation pathways. The structures and mechanisms are combined and modified from Schulz, A., Trage, C., Schwarz, H., Kroh, L.W., 2007. As mentioned in the section about [The Major Steps in the Development of the Maillard Reaction](#), CML ([Fig. 2C](#)) and CEL are AGEs formed during the Maillard reaction. However, both CML and CEL are also detected as products of lipid peroxidation, where they formed directly from glyoxal or methylglyoxal, or from other precursors, during the metal-catalyzed oxidation of PUFA in the presence of protein ([Nursten, 2005b](#)). The formation of CML and CEL, along with protein adducts of MDA and HNE during lipid peroxidation is inhibited by AGEs inhibitors (i.e. aminoguanidine and pyridoxamine) ([Brownlee et al., 1986](#); [Booth et al., 1997](#)).

Owing to the similarity of some reaction products of the Maillard, caramelization and lipid oxidation reactions it was proposed to be more suitable to use the term advanced Maillard reaction product (AMRP) to describe the broad range of products formed by carbonyl-amine chemistry during the Maillard reaction *in vivo* ([Nursten, 2005b](#)). In this scenario, AMRPs may be divided into AGEs and advanced lipoxidation end-products (ALEs), as well as into a mixed group. While the formation of AGEs may or may not require oxygen, the formation of ALEs is an oxygen-dependent process ([Nursten, 2005b](#)). To learn more on the contribution of lipid oxidation to the Maillard reaction and vice versa refer to [Zamora and Hidalgo \(2005\)](#), [Negre-Salvayre et al. \(2008\)](#), [Uchida \(2003\)](#), and [Hidalgo and Zamora \(2000, 2005\)](#).

## Role of MRP and Their Applications

Maillard reaction and its products are one of the most important during food processing and storage. As noted in the previous section due to some level of the structural similarity between the reaction products derived from the Maillard reaction, caramelization and ascorbic acid degradation collective term “Maillard reaction end products” (MRPs) can be applied. Due to the complexity of the food matrixes, major types of browning reactions can occur simultaneously resulting in a great variety of MRPs.

The role of the MRPs in food is diverse and at the same time controversial. It is well-known that Maillard reaction affects multiple qualities of food, including color, organoleptic properties and protein functionality. While it contributes to the development of pleasant aromas of baked goods, roasted meats and coffee, its advancement to the later stages yields bitter and burnt flavors and reduced protein functionality. The effect of Maillard reaction on the nutritional qualities of foods is also debatable, where some studies report the beneficial side of MRPs, while the others show the adverse effects. These conflicting findings once again confirm the versatility of MRPs and thus tremendous possibilities in food and pharmaceutical biotechnology.

## Nonenzymatic Browning in Fruits and Vegetables

MRPs have an important role in fruit/vegetable processing and cooking. They mostly contribute to flavor and aroma via nonenzymatic browning and caramelization reactions during high heat processing. Depending on cooking pattern beneficial or toxic MRP are produced. [Wellner et al. \(2011\)](#) showed that low temperature treatments during vegetable processing can induce pro-oxidant compounds, while higher temperatures induce MRP formation and thus contributes towards antioxidant property. [Billaud et al. \(2005\)](#) reported MRPs can significantly inhibit initial step of enzymatic browning caused by polyphenol oxidase and thus help to maintain food quality. This finding demonstrated protective role of MRPs against polyphenol oxidases and tyrosinases-mediated oxidative degradation of phenolic compounds produced in fruits and vegetables. Along with these properties anti-allergenic property of MRPs were also reported by [Gruber et al. \(2004\)](#). Along with beneficial properties of MRPs there are several reports ([Hofmann, 1998](#)) which demonstrate pro-oxidant and mutagenic property ([Nagao et al., 1977](#); [Gazzani et al., 1987](#); [Kim et al., 1991](#); [Kitts et al., 1993](#)) of these compounds. [Nagao et al. \(1977\)](#) discovered several heterocyclic amines which act as multi-site tumor inducer and it was further demonstrated that some of the metabolized products of these amine compound can make adduct with DNA which causes further toxicity ([Felton and Knize, 1998](#)).

## The Effect of Nonenzymatic Browning on Milk and Milk Products

Milk is required to undergo thermal treatment during production to guarantee its safety and to prolong the shelf life ([Troise et al., 2014](#)). In addition to lactose some other reducing species that could participate in the Maillard reaction can be found in milk-based products, including infant formulas or PUFA- and vitamin-enriched liquid milk ([Morales and Jiménez-Pérez, 2000](#)). For instance, other reducing sugars, vitamin C, and other low molecular weight compounds can be added or generated from other reactions (i.e. lipid oxidation, sugar molecule degradation) ([Labuza and Schmidl, 1986](#)). These compounds can react with proteins causing protein polymerization, development of brown color due to the formation of melanoidins and formation of undesired off-flavors ([Morales and Jiménez-Pérez, 2000](#)).

MRPs in milk products and their concentrations increases according to thermal treatment and water activity, where pasteurization > UHT > sterilization > milk powders ([Leclère and Birlouez-Aragon, 2001](#)). Negative flavor changes (i.e. “cooked” and bitter) in UHT milk develop during heat treatment and ambient storage are associated with the Maillard reaction and lipid oxidation ([Simon et al., 2001](#)). [Finot \(1983\)](#) discussed this issue of MRP formation during dried milk storage. Previously [Isaacs and Coulson \(1996\)](#) also reported that spray-dried whey contains significant amounts of lactose and protein thus conventional high temperature processing easily leads to MRPs formation. MRPs formation and its subsequent correlation with nutritional value of milk showed that production of lactulosyllisine significantly changes the protein bioavailability ([Evangelisti et al., 1994](#); [Pizzoferrato et al., 1998](#)). Hydroxymethylfurfural is another important MRP which can be obtained during milk processing and quantitatively this compound is assessed to determine the quality of processed milk ([Albalá-Hurtado et al., 1999](#)).

Cattle are ruminants and their digestive system is specialized for feed with large amounts of roughage. To increase the production of milk of dairy cows, modern feeding practices includes feed with a greater energy density and more nitrogen compared to its natural food sources (Schwarzenbolz et al., 2016). Hence, the addition of molasses, coarse colza, and soy, rapeseed and sugar beet are used in conventional farming with the consequence of elevated MRP levels in modern cow's nutrition (Schwarzenbolz et al., 2016; Allen, 2000). Schwarzenbolz et al. (2016) compared commercial milk originating from "organic" or "conventional" farming and reported great variations in the amounts of the individual MRPs (i.e. CML, pyrroline, MG-H, fructosyllysine), likely due the nutritional uptake of glycated proteins. For instance, significant differences in the content of free pyrroline (organic milk, 20–300 pmol mL<sup>-1</sup>; conventional milk, 400–1000 pmol mL<sup>-1</sup>) were reported. These signifies not only the effect of processing conditions (i.e. temperature of thermal treatment), but also importance of dairy animals feeding practices.

### Nonenzymatic Browning in Meat

Among the MRPs found in cooked meat, heterocyclic aromatic amines are among the most studied due to reports of increased incidences of cancer in individuals who frequently consume grilled meats, in particular well-done meats (Lang et al., 1994; Zheng et al., 2001). However, the relationship between HAA consumption and a risk of cancer is not conclusive (Barrett et al., 2003). The structures of some of the common HAAs found in cooked meats are shown in Fig. 6 (Pais et al., 1999). For a comprehensive review on the HAAs formation and risk evaluation refer to the reviews of Skog (1993) and Skog et al. (1998). Generation of HAAs in cooked meats is dependent on the type of meat, temperature and duration of cooking, resulting in high variability of HAAs concentration by more than 100-fold (Guy et al., 2000). Typically HAAs are formed at normal temperatures of cooking, however their concentration increases with higher temperatures and longer cooking time. For instance, Hatch et al. (1988), reported that meat cooked at lower than 150 °C to rare or medium-rare doneness showed lower content of HAAs compared to well-done meat cooked at higher than 150 °C.

Sinha et al. (1998) evaluated the HAAs content of different pork products and reported that HAA type and level varied substantially by product type (pork chops, ham slices, bacon, hot dogs, sausages or patties), cooking method (pan-frying, oven-broiling, grilling/barbecue or boiling) and degree of doneness/surface browning (just until done, well done or very well done). Puangsombat et al. (2011) ranked ready-to-eat (RTE) meat products in the following order of increasing total HAAs content: pepperoni < hot dogs and deli meat products < fully cooked bacon < rotisserie chicken meat < rotisserie chicken skin. They suggested that consumption of RTE meat products contributes very little to HAA intake.

### Bioactivities of the Maillard Reaction Products

MRPs have different bioactivities which can be used in food and pharmaceutical industries. Antioxidant properties of MRPs were first reported as early as in 1950s (Franzke and Iwainsky, 1954). Later studies reported comparable activity between well-known synthetic antioxidants butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) and xylose-glucose derived MRPs. Casein-glucose heated mixtures produced MRPs reported to increase the shelf life of full-cream products (McGookin and Augustin, 1997) and decrease the oxidation of deoxyribose in a Fenton reaction system (Jing and Kitts, 2002). Though, the mechanism of antioxidant action depends on the type of MRPs, midstage or late stages, it can be generalized to the following abilities (1) strong

**Figure 6** Structure formulas of representative heterocyclic aromatic amines formed in cooked meats: 2-amino-3-methylimidazo[4,5-f]quinoline (IQ), 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline (MeIQx), 2-amino-3,4,8-trimethylimidazo[4,5-f]quinoxaline (4,8-DiMeIQx), 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) and 3-amino-1,4-dimethyl-5H-pyrido[4,3-b]indole (Trp-P-1). The structures are adapted from Pais, P., Salmon, C.P., Knize, M.G., Felton, J.S., 1999. Formation of mutagenic/carcinogenic heterocyclic amines in dry-heated model systems, meats, and meat drippings. *J. Agric. Food Chem.* 47, 1098–1108. Copyright 1999 American Chemical Society.

reducing power (2) ability to scavenge free radicals and reactive oxygen species (ROS) (Yoshimura et al., 1997), (3) capacity to chelate potential metal prooxidants (Dittrich et al., 2003) and (4) the ability to inhibit hexanal oxidation and lipid peroxidation reaction (Chawla et al., 2007). In contrast, there are studies which found the prooxidant and genotoxic activities of MRPs in the presence of iron and copper (Wijewickreme and Kitts, 1997; Deguine et al., 1998). More on toxicology antioxidant activities of MRPs can be found in the review of Lee and Shibamoto (2002).

Beside antioxidant powers MRPs also possess antimicrobial properties (Hiramoto et al., 2004; Rufián-Henares and Morales, 2007). Some early stage MRPs (i.e. aminoreductones) are recognized for their antimicrobial potential (Knerr et al., 2001; Pischetsrieder et al., 1998; Trang et al., 2013). Trang et al. (2009) and Trang et al. (2011) demonstrated that aminoreductones significantly inhibit the growth of different *Helicobacter pylori* and *Staphylococcus aureus* species. Gobbo et al. (2002) demonstrated addition of sugar to a peptide can strongly influence their antimicrobial activity. Hrynets et al. (2016) and Bhattacharjee et al. (2016) demonstrated the antimicrobial activity of fructosazine, glucosamine (Heyns compound) self-condensation product, and glucosamine-derived  $\alpha$ -dicarbonyls against a heat resistant strain of *Escherichia coli*. To contribute significantly towards human health MRPs need to be bioavailable. There are a few studies that have demonstrated fructose and lysine-derived MRPs have poor bioavailability (Erbersdobler et al., 1981; Hellwig et al., 2011; Grunwald et al., 2006). However Hellwig et al. (2009) also demonstrated peptide-bound MRP (pyrraline) can be transported across a human intestinal cell line. The uptake of advanced glycation end-products (AGEs) like alanylpyrraline and pyrralylalanine were also reported by the human proton-coupled peptide transporter hPEPT1 (Geissler et al., 2010). These studies indicate that the transport of MRPs widely varies depending on their structure, however it is still not clear how these MRPs can pass across the intestinal cell barrier. Feng and Betti (2017) reported that chemically synthesized glycopeptides can pass across the Caco-2 cell membrane by using peptide transporter PEPT-1 and glucose transporters (GLUT). This study was further supported by Bhattacharjee et al. (2017), where the role of hexose transporters in transport of fructosazine across human intestinal cell line was shown. Further studies are required to access the MRP transport across human cell line to measure bioavailability and establish their merit and relevance to human health.

# Pulsed Electric Fields Processing of Plant-Based Foods: An Overview

Sze Ying Leong<sup>a,b</sup> and Indrawati Oey<sup>a</sup>, <sup>a</sup> Department of Food Science, University of Otago, Dunedin, New Zealand; and <sup>b</sup> Riddet Institute, Palmerston North, New Zealand

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Pulsed Electric Fields (PEF) processing involves the application of short electric pulses (typically in the range of micro-to milliseconds) of high voltage across a food product placed between two conducting electrodes. As a consequence, the integrity of cell structure could be disrupted leading to cell leakage (Fincan and Dejmek, 2002). PEF applications are based on the “cell electroporation” principle (Weaver and Chizmadzhev, 1996) that induce local structural changes and breakdown of the cellular membranes (Zimmermann et al., 1974). The process of electroporation in a biological cell takes place in 4 consecutive steps: (i) formation of a transmembrane potential across the cytoplasmic membrane to destabilise the lipid bilayer and proteins of the membrane, (ii) formation of small metastable hydrophilic pores at the membrane when the transmembrane potential has built up, (iii) increment in size and number of pores, and (iv) post-treatment stage involving the formation of reversible pores (transient pores in which pore shrinkage and disappearance is taking place) or irreversible pores (permanent pores in which leakage of intracellular compounds occurs) after the applied electric field strength is removed. Depending on the level of electric field strength applied, reversible electroporation is commonly used for biotechnological applications for stress induction (Ye et al., 2004) or gene electrotransfer (Guo et al., 2014), whereas killing microorganisms (Castro et al., 1993) and mass transfer improvement (Donsì et al., 2010b) require irreversible electroporation.

In general, the required PEF processing parameters to perform specific food applications or to obtain desired quality improvement in the final product can be typically classified into low intensity ( $E < 2$  kV/cm) and high intensity ( $E > 15$  kV/cm) electric field strengths (Soliva-Fortuny et al., 2009). High intensity PEF processing ( $E > 15$  kV/cm) can be very effective for microorganism inactivation in liquid foods, leading to production of safe and stable food products (Jermann et al., 2015). On the other hand, low intensity PEF processing ( $E < 2$  kV/cm) would be sufficient to cause structural changes in the cell membrane of plant tissues, leading to improvement in mass transfer process, extractability of valuable phytochemicals, texture modification and to increase the efficiency of many existing food processes (Oey et al., 2016).

The aim of the present work is to provide introductory knowledge on the different technological applications that PEF can potentially offer to improve the process efficiency and the final quality of plant-based foods. The critical processing parameters of PEF recommended in the literature to achieve certain technological applications are summarised and specific examples of PEF-assisted processing of plant tissues from selected technological applications are discussed.

## Critical Processing Parameters of PEF to Achieve Cell Electroporation Effects on Plant Tissues

Plant tissues are highly heterogeneous matrices, which is a challenge to deliver evenly high voltage with very short electric pulses to affect the targeted plant tissue. The effectiveness of PEF processing to achieve cell electroporation varies depending on the processing parameters applied as well as the physical characteristics of plant materials (e.g. electrical conductivity and resistivity, particle size, size and type of cells, chemical composition, pH, temperature, etc.) placed between the conducting electrodes (Barsotti and Cheftel, 1999). Key processing parameters of PEF to achieve specific food applications or to obtain desired quality improvement in the final product include electric field strength ( $E$ ), specific energy input ( $W$ ), pulse duration or pulse width ( $\tau$ ), number of pulses ( $N$ ), treatment time ( $t$ ), pulse repetition rate or pulse frequency ( $f$ ), and pulse shape or pulse polarity (Barsotti et al., 1999). Many of these processing parameters are interdependent; for example, the specific energy input varies according to the applied electric field strength or the treatment time, whereas the effective treatment time depends on the pulse width and the number of pulses.

### Electric Field Strength ( $E$ )

Electric field strength is the most critical processing parameter of PEF processing affecting the degree of cell membrane electroporation. The intensity of electric field strength (units in kV/cm) is determined by the amount of voltage discharged (in kV) into the chamber and the distance (in cm) between the two electrodes, where the plant tissue is placed. Other factors including the electrode configuration (parallel, collinear, coaxial, etc.), treatment chamber design and presence of gas bubbles in the plant material would affect the homogenous distribution of electric field strength inside the treatment chamber (Puértolas et al., 2012).

When plant tissue is exposed to an external electric field strength, its transmembrane potential increases because of the charging process at the cell membrane by PEF. Application of a low electric field strength ( $E < 0.2$  kV/cm) with short pulse width ( $\tau < 10$   $\mu$ s) is usually below the critical value ( $E_c$ ) of the transmembrane potential difference of plant cell. Thus, transient or reversible pore formation occurs spontaneously and the cell membrane reseals when the external field strength is removed (Weaver and Chizmadzhev, 1996). However, electric field strengths applied between 0.5 and 2 kV/cm are generally effective to rupture permanently the cell membrane of plant tissue through establishment of high transmembrane potential difference, in which the induced membrane potential exceeds the critical value (Weaver and Chizmadzhev, 1996). Once the electric field strength applied is beyond the critical

**Table 1** Summary of critical electric field strengths for different plant tissues

Plant tissue	Critical electric field strength (kV/cm)	Other PEF processing parameters involved	References

Abbreviation for PEF processing parameters:  $N$ , pulse number;  $t$ , treatment time (ms);  $P$ , pulse shape (exponential decay or square waveform) and polarity (mono- or bi-polar);  $f$ , pulse frequency (Hz);  $\tau$ , pulse width ( $\mu\text{s}$ );  $W$ , specific energy input (kJ/kg); batch or continuous mode PEF treatment. n.d., no data available.

value of cell ( $E \gg E_c$ ), permanent pores formed at cell membrane and plant tissues lose their cell permeability. **Table 1** summarises the optimum range of critical electric field strengths necessary to initiate drastic membrane rupture for different plant tissues with variation in physical and biological characteristics. Application of electric field strength between 0.4 and 0.8 kV/cm has been recommended to cause a significant cell electroporation for plant cells with size averaged between 50 and 120  $\mu\text{m}$  (Angersbach et al., 2000).

### Pulse Frequency ( $f$ )

Pulse frequency is defined as the number of pulses discharged per second (units in Hz) (Puértolas et al., 2012). The effectiveness of PEF to induce a greater cell electroporation effect on plant tissue is highly influenced by the pulse frequency. It has been demonstrated that apple tissue treated with low pulse frequencies between 0.02 and 100 Hz resulted in more tissue damage, while increasing the pulse frequency beyond 100 Hz would not lead to a higher cell membrane electroporation (Lebovka et al., 2001). Likewise, Asavasanti et al. (2011) reported that lower pulse frequencies ( $f < 1$  Hz) caused more damage to the integrity of onion tissue than higher pulse frequencies ( $f = 1$  to 5000 Hz). It appeared that high pulse frequency permits only a very short pause between two consecutive pulses, which has prevented the cell membrane to return to the pre-pulse state. Consequently, the cell membrane showed less resistance towards the electric pulses and exerted no remarkable cell electroporation effect. Overall, the application of low pulse frequency between 0.5 and 10 Hz would be sufficient to cause cell electroporation in plant tissue. However, increasing the pulse frequency is preferable to achieve higher enzyme inactivation (Terefe et al., 2013).

### Pulse Shape and Polarity

Pulse shape influences the way voltage is introduced across the food placed within two conducting electrodes. Exponential decay and square waveform are the most commonly applied pulse shapes for PEF processing, with square waveform considered as an ideal pulse shape because intensity of the applied electric field strength will remain constant during the predefined pulse duration/width. Additionally, square waveform could reduce the absorption energy by the treated plant material, which will be eventually transformed into heat (Knorr et al., 1994). Exponential decay pulses are less effective for cell electroporation because the applied voltage may diminish exponentially, or decrease at least 37% of the peak value, after reaching the peak pulse voltage.

Pulses can be modulated in different polarities, namely unipolar (retains positive charge and involves no reversal of polarity in the electric field) and bipolar (instant reversal of charges which rapidly reverse the electric field orientation) pulses. Compared to unipolar pulses, plant tissues exposed to bipolar pulses are expected to experience a greater structural fatigue at the cell membrane and became more susceptible towards cell membrane breakdown under PEF exposure. Moreover, bipolar pulses have been found to be more effective to result in a higher level of enzyme activity reduction (Terefe et al., 2013) and microbial inactivation (Evrendilek and Zhang, 2005).

### Pulse Width ( $\tau$ ) and Treatment Time

Pulse width (or pulse duration) is the amount of time a pulse is held at an effective voltage. Pulse duration is determined depending on pulse shape applied. For square waveform, effective pulse width is measured at 50% of peak voltage since an ideal/perfect square pulse shape is hardly achieved. For exponential decay pulses, the effective pulse width is defined as the time until the electric field decreases to 37% of peak voltage (Reberšek, 2017).

Treatment time of PEF is defined as a function of the pulse width ( $\tau$ ) and the number of pulses ( $N$ ) applied. This indicates that a longer effective treatment time of PEF at which the plant cells are exposed to the applied electric field strength can be achieved by increasing the pulse width. The work of De Vito et al. (2008) has reported that the efficiency of apple tissue electroporation by PEF improved with increasing pulse width. The reason for this could be due to the long pulse width that allows longer membrane charging time. As plant cells are generally larger in size (10–200  $\mu\text{m}$ ) compared to microbial cells (1–10  $\mu\text{m}$ ), it is expected that effective cell membrane electroporation and leakage of cell contents from plant tissue induced by PEF requires more time to charge up the membrane, leading to dramatic cellular damage.

### Specific Energy Input ( $W$ )

Specific energy input is an integrated processing parameter of PEF that takes into account the voltage applied, treatment time and resistance of the treatment chamber (Heinz et al., 2001). The resistance parameter depends on the cross-sectional area of the treatment chamber as well as the electrical properties (or conductivity) of plant material to be treated. Electrical properties of plant tissue can affect the ability of electrical current to pass through it. Calculation of specific energy input is important to allow a comparison on the treatment efficiency of PEF with other technologies and provides an estimation on the energy consumption and processing cost. This would be valuable information for the food industry when deciding for the implementation of PEF processing at a commercial level.

## Technological Applications of PEF for the Production of Plant-Based Foods

### Improvement in Juice Extraction and Clarification

It is always a challenge to the juice and beverage industries in finding effective methods to enhance the rate of mass transfer that can ease the release of natural intracellular liquid, i.e. juice contained in fruit and vegetable matrix, without compromising their inherent organoleptic attributes. Being a gentle cell membrane rupturing technique, PEF pre-treatment applied at moderate field strengths between 0.4 and 3 kV/cm has been shown to improve the juice yield (increase at least 2.5% to 45%) from various fruit and vegetables (e.g. apple, carrot, sugar beet, potato, fennel, pepper, alfalfa, and chicory) (Donsì et al., 2010b). Therefore, PEF has been proposed as an alternative to conventional enzyme-assisted and thermal-assisted juice extraction. For better juice extraction, this technology can also be applied either as a pre-treatment before juice pressing or intermediate treatment during juice pressing (Praporscić et al., 2007). A study by Grimi et al. (2009) has shown that the application of PEF treatment on grapes, at an electric field strength of 0.4 kV/cm for 10 square-wave bipolar pulses, during pressing (pressure increased from 0 to 1 bar for 60 min) can lead to at least 8% increase in juice yield. It is clear that PEF can assist the pressing process of plant material and provides a more efficient mass transfer phenomenon that considerably accelerates the juice extraction kinetics. The reason behind a higher juice yield is due to the increased permeability of the cellular membrane after PEF processing.

Apart from gaining a higher juice yield, juice extracted from PEF-treated plant tissue has been demonstrated to possess better qualitative characteristics, such as higher purity, less turbidity, and can be more easily purified (Loginov et al., 2011; Mhemdi et al., 2012). The increase in juice clarity and purity after a PEF treatment application is most likely because of the selective permeability of cell membranes by PEF. Therefore, lesser amounts of high molecular weight impurity compounds (proteins, pectin and colloids) can be detected in the extracted juice after PEF, which prevents the sedimentation of suspended particles and cloudiness in juice over storage time.

### Improvement in the Extraction of Phytochemicals

Nutritious phytochemicals such as anthocyanins, carotenoids and vitamin C are either bound to cell walls or enclosed inside the vacuole and other organelles of plant cells. Therefore, the degradation of the semi-permeable cell membrane is a fundamental step to reduce the resistance to mass transfer processes and promote the release or the extraction of phytochemicals from their localisation in the plant cell. PEF technology increases the cell permeability of plant tissue that leads to mass transfer enhancement of cell contents or phytochemical compounds from semi-solid plant-based foods. With the aim of enhancing mass transfer by electroporation, extraction of nutritious phytochemicals can be achieved at moderate electric field strengths of 0.5 to 5 kV/cm and treatment times in the range of 0.1 and 10 ms (Vorobiev and Lebovka, 2006).

#### Anthocyanins

Anthocyanins are water-soluble red pigments located in the cell vacuoles of plant cells, and hence they are extracted easily under the influence of PEF. The effect of PEF treatment ( $E = 2.5$  kV/cm,  $W = 16$  kJ/kg,  $\tau = 15$   $\mu\text{s}$ ,  $f = 1$  Hz and  $N = 50$  exponential decay

pulses) on red cabbage mash has been shown to extract at least 2.15-fold greater amount of total anthocyanins (Gachovska et al., 2010). On the other hand, PEF applied at an electric field strength of 13.3 kV/cm was able to release a 6-fold higher amount of total anthocyanin from blackberry fruits (Barba et al., 2015). It is clear that once the electric field strength applied to plant tissue is sufficient to create electroporation at the cell membranes, this occurrence favours mass transfer process allowing more anthocyanins to release immediately after PEF. While mass transfer is a time-dependent process, it should be expected that the release of anthocyanins from PEF-treated plant material would increase progressively after PEF. The release of anthocyanins in red raspberry fruit was found to reach its maximum level (more than 50% from untreated fruits) within 3 h after PEF treatment ( $E = 3$  kV/cm,  $\tau = 0.5$ – $1.5$   $\mu$ s,  $f = 1$  Hz and  $N = 420$  exponential decay pulses) (Luo et al., 2008). Similarly, PEF-treated cherries were also found to release a substantial amount of cyanidin-glucoside within 24 h after PEF ( $E = 2.5$  kV/cm,  $\tau = 20$   $\mu$ s,  $f = 100$  Hz and  $W = 45$  kJ/kg) (Sotelo et al., 2018).

### Carotenoids

Carotenoids are hydrophobic and lipophilic plant molecules due to their long unsaturated aliphatic chains. Moreover, the physical state and localisation of carotenoids in plants have limited their extractability. Despite this, PEF applied at low electric field strength ( $E < 2$  kV/cm) has been found adequate in inducing a cell electroporation effect that fosters an increase in the extractability of carotenoids from the carrot matrix (Roohinejad et al., 2014) and even helps to improve the carotenoids extractable yield from yellow coloured carrot cultivar with low initial amount of carotenoids (Leong et al., 2016c). Another study on tomato demonstrated that PEF treatment ( $E = 1.2$  kV/cm,  $\tau = 4$   $\mu$ s,  $f = 0.1$  Hz and  $N = 5$  monopolar square wave pulses) on intact tomato fruits can lead to substantial increase in the relative lycopene content (+32%) and total carotenoid content (+38%) (Vallverdú-Queralt et al., 2013). The PEF-treated tomato fruits were also found to contain higher concentrations of *trans*-lycopene (27%),  $\beta$ -carotene (28%), 15-*cis*-lycopene (33%), 9-*cis*  $\beta$ -carotene (44%),  $\alpha$ -carotene (93%), 9-*cis*-lycopene (94%), and 13-*cis*-lycopene (140%).

### Vitamin C

There is a huge interest in using PEF technology to improve the retention of vitamin C in plant-based foods since vitamin C is known to be the most heat-labile vitamin. Studies on oranges (Elez-Martínez and Martín-Belloso, 2007), tomatoes (Odrizola-Serrano et al., 2007), and watermelon (Oms-Oliu et al., 2009) have shown that PEF, applied at high electric field strengths ( $E = 25$ – $40$  kV/cm) with the aim to assure microbial inactivation for safe consumption, can minimise vitamin C degradation of up to 90% retention of the initial content. The effect of PEF, applied at a milder PEF processing condition (by lowering the electric field strength, the treatment time, the pulse frequency or the pulse width), on the vitamin C content of plant tissues whilst facilitating the mass transfer of other important phytochemicals (e.g. anthocyanins and carotenoids) has also been studied. Red bell peppers exposed to PEF ( $E = 2$  kV/cm,  $W = 0.32$  kJ/kg,  $\tau = 400$   $\mu$ s and  $N = 50$  exponential decay wave pulses) were found to experience minimal loss of vitamin C (<10%) (Ade-Omowaye et al., 2003). Likewise, the vitamin C content was better preserved in extracts obtained from fennel slices treated by PEF ( $E = 0.4$  kV/cm and  $N = 450$  monopolar square wave pulses) (El-Belghiti et al., 2008). One plausible explanation for the better retention of vitamin C content in PEF-treated plant foods is the inactivation of vitamin C degrading enzyme namely ascorbic acid oxidase (AAO). Recent work showed that AAO extracted from carrots was rather susceptible to PEF treatment (Leong et al., 2015).

### Raw Material Pre-treatment to Improve Existing Processing Lines

Plant tissues exposed to PEF can lead to disintegration of cellular tissues through electroporation that physically changes the membrane components and structural properties of the tissue. Consequently, PEF can be implemented as a pre-treatment or processing aid to help transforming plant tissue to a state that suits the subsequent processing unit operations. Examples of PEF application as raw material pre-treatment to improve existing potato frying, production of dried, canned and frozen products and the winemaking process will be discussed.

#### Potato Frying

Potato tubers are one of the produce types with a very firm texture and hence they require considerable mechanical force or energy to cut them for further processing. PEF technology induces electroporation leading to increased cell membrane permeability, which also affects tissue structure in a way that softens the potato tissues, resulting in better cutting quality and accuracy (Ignat et al., 2015). Such changes in the potato texture is promising for French fries or potato chips/crisps production to solve product quality issues due to cutting. The improved cutting behaviour offered by PEF-treated potatoes is expected to produce a smoother cut surface, reduce surface feathering, minimise breakage/fracture during cutting, and produce longer fries (Botero-Urbe et al., 2017).

Production of deep-fried potato products (French fries or chips) comprises a series of sequential processes, namely washing and sorting, steam peeling, cutting, blanching, pre-drying, par-frying and freezing (exclusive for French fries making), and frying (Botero-Urbe et al., 2017). While PEF treatment is recommended to apply on potatoes before cutting to produce softer potato that is much easier to cut, changes in the tuber structure by PEF can have implications on how the subsequent unit operations in the production of French fries or potato chips affect the final quality of the fried potato products. Evidences of process and final quality improvements for fried potato products as result of structural modifications by a PEF pre-treatment are summarised as follows:

- PEF-treated potatoes ( $E = 0.75$  kV/cm,  $W = 18.9$  kJ/kg,  $\tau = 20$   $\mu$ s,  $f = 250$  Hz,  $N = 9000$  bipolar square wave pulses) contained lesser amount of fat after frying ( $190^\circ\text{C}$ ) since a smooth and even cut surface after PEF can contribute towards decreased oil uptake during frying and allow better oil drainage after frying (Ignat et al., 2015). The probable reason is that PEF treated potato cells might experience increased cell liquid (or water) diffusion towards the potato surface, which result in a higher vapour pressure difference between surface water and oil and hence formation of thicker water vapour layer may act as a barrier against the oil that prevents oil uptake during frying.
- Electroporated potato cells ( $E = 1.5$ – $2.5$  kV/cm,  $f = 2$  Hz and  $N = 20$  exponential decay pulses) were found to release more intracellular compounds such as reducing sugars and low-molecular substrates involved in the Maillard reaction and hence reduce the tendency of fried potatoes to brown due to acrylamide formation (Janositz et al., 2011).
- Higher release of cell liquid (e.g. free water) from PEF-treated potatoes ( $E = 1.5$ – $2.5$  kV/cm,  $f = 2$  Hz and  $N = 20$  exponential decay pulses) has been reported (Janositz et al., 2011), which increases the dry matter of potato and absorbs less oil during frying, hence producing low-fat French fries or potato chips with mealy texture.

Indeed, there is strong evidence highlighting the practical use of PEF in the potato industry for reducing cutting forces, increasing mass transfer during frying, lowering oil uptake and hence providing consumers with a healthier option (i.e. less oil or low-fat) of potato chips and French fries. Such technological advances achieved in the potato industry through PEF technology should be considered for other underutilised crops such as sweet potato, taro, parsnip, cassava, carrot and beetroot to enable value adding and creating more product variation (e.g. vege chips/fries).

### Drying of Fruits and Vegetables

Drying of fruits and vegetables at high temperatures, for a long time, with constant exposure to oxygen can cause oxidative degradation and heat damage of many nutrients (Sablani, 2006). However, these degradations can be reduced by pre-treating the plant tissues with PEF, leading to formation of permanent “micro-holes/channels” in cell membranes and increasing cell permeability (Ade-Omowaye et al., 2001). Consequently, electroporated cell membranes exert a lower resistance to mass transfer. When mass transfer rates are enhanced after PEF, free water over a large surface area in the electroporated plant tissue can be released or be evaporated quickly; thus increasing the drying rate and reducing the overall drying time needed (a least 20% shorter duration depending on the fruit types) while achieving better retention of nutrients.

Although osmotic dehydration (OD) has been a popular technique to prevent oxygen penetrating into the tissues during drying that could affect the food quality negatively, OD is still considered a very slow drying process (Torreggiani and Bertolo, 2001). Interestingly, a PEF pre-treatment ( $E = 2$  kV/cm and  $\tau = 400$   $\mu$ s) of red bell peppers was found to be effective in enhancing the efficiency of the subsequent OD process by promoting a faster rate of water loss and minimal loss of vitamin C (reduced from 24% to 11%) during convective air drying (Ade-Omowaye et al., 2003). The cell electroporation effect of PEF ( $E = 1.8$  kV/cm,  $\tau = 15$   $\mu$ s,  $f = 300$  Hz,  $W = 42.3$  kJ/kg and  $N = 250$  pulses) has also been reported to effectively facilitate the infusion of hypertonic sugar or salt solutions of high osmotic pressure/low water activity and consequently speed up the osmotic dehydration process of kiwifruit slices (Dermesonlouoglou et al., 2016). Overall, there is strong evidence supporting the potential use of PEF as a pre-treatment to facilitate enhanced water loss during drying.

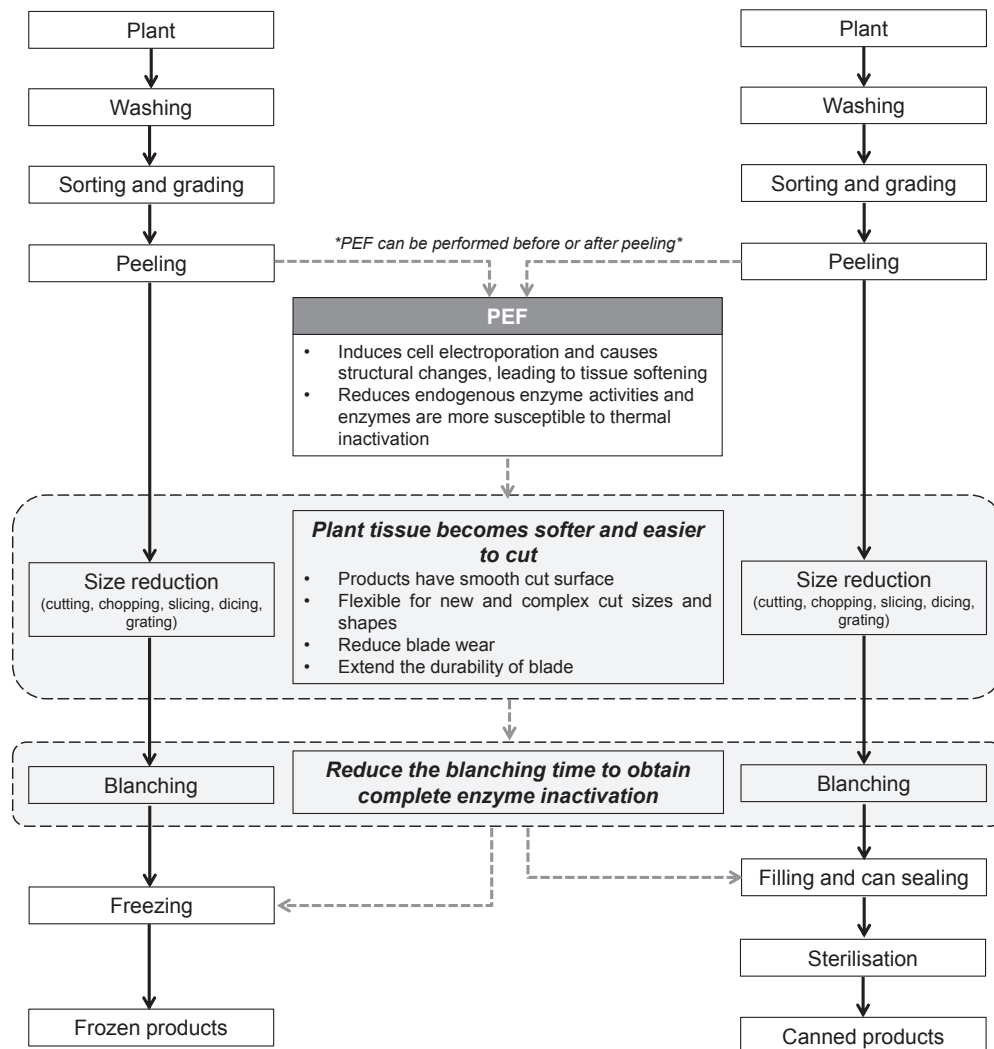

### Production of Canned and Frozen Fruit and Vegetable Products

Fruit and vegetables are highly perishable after harvest and can undergo a progressive loss of quality and nutrients deterioration. Most fruits and vegetables can be processed or preserved, in which the processing techniques involved have the ability to inactivate enzymes causing undesirable quality-related changes and to eliminate microorganisms and pathogens causing spoilage. Fresh produces are often pre-blanching (heating at high temperature for short time) to inactivate undesirable quality-related enzymes before they are cut (or diced, sliced, shredded, grated, etc.) and processed into canned or frozen products. Blanching however may have negative implications on the final products including unwanted changes in colour, excessive texture softening, flavour loss and degradation of heat-sensitive nutrients. PEF processing on plant tissues is very effective in reducing the activity of undesirable quality-related enzymes such as ascorbic acid oxidase (AAO) and peroxidase, without negatively affecting the temperature sensitive components (Leong et al., 2014). A recent investigation by Leong et al. (2015) also showed a major advantage of PEF as an upstream treatment in better controlling the sensitivity of vitamin C degrading enzyme (i.e. AAO) of carrots towards thermal inactivation and hence increase the overall process efficiency. While the initial thermal stability of AAO varied greatly between different carrot cultivars, the application of PEF at similar intensity ( $E = 0.8$  kV/cm,  $W = 35$  kJ/kg,  $\tau = 20$   $\mu$ s and square wave pulses) can reduce such variability and consequently narrow the window of heat processing temperature and time combinations to achieve the same degree of AAO inactivation after PEF. Such findings could benefit fruit and vegetable processing plants adopting multiple streams of fruit and/or vegetable with variable enzyme activities, as PEF appeared to make endogenous enzymes, from a range of raw materials, to respond similarly during the subsequent thermal inactivation treatments and hence more temperature sensitive for inactivation (Leong et al., 2015). It is then recommended that the intensity (temperature–time combination) of blanching to achieve complete enzyme inactivation could be reduced for plant tissues that have been pre-treated with PEF.

Apart from minimising the heat load required for complete enzyme inactivation during blanching, the cell electroporation effect of PEF can induce a certain degree of structural and textural changes of the plant tissues. This would benefit the subsequent size reduction unit operation by producing smaller sizes of fruits and vegetables with significantly reduced mechanical or cutting force

and improved cost-efficiency. Previous studies showed that the hardness of produce with high cellular integrity such as apple (Lebovka et al., 2004), carrot (Leong et al., 2014) and sugar beet (Mhemdi et al., 2013) reduced after PEF. The tissue softening was particularly prominent when combined with mild temperature conditioning (preheating between 20 and 60 °C) prior to or during PEF treatment. Moreover, the study of Leong et al. (2014) showed that PEF-treated carrots have improved smoothness at the cutting surface and a better cutting accuracy. Therefore, a PEF pre-treatment on plant could be an optimal solution to reduce blade wear and increase cutting knife durability since the electroporated plant tissues are softer and flexible and hence provide lesser resistance towards the cutting action. PEF could also offer possibilities in using industrial cutting knives and blades for fruit and vegetable processing with complex edges such as zigzag blade and figured blade (circular, straight, curved, convex, toothed or scalloped) in order to achieve final products with variation in sizes and shapes.

Overall, PEF processing is evidenced to be effective for enzyme inactivation as well as improvement in tissue softening for reduced cutting force and better cutting accuracy. Therefore, PEF can be easily implemented in the canned and frozen fruit and vegetable industries without any major modification of the existing processing line (Fig. 1). Within canned products processing line, PEF treatment can be applied to reduce the heat load required to inactivate enzymes during the sequential blanching process before performing aseptic can filling unit operation. For frozen products processing line, PEF treatment can be combined with mild temperature conditioning to shorten the subsequent blanching time for enzyme inactivation and will require a smaller mechanical force for size reduction. Another interesting feature of PEF for cell electroporation that has yet to be exploited in the freezing operation is to facilitate the infusion of a cryoprotectant such as trehalose across the electroporated cell membranes ( $E = 0.58 \text{ kV/cm}$ ,  $\tau = 25 \text{ }\mu\text{s}$  and square wave pulses) to improve the freezing tolerance of spinach leaves (Phoon et al., 2008).

**Figure 1** Simplified flowchart for the possible integration of PEF treatment in the production of canned and frozen fruit and vegetable products. Authors own elaboration.

### Red Winemaking

One of the essential prerequisites for red winemaking is to allow extraction or release of adequate anthocyanins and phenolics from grape skin cells. Strategies such as extending maceration duration, increasing maceration temperature (thermo-vinification) and addition of pectinolytic enzymes are common practice in wineries (Sacchi et al., 2005). However, extending the maceration duration and increasing the maceration temperature will add processing cost and also it is limited by the capacity and availability of maceration-fermentation tanks especially when they need to handle large volumes of grapes within a short harvest time. Therefore, a gentle extraction technique on grape mash that has the capability to reduce the maceration duration and does not require a high maceration temperature whilst extracting a greater amount of anthocyanins and phenolics is desired. In this context, PEF technology is used as a novel low-energy consumption extraction technique to reach these objectives.

It is recommended to process the grapes immediately after harvest. The grapes are destemmed to produce grape must/mash (consisting of seeds, skins and pulps) before the initiation of maceration-fermentation step. Previous study has reported that PEF-assisted extraction ( $E = 4\text{--}5\text{ kV/cm}$ ) of Cabernet Sauvignon grape mashes accelerated the release of anthocyanins, thus reducing the overall maceration duration (from 144 h to 96 h,  $25^\circ\text{C}$ ) and the finished red wines contained a higher anthocyanin content as compared to the control wines produced from grapes that were macerated for a longer time (Puértolas et al., 2010). Moreover, a PEF pre-treatment ( $E = 1.5\text{ kV/cm}$ ,  $W = 70\text{ kJ/kg}$ ,  $\tau = 20\text{ }\mu\text{s}$ ,  $f = 50\text{ Hz}$  and square wave pulses) on Merlot and Pinot Noir grapes prior to maceration has also shown that the overall maceration duration can be reduced to 4 and 8 days (vs. 14 days with control) respectively to achieve similar level of anthocyanins content and colour characteristics (Leong et al., 2016a, 2016b).

While winemakers have used pectinolytic enzymes to degrade the cell wall material in order to enhance the release of polyphenols and anthocyanins from the skin cells, the use of PEF for red winemaking can solve the problems arising from the use of pectinolytic enzymes, such as incorrect enzyme types, dosage, hydrolysis time, and temperature that can have consequences on the quality of the final wines. The cell electroporation effect of PEF treatment ( $E = 1.5\text{ kV/cm}$ ,  $f = 1\text{ Hz}$ ,  $W = 25\text{ kJ/kg}$ ,  $\tau = 10\text{ }\mu\text{s}$  and  $N = 2500$  square wave pulses) to Aglianico grapes before maceration was more effective in anthocyanins extraction than the addition of pectinolytic enzymes, in which the total anthocyanin content of the finished wine from PEF-treated grapes was higher than enzymatically-treated grapes by at least 20% (Donsi, Ferrari, Fruilo and Pataro, 2010a). Likewise, Puértolas et al. (2009) showed that the finished wine of Cabernet Sauvignon grapes pre-treated with PEF ( $E = 5\text{ kV/cm}$ ,  $W = 2.1\text{ kJ/kg}$ ,  $f = 1\text{ Hz}$  and  $N = 50$  exponential decay wave pulses) contained higher content of anthocyanins (+12%) and better colour characteristics when compared to the wine produced from enzymatically-treated grapes.

It is clear that PEF can facilitate more anthocyanin release from grape mash during maceration and this enhancement effect has been reported to be maintained during fermentation and after a certain period of ageing. The anthocyanin composition of wines was found to be qualitatively similar but quantitatively higher to the control wines after aging for the similar period of time (Delsart et al., 2014; López et al., 2009). Findings from previous studies have successfully pinpointed the potential implementation of this non-thermal technology in the commercial winery settings. However, before implementing this technology to the wineries, it is important to note that grape variety remains a significant factor in determining the effectiveness of the applied PEF processing parameters to improve the extraction of anthocyanins and phenolic compounds since differences in the grape skin structure (i.e. cell thickness, cell wall material composition) can limit their susceptibility towards the cell electroporation of PEF.

### Food Preservation, Safety and Shelf-Life Extension

Apart from inducing the formation of permanent holes at the cell membrane that cause leakage of cell contents from plant tissues, PEF is able to convey the same cell electroporation impact on microorganisms. Consequently, microorganisms will lose their cell viability and lead to cell death. This important feature of PEF can destroy microorganisms, as well as preserving the content and stability of nutritional components and organoleptic qualities of the food product since undesirable quality-related enzymes are rather prone to inactivation under PEF exposure, too. It is important to note that food preservation by PEF technology is only achievable at high intensity electric field strength ( $E > 15\text{ kV/cm}$ ) and microbial inactivation where PEF is more effective for liquid or pump-able food products such as juices, milk and smoothies. Implementation of PEF at industrial scale has already been considered to replace the conventional thermal pasteurisation process, in which the United States Food and Drug Administration (FDA) approved the first commercial application of PEF for fruit juice processing in 2006. To date, Netherlands-based companies such as Hoogesteger, Fruity King and Juicy Line have already adopted PEF technology for different types of juice production.

### Microbial Inactivation

To obtain microbiological-safe and shelf-stable food products, employing PEF at high electric field strength, typically between 30 and 50 kV/cm, is necessary. As a result of PEF treatment applied at high electric field strength, food pathogens and spoilage microorganisms, yeast and mould are reported to be susceptible towards inactivation. Based on previous studies, it was observed that 3.25- to 5-log reduction for vegetative yeast cells and the ascospores of *Zygosaccharomyces bailii* in cranberry and grape juice (Raso et al., 1998), a 6-log reduction for *Escherichia coli* in cranberry juice (Sen Gupta et al., 2005), and 2- to 4-log reduction for *Kloeckera apiculata*, *Saccharomyces cerevisiae*, *Lactobacillus plantarum*, *Lactobacillus hilgardii* and *Gluconobacter oxydans* in grape juice (Marsellés-Fontanet et al., 2009), can be achieved with the use of high intensity PEF processing ( $E > 15\text{ kV/cm}$ ).

While PEF has the capability to stabilise berry juice microbiologically, there is evidence showing no vast change in the nutritional and organoleptic qualities of the juices after PEF exposure. A higher retention of vitamin C, total phenolics, anthocyanins, carotenoids

and lycopene and total antioxidant capacity has been found in blueberry juice (Barba et al., 2012), grape juice (Marsellés-Fontanet et al., 2013), strawberry juice (Odriozola-Serrano et al., 2008) and tomato juice (Odriozola-Serrano et al., 2007) when compared to their thermally-treated counterparts. Moreover, PEF-treated juices were described to retain the characteristic fresh fruit volatiles (Jin and Zhang, 1999), have better colour retention and where non-enzymatic browning was minimised (Aguiló-Aguayo et al., 2009a).

### Enzyme Inactivation

The presence of food quality related enzymes in either raw or processed plant-based foods is critical as their residual enzyme activity may lead to food quality losses during storage (Adams, 1991). Therefore, enzyme inactivation through food processing is often desirable to preserve the quality (texture, colour, flavour, and nutritional quality) of foods. PEF processing is well recognised to provide new opportunities to meet specific quality targets in foods without employing excessive heat load when compared with conventional heat treatment. In this regard, extensive research in the past years has shown that PEF is a promising preservation technology resulting in substantial inactivation (up to 90%) of most enzymes in juices originating from various plant sources (Table 2). However, this goal is usually achieved with the requirement of intense PEF processing parameters, for example application of electric field strength at least greater than 15 kV/cm, high specific energy input, high pulse frequency, long treatment time or delivery of pulses in bipolar mode. Factors such as origin (species and types) of the enzyme, the composition of treatment medium and PEF processing parameters affect the degree of enzyme inactivation. The mechanisms involved in enzyme inactivation by PEF are not yet fully understood although both electrochemical effects and Ohmic heating occurring under the influence of these intense processing parameters are said to contribute to the observed inactivation (Terefe et al., 2013).

### Conclusion

In the last decades, the main area of PEF application has been concentrated on inactivation of microorganisms. However, current research has clearly indicated that PEF can offer numerous potential applications for plant-based food products and can be easily adopted by food industries or integrated into existing processing lines. In fact, there is an emerging interest among the food processors concerning the use of PEF as an efficient, low energy upstream process, e.g. pre-treatment of plant tissue for juice expression, phytochemicals extraction, potato frying and to improve the process efficiency of drying, canning, freezing and winemaking. Forthcoming research is still needed to understand whether changes in the plant material induced by PEF might affect the nutritional, health-promoting and sensorial attributes as well as the storage/shelf life of the final products. It is also important to note that plants are a highly variable material and hence testing the effectiveness of a certain PEF processing parameter to achieve certain food application on a wide range of plant from different species, cultivars, tissue types and arrangement, cell size and structures should be considered for successful industrial implementation of PEF.

**Table 2** Summary of representative studies on the effect of PEF processing on quality-related enzymes from different plant sources

Enzymes	Matrices	PEF processing parameters	Residual enzyme activity (%)	References
<b>I. Texture-related enzyme</b>				
Pectin methylesterase	Tomato juice	$E = 35$ , $N = \text{n.d.}$ , $t = 1$ , $P = \text{square}$ , bipolar, $f = 250$ , $\tau = 7$ , $W = 5512$ kJ/L, continuous, 60 mL/min flow rate	8	Aguiló-Aguayo et al. (2009b)
	Orange juice	$E = 35$ , $N = \text{n.d.}$ , $t = \text{n.d.}$ , $P = \text{square}$ , monopolar, $f = 600$ , $\tau = 1.4$ , $W = \text{n.d.}$ , continuous, 1633.33 mL/min flow rate	10	Yeom et al. (2000)
<b>II. Colour-related enzyme</b>				
Polyphenoloxidase	Apple extract	$E = 24.6$ , $N = \text{n.d.}$ , $t = 6$ , $P = \text{exponential decay}$ , bipolar, $f = \text{n.d.}$ , $\tau = 20$ , $W = 114$ kJ/kg	3	Giner et al. (2001)
<b>III. Flavour- and colour- related enzyme</b>				
Peroxidase	Orange juice	$E = 35$ , $N = \text{n.d.}$ , $t = 1.5$ , $P = \text{square}$ , bipolar, $f = 200$ , $\tau = 4$ , $W = \text{n.d.}$ , continuous, 60 mL/min	0	Elez-Martínez et al. (2006)

Abbreviation for PEF processing parameters:  $E$ , electric field strength (kV/cm);  $N$ , pulse number;  $t$ , treatment time (ms);  $P$ , pulse shape (exponential decay or square waveform) and polarity (mono- or bi-polar);  $f$ , pulse frequency (Hz);  $\tau$ , pulse width ( $\mu\text{s}$ );  $W$ , specific energy input; batch or continuous mode PEF treatment. n.d., no data available.

# Oleogels in Food

Kristin D Mattice and Alejandro G Marangoni, University of Guelph, Guelph, ON, Canada

## Introduction

Solid fat provides functionality, flavour, mouthfeel and texture to foods, playing a distinct and essential role in a large variety of food products. These fats contain a large proportion of high melting triacylglycerols (TAGs) that crystallize at room temperature into a network that confines the lower melting liquid TAGs within it. In general, the high melting TAGs are made up of a combination of saturated and/or *trans* fatty acids, while low melting TAGs are commonly unsaturated fatty acids (Marangoni and Garti, 2011). While lipids are an important component of the diet, it is recommended to limit consumption of saturated and *trans* fatty acids due to their well-documented association with adverse effects on cardiovascular health (Judd et al., 1994; Mensink and Katan, 1990; Mensink et al., 2003; Mozaffarian et al., 2006). In contrast, there are recognized beneficial health effects from increasing unsaturated fatty acid consumption (Lunn and Theobald, 2006). For this reason, the concept of replacing saturated and *trans* fatty acids with unsaturated fatty acids in foods is gaining popularity. However, direct replacement of solid fat with oils is usually not an option due to differences in their physical and sensory properties.

The use of oleogels has the potential for creating foods with desirable physical and sensory properties, in addition to satisfying health concerns. There are many different oleogelators capable of structuring edible oils, and each gelator will produce gels with unique properties. Different foods require the functionality of solid fats possessing different physical properties, including thermal behaviour, mechanical strength and rheology. Oleogels must therefore be produced to match the functionality of the fat source they are intended to replace, in order to achieve all the characteristic or desired properties for the specific product. Outside of solid fat replacement, the concept of oleogelation can also be used to address oil migration in foods, or to protect and deliver hydrophobic molecules. There is also work to determine if oleogels on their own can be used as spreadable alternatives to margarine or butter.

## Types of Oleogels

### Ethylcellulose Oleogels

Ethylcellulose (EC) is one polymer capable of structuring oils into solid gel networks, and is currently the only known food-grade polymer capable of structuring oil. EC is a semi-crystalline cellulose polymer derivative, consisting of a cellulose backbone with ethoxyl substitutions at hydroxyl groups (Atalla and Isogai, 1998; Davidovich-Pinhas et al., 2015a; Roy et al., 2009; Stortz et al., 2012). The degree of substitution (DS), or ethoxy content, is used to characterize the final EC, where lipophilicity is achieved with a DS of 2.4–2.5 (Koch, 1937). EC gels are prepared by heating an EC-oil mixture above the glass transition temperature of the EC, approximately 130–140 °C (dependent on the MW of the EC), at which point the EC will dissolve fully in the oil (Davidovich-Pinhas et al., 2014; Davidovich-Pinhas et al., 2015a; Stortz et al., 2012). Dissolution of EC into the oil above this glass transition temperature takes place due to the melting of the glassy regions of the polymer melt, resulting in exposure of the ethoxy groups to the solvent.

Many EC products are commercially available for use as a food additive, and are differentiated according to the viscosity in centipoise (cP) of the solution that they will create when dispersed in 80% toluene and 20% ethanol. Commonly used EC ranges from, 10, 20 or 45 cP, which is based on the average molecular weight (MW) of polymers present, where a higher MW corresponds to a greater viscosity (Dow Cellulosics, 2005). Increasing the viscosity, and MW, of the EC used results in increasing gel strength, making the selection of EC by viscosity (in cP) or MW can be a simple method for controlling oleogel hardness (Bemer et al., 2016; Davidovich-Pinhas et al., 2015a; Dey et al., 2011). Several studies have also shown that the gel strength can be manipulated by changing the type of oil used, EC concentration or by the addition of surfactants (Davidovich-Pinhas et al., 2015c; Davidovich-Pinhas et al., 2015b; Gravelle et al., 2014; Zetzel et al., 2012, 2014). More recent efforts have focused on enhancing the plasticity of EC oleogels through the addition of stearic acid and stearyl alcohol (Gravelle et al., 2017a,b).

### Wax Oleogels

Wax based oleogels are a large category of oleogels, where waxes form a continuous crystal network capable of structuring liquid oil within. The list of waxes used in this application is long, many of which are approved for use in foods. Studied wax oleogelators include rice bran wax, sunflower wax, carnauba wax, candelilla wax, beeswax, fruit wax and shellac wax. Interest in wax oleogels is due to the low concentration of wax required to form a gel (as low as 1%–4% w/w), the stability of the gels that they create, the wide range of properties the gels can attain, and natural origin of the wax gelators. Waxes are composed of a mixture of wax esters, free fatty acids, free fatty alcohols and hydrocarbons, each of varying carbon chain length, as well as a variety of minor components. It is the content wax esters that is generally considered responsible for the gelation behaviour of natural waxes (Blake et al., 2014; Hwang et al., 2012; Patel et al., 2015).

Properties of wax oleogels depend on many critical variables. Each type of wax takes on a characteristic morphology and crystal size. The compositional diversity between waxes causes these differences, which subsequently affects the overall properties of the three-dimensional crystal network that is formed. These differences also cause variation in solubility in different types of oil, making the choice of oil type significant. In addition, the presence of impurities or surfactants, can impact the physical properties of a gel (Chopin-Doroteo et al., 2011). There have also been studies published which demonstrate the use of different cooling rates or the use of shear during cooling as a means of modifying gel functionality (Blake and Marangoni, 2015b,c,d; Morales-Rueda et al., 2009; Toro-Vazquez et al., 2007). Modification of these parameters produces changes in the nucleation and crystal growth rates, which are critical to the microstructure formation and physical properties of the gels.

### Monoglyceride Oleogels

With hydrophobic tails, and hydrophilic heads, monoglycerides (MAGs) are commonly used in foods as emulsifiers. Because of this structure, saturated MAGs form structured w/o emulsions with water through self-assembly into a three-dimensional network of bilayers (Co and Marangoni, 2012). They can also structure liquid oils through formation of inverse bilayers that grow into platelets and form a continuous network (Valoppi et al., 2017b). The use of MAGs in this application is economical, and therefore presents an encouraging oleogelation strategy. The physical properties of MAG gels can be altered by MAG concentration, type of oil used, addition of surfactants, cooling rate and the application of shear (Lopez-Martinez et al., 2014; Ojijo et al., 2004; Valoppi et al., 2017b). It is common for MAGs to be used in combination with other oleogelators, including EC, waxes or phytosterols, due to MAG gel polymorphic instability over time and the desire to improve the viscoelasticity of the gels (Lopez-Martinez et al., 2015; Sintang et al., 2017; Toro-Vazquez et al., 2013).

### Phytosterol Oleogels

Phytosterols are substances naturally occurring in plants, and some, in combination with the sterol ester  $\gamma$ -oryzanol, can be used to structure edible oils at levels as low as 2%–4% w/w. The mixture commonly contains roughly equal molar proportions of sterol to sterol ester, where no gelation can occur in the absence of the other. Together, the components self-assemble uniquely into nano-scale tubules, made possible by distinct elements in their structure (Bot and Agterof, 2006). The tubules will interact and aggregate to form a solid network that can entrap liquid oil. The most common phytosterol used is  $\beta$ -sitosterol, but dihydrocholesterol, cholesterol and stigmasterol can also be used. Gel properties are affected by the type of sterol used, the amount of structurant used, the relative proportions of sterol to sterol ester, cooling rate and application of shear.

### Other Types of Oleogels

While there are many oleogelators that have been investigated, only a small number have actually been used in foods. This section will briefly cover some of those that have the potential for use, but have not yet been extensively studied for the specific uses in foods. First, saturated fatty acids and saturated fatty alcohols can structure oil by crystallizing at ambient temperatures. Both the mechanical properties of these gels, as well as the oil retention properties depend on the carbon chain length, where longer chain lengths (C18–C22) show more efficient gelation properties (Valoppi et al., 2017a). The required concentration for gelation varies greatly based on the fatty acid or alcohol chosen, where those with longer chain lengths induce gelation at lower concentrations (Gandolfo et al., 2004). Additionally, a synergistic effect is observed when using a combination of fatty acids and fatty alcohols, resulting in harder, more elastic gels. One extensively studied combination with a high structuring capacity is stearyl alcohol and stearic acid, commonly referred to together as SOSA. The resultant gels' mechanical properties depend on the SO:SA ratios, and the greatest mechanical strength has been found to result from ratios of 7:3 or 8:2 (Blach et al., 2016). Hydroxylated fatty acids, long chain saturated compounds where substitution of a hydroxyl group has occurred, are very efficient oleogelators, requiring as low as 1% w/w. Commonly used examples are 12-hydroxystearic acid (12-HSA) and ricinelaidic acid, which are obtained from fully or partially hydrogenated castor oil, respectively (Co and Marangoni, 2012; Rogers et al., 2008). Although, hydroxylated fatty acids are not currently approved for use in foods. Finally, Ceramide sphingolipids, formed through fatty acid amidation onto the amine group of sphingosine, will crystallize into bilayers capable of gelling oil. Gelation by ceramides is affected by the fatty acid chain length, where, contrary to fatty acids and alcohols, shorter chain lengths are associated with greater gelation efficiency (Rogers et al., 2009).

### Health Implications of Oleogel Consumption

Replacement of solid fat with novel ingredients in food products must take into account the digestibility of the new component, however extensive research in this area is lacking. A study by Duffy et al. (2009) concluded that the structure of an oleogel can partially limit interactions between lipases and oil, determined by *in vitro* digestion of phytosterol gelled oleogels. However, contradictory results were reported by Hughes et al. after an investigation into consumption of 12-HSA oleogels found the post-prandial increase in serum lipids resultant from digestion of the oleogel was not significantly different from that of liquid oil (Hughes et al., 2009). Yu et al. (2012) also determined that there was no significant difference in the extent of lipolysis between gelled and liquid oil systems after a 30 minute *in vitro* digestion experiment with medium TAG systems gelled by monoglycerides and containing

sorbitan monolaurate. Investigation by O'Sullivan et al. found through *in vitro* methods that the hardness of an EC oleogel is a significant factor with regards to digestion of the oleogel, as hardness influences mastication breakdown, the particle size swallowed, and the eventual breakdown in the body by lipases (Guo et al., 2013, 2016; O'Sullivan et al., 2016). Harder EC gels showed a significantly lower extent of lipolysis and appeared to be more resistant to breakdown when compared to un-gelled oil control samples and weak oleogels. This leads to the conclusion that, while weaker oleogels retain the digestibility of edible oils, digestion of harder oleogels is altered. Tan et al. (2017) found similar results during *in vivo* digestion of EC oleogels after feeding coconut oil or an EC coconut oil oleogel with carbohydrate rich meals. Harder oleogels experienced delays in digestion, and the monitored postprandial glucose and insulin levels were more similar to meals containing no fat than meals containing ungelled coconut oil. However, it must be noted that this study was not conducted on a representative group of individuals and only indirectly measured lipid digestibility by postprandial TAG levels. Together, these studies demonstrate that the digestibility of the oleogels depends on the type of oleogelator used. Therefore, oleogel digestion cannot be summarized into one general trend; instead, each must be treated individually. Additionally, more *in vivo* studies are required before strong conclusions can be made.

## Oleogels in Food Systems

The use of oleogels in food systems must consider many variables. This includes the approval of the gelator as a food additive, the processing conditions required in both the food and oleogel production, and the impact of oleogels on the food's physical properties. Significant research has been done to determine the different types of foods that can best incorporate oleogels, and which types of oleogels are best for each system. A summary of the documented uses of different types of oleogels in specific food applications can be found in Table 1.

### Processing Conditions

Oleogels are strongly influenced by the processing conditions involved in their production and during incorporation into food products. Important conditions include the cooling rate used and the application of shear. Because of their structured nature, most oleogels will break and leak oil if sheared after gelation, therefore successful integration of gels into food matrices can require strategic planning. Another consideration is heating, where temperatures as high as 80–140 °C are required for oleogelation. Some foods are capable of withstanding these high temperatures, therefore certain food applications may be able to employ direct dispersion of EC into an oil containing food matrix. In most cases, this temperature exceeds that which the food materials can withstand, and gels must be prepared prior to incorporation. The high temperatures during oleogel production must also be monitored closely, as oil held for excessive time at this temperature will oxidize and the oxidation products that develop create off-flavors. Gravelle et al. (2016) demonstrated that after just 20 minutes of holding at 140 °C, canola oil will contain over 10 meq peroxide/kg canola

**Table 1** Applications of oleogels in food systems

Oleogel type	Food system	Oleogel function	References
Ethylcellulose	Cream cheese	Saturated fat reduction	Bemer et al. (2016)
	Frankfurters/comminuted meats	Saturated fat reduction	Barbut et al. (2016b) and Zetzi et al. (2012)
	Breakfast sausages	Saturated fat reduction	Barbut et al. (2016a)
	Cookies and cream fillings	Reduction of oil migration	Stortz et al. (2012)
Waxes	Spreadable fat alternatives	Saturated fat reduction	Patel et al. (2014) and Yilmaz and Ögütcü (2015)
	Ice cream	Saturated fat reduction	Zulim Botega et al. (2013)
	Cookies	Saturated fat reduction	Hwang et al. (2016), Jang et al. (2015), Mert and Demirkisen (2016), and Yölmaz and Ögütcü (2015)
	Deep frying	Decreased oil absorption; saturated fat reduction	Lim et al. (2017)
	Chocolate paste	Replacement of oil binder; partial replacement of palm oil	Patel et al. (2014)
	Cream cheese	Saturated fat reduction	Bemer et al. (2016)
	Cake shortening	Saturated fat reduction	Patel et al. (2014)
	Sweet bread	Saturated fat reduction	Calligaris et al. (2013)
Monoglycerides	Pastry and sweet bread	Saturated fat reduction	Manzocco et al. (2012a,b)
Phytosterols	Frankfurters	Saturated fat reduction	Panagiotopoulou et al. (2016)
Monoglycerides + phytosterols	Frankfurters	Saturated fat reduction	Kouzounis et al. (2017)
	Flavor delivery system	Controlled volatile release	Yang et al. (2017)
Waxes + monoglycerides	Spreadable margarine alternative	Saturated fat reduction	Ögütcü and Yölmaz (2014)
	Laminating shortening	Saturated fat reduction	Blake and Marangoni (2015a)

oil, and can no longer be termed “fresh” oil. Adding food-grade antioxidants can reduce the extent of oil oxidation during heating, added in concentrations ranging from 100 to 500 ppm by weight of oil (Ergun et al., 2016). Barbut et al. (2016b) cite the use of butylated hydroxytoluene (BHT) in combination with rosemary extract, added to oil prior to heating, to reduce the off flavors associated with oil oxidation in beef frankfurters. It is also possible to limit oxidation by heating oil under inert atmospheric conditions, such as under vacuum or 100% nitrogen (Ergun et al., 2016).

### Impact on Texture

Oils and fats contained in food are distributed differently, attributing different characteristics to the food product. Generally, oil globules are distributed evenly and are micrometers in size, while solid fats exist as larger globules varying in size, with a minimum around 100  $\mu\text{m}$  (Youssef and Barbut, 2009). This difference prevents the direct substitution of solid fat with oil as large changes in texture and rheological properties will result. Studies have shown that presence of very small non-gelled oil globules cause a harder, rubbery texture in cream cheese and frankfurters, likely observed due to the increased fat globule surface area, resulting in the ability of proteins to form a stronger network (Bemer et al., 2016; Zetzl et al., 2012). These studies also found that oleogels (of either wax or EC) created statistically similar microstructures and fat globule size distributions to solid fat in cream cheese and comminuted meat systems, leading to comparable hardness by instrumental testing. Breakfast sausages containing harder EC oleogels with added sorbitan monostearate (SMS), a common surfactant, were also found to have comparable instrumental hardness to pork fat controls (Barbut et al., 2016a). Contrasting previous investigations, pork fat sausages in this study were the hardest of the samples, while samples containing liquid oil or softer oleogels were significantly softer. Despite comparable hardness values by instrumental analysis in the harder oleogel samples, sensory analysis revealed that differences in hardness and texture are still perceivable by consumers. All oleogel samples received notably lower hardness scores from panelists when compared to pork fat. These studies all emphasize the need to tailor the physical properties of oleogels for the application, as well as the need for sensory analysis.

Textural implications resulting from the incorporation of oleogels into bakery products have been documented in many studies. Replacement of solid fat with liquid oils in baked products causes problems due to the loss of functionality – namely, the ability of solid fat to stabilize air bubbles throughout the batter or dough – as well as an increase in greasiness or oiliness. Since bakery products are often high in saturated or *trans* fat, many studies have explored the use of oleogels, finding it extremely intriguing and promising. The use of oleogels in cakes or sweet breads was shown to increase the density, decrease height and cause a crumbly texture, however, oleogel based structured emulsions had much greater success (Manzocco et al., 2012a; Patel et al., 2014). In general, the use of oleogels in cookies has been shown to effect hardness and dough spreadability during baking, with the exact magnitude depending on the gelator used (Blake and Marangoni, 2015a; Hwang et al., 2016; Jang et al., 2015; Mert and Demirkesen, 2016; Yölmaz and Ögütçü, 2015). Though, one sensory study found that the differences observed were not beyond what panelists deemed acceptable, and cookies containing wax oleogels were still found to have acceptable flavor, texture, smell and appearance (Yölmaz and Ögütçü, 2015).

Another consideration is the texture or consistency of the food when in the mouth, because the melting temperature of oleogels is greater than traditional solid fats. This higher melting temperature eliminates the common and desirable “melt in your mouth” sensation, especially when considering replacement of butter with oleogels. However, when melting is a key product attribute, it is possible that beginning with only partial replacement could produce products that are more comparable.

### Added Functionality

From a food and nutritional perspective, certain oleogels have more advantages than others do. Phytosterol and sterol ester oleogels have the inherent benefit that phytosterols themselves are bioactive molecules. Studies surrounding the consumption of plant phytosterols have found many beneficial health effects, including lowering LDL cholesterol levels, and therefore decreasing risk of cardiovascular disease, as well as decreasing the risk of certain cancers, including breast, colon and prostate (Awad and Fink, 2000; Bradford and Awad, 2007; Moghadasian and Frohlich, 1999). Though, the bioactivity of phytosterols contained within sterol and sterol ester oleogels has not been investigated, and it is unknown whether the digestibility of the oleogels would affect the deliverability and bioactivity of these molecules.

In the case of EC oleogels, it appears oleogel strength or hardness can impact the residence time of the material in the digestive tract (McClements et al., 2008; O’Sullivan et al., 2016; Tan et al., 2017). This has potential benefits, where harder oleogels could act, for example, as carriers for highly lipophilic bioactive molecules protected by the undigested oleogel structures. An example would be carotenoids, more specifically  $\beta$ -carotene, known to be potent antioxidants, provide some dietary vitamin A, and are also associated with reducing the risk of chronic diseases, such as cardiovascular diseases and cancer (Cooper et al., 1999; Krinsky and Johnson, 2005; Rao and Rao, 2007). Oleogels of sufficient hardness could be capable of providing protection to  $\beta$ -carotene, and therefore have potential controlled release delivery applications (O’Sullivan et al., 2017).

### Conclusions

The use of oleogels can improve the nutritional properties of high saturated and *trans* fat foods through solid fat replacement with unsaturated sources. Additionally, manipulation of known variables allows oleogels to be produced having specific mechanical

properties, similar to that of the solid fat that they will replace and specific to the particular food application. Many oleogelators have been successfully incorporated into different food products, including ground or comminuted meats, soft cheeses, and high fat bakery products. However, there is currently a lack of sensory analysis on oleogel containing foods, knowledge for how oleogels are digested, and the feasibility of large-scale oleogel production. Additionally, taste considerations must be acknowledged to ensure that the gelators themselves, or products of oil oxidization as a result of heating, do not create overwhelming off flavors. Further investigation into aspects inherent in industrial scale production of oleogel containing products, including storage conditions and shelf life, should also be considered.

# Oxidative Rancidity

## Introduction

In foods, lipids are mainly found in the form of triacylglycerols (triacylglycerides) (TAG), which make up to 99% of lipids of plant and animal origin (Fennema, 1996). Phospholipids (PL) are important structural lipids in foods and cell membranes. Most of the PL are removed by degumming in the refining of vegetable and fish oils (Frankel, 2005) and these oils therefore mainly consist of triacylglycerols, but in foods such as egg, meat and fish, phospholipids can constitute a larger part of the lipids (e.g. cod phospholipids constitute 87% of the total lipids). Oxidation of the lipids in foods is one of the most important factors limiting their shelf life. PL are more susceptible to lipid oxidation than TAG, partly because they are more unsaturated. Lipid oxidation gives rise to the formation of unhealthy compounds such as free radicals and reactive aldehydes and it reduces the nutritional value of lipids. The negative health effects of lipid oxidation is not acute and therefore the consumer will not be affected immediately. However, lipid oxidation will also result in significant changes in the sensory properties including odor, flavor, color and texture. These changes can be detected by the consumer and may thus determine the shelf life of the product. The term rancid is often used to describe the sensory changes caused by lipid oxidation. Oxidative rancidity is in this case the oxidative deterioration of oils/fats or foods containing oils/fats during food processing and storage. However, rancidity can also occur due to lipid hydrolysis. In this case, we use the term hydrolytic rancidity to describe the chemical deterioration of the food lipids. As an example, both hydrolytic and oxidative rancidity are important reactions in non-pasteurized milk, where oxidation of milk lipids will lead to oxidative rancidity and lipolytic enzymes will give rise to hydrolytic rancidity. In products containing both lipids and protein such as milk, meat and fish, lipid oxidation will go hand in hand with oxidation of the proteins. This chapter will, however, not discuss protein oxidation any further.

## Lipid Oxidation Processes

Unsaturated fatty acids bound in the lipid molecules (TAG or PL) or as free fatty acids are the basic substrate of lipid oxidation. The direct oxidation of unsaturated fatty acids by low energy, ground state oxygen (triplet oxygen  $^3\text{O}_2$ ) is spin forbidden, but this barrier can be overcome in the presence of initiators that can produce radicals or by other means. Thus, three different types of lipid oxidation reactions can occur: 1) Enzymatic lipid oxidation, 2) Autoxidation, which is a reaction between free lipid radicals with oxygen, and 3) Photooxidation resulting from exposure of lipids to light in the presence of photosensitizers. In case of autoxidation (see Fig. 1), the presence of initiators (e.g. metal ions, heat, protein or already existing lipid radicals) causes unsaturated fatty acids (LH) to form alkyl radicals ( $\text{L}\cdot$ ). These radicals react fast with oxygen to form peroxy radicals ( $\text{LOO}\cdot$ ). The peroxy radical reacts with a new unsaturated fatty acid to form hydroperoxides ( $\text{LOOH}$ ) and a new lipid radical, which will subsequently propagate the chain reactions. Lipid hydroperoxides are the primary products of autoxidation. Because of their low volatility they are taste- and odorless. The free radical chain reaction propagates until two free radicals join and form a non-radical product, which will terminate the chain reaction.

The lipid hydroperoxides can be decomposed to alkoxy and peroxy radical intermediates ( $\text{LO}\cdot$  and  $\text{LOO}\cdot$ ) by thermal dissociation or by the presence of trace metals such as iron and copper. Both radicals can effectively propagate the free radical chain

Figure 1 Lipid autoxidation process.

to form new hydroperoxides (Frankel, 1991). Lipids consist of a mixture of different fatty acids, which will result in a complex mixture of lipid hydroperoxides, differing in chain length, the position of the HOO-group and the geometrical structure of the double bonds. In muscle food, decomposition of lipid hydroperoxides is primarily catalysed by heme iron. Both myoglobin (Mb) and hemoglobin (Hb) appear to control the onset of oxidation via several different complex mechanisms as reviewed by Undeland (2016). Hb is a tetrameric molecule with allosteric O<sub>2</sub>-binding properties while Mb is a monomer without allosterism. The ratio between Hb and Mb is approximately equal in dark muscle while Hb dominate in light fish muscle (O'Brien et al., 1992). In general, the ratio between Mb and Hb is lower in fish than in beef (Livingston and Brown, 1981; Matsuura and Hashimoto, 1954).

In the presence of light and photosensitizers (e.g. riboflavin in milk, chlorophyll in unrefined oils) photooxidation of unsaturated fatty acids can occur. The photosensitizers will be activated by absorbing visible or near-UV light. There are two types of photosensitizers with different reaction mechanisms. Type I sensitizers react with the lipids whereby lipid radicals are formed and they subsequently react with oxygen in a similar way as described for autooxidation. Type II sensitizers react directly with triplet oxygen, transforming it into the short-lived but highly reactive singlet oxygen, <sup>1</sup>O<sub>2</sub> (Fig. 2). The double bond of the unsaturated fatty acids then reacts with singlet oxygen to form hydroperoxides (ROOH) (Frankel, 2005). This is a non-free-radical process and will generate other types of lipid hydroperoxides (non-conjugated hydroperoxides) in addition to those formed through the free radical oxidation process (conjugated hydroperoxides) (Fig. 3).

As mentioned earlier alkoxyl radicals are readily formed from decomposition of lipid hydroperoxides at high temperatures and/or in the presence of traces of transition metals. Alkoxyl radicals may further decompose to form a variety of non-volatile and volatile secondary oxidation products (Frankel, 1991). The latter compounds are responsible for the flavor deterioration that is a result of lipid oxidation (Aidos et al., 2002; Aro et al., 2003; Frankel, 1983; Kulås et al., 2002; Venkateshwarlu et al., 2004).

Photosensitizers become electronically excited  
by absorbing light: UV or visible

Photosensitizers have two excited states

Singlet state: <sup>1</sup>Sens and Triplet state: <sup>3</sup>Sens

There are two types of photosensitized reactions:

#### Type 1:

#### Type 2: Singlet oxygen production

Figure 2 Photosensitized lipid oxidation.

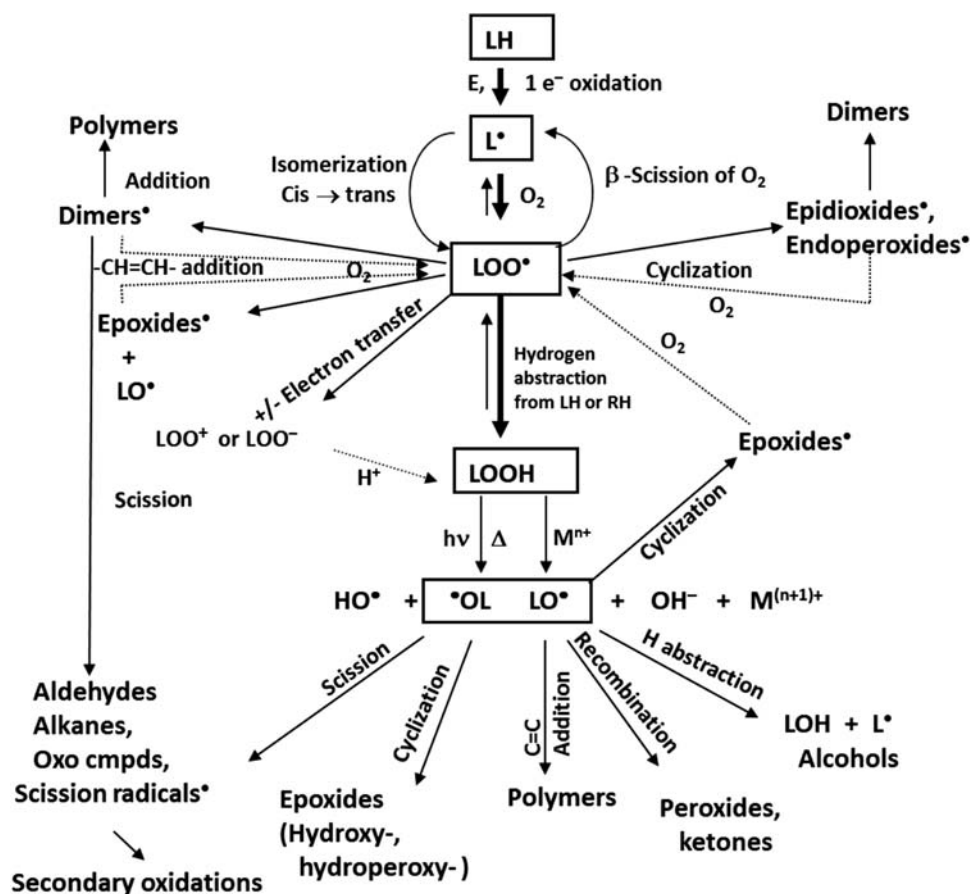

Figure 3 Formation of non-conjugated and conjugated lipid hydroperoxides.

**Figure 4** Reaction scheme for lipid oxidation integrating alternate pathways. From Schaich, K., 2005. Lipid oxidation in fats and oils: theoretical aspects. In: Shahidi, F. (Ed.), *Bailey's Industrial Fats and Oils*, sixth ed. John Wiley, New York, pp. 2681–2767. Used with permission.

From the chain reactions described above a specific sequence in formation of products is expected from an analytical point of view. Thus, first conjugated dienes, then lipid hydroperoxides, and then secondary volatile oxidation products, which would only evolve after hydroperoxide decomposition. However, because experimental results for both kinetics and products often have been inconsistent with the traditional reaction scheme a more complex, integrated reaction scheme that may more fully and more accurately describe the complex reactions of lipid oxidation have been developed in the recent years (Fig. 4) (Schaich, 2012, 2016). This reaction scheme shows the existence of simultaneous alternate pathways, which includes addition, rearrangement, and dismutation reactions of lipid peroxy radicals ( $\text{LOO}^\bullet$ ), which generate dimers, epoxides, and aldehydes from the beginning of oxidation in parallel with hydroperoxides, and they can divert radicals from formation of hydroperoxides. The existence of these alternate pathways has consequences for the type of measurements that should be made to follow lipid oxidation during storage. See further discussion in the section about methods for measuring lipid oxidation.

### Sensory Impact of Lipid Oxidation

Only the secondary volatile oxidation products formed during lipid oxidation are responsible for the undesirable changes in the aroma and flavor properties of foods. Among these compounds the vinyl ketones and the trans, cis-alkadienals have the lowest flavor thresholds in oils (Table 1). In contrast, hydrocarbons (alkanes and alkenes) have the highest flavor thresholds (Frankel, 2005).

The same volatile oxidation product can give rise to different off-odors and off-flavors depending on its concentration and on the food matrix in which it occurs. Lipid oxidation of neat oils will give rise to off-flavors ranging from nutty through green, grass cucumber to rancid and synthetic. For fish oils, the term train oil or fishy has frequently been used. The oil may even develop a painty odor if lipid oxidation is extreme.

Flavor defects caused by lipid oxidation in milk and cream are usually referred to as “oxidized flavor” and in butter they are referred to as “metallic” or “tallowy” (Frankel, 2005). Oxidized flavors are very easily detected in fluid milk even at very low oxidation levels ( $\text{PV} < 1 \text{ meq/kg}$ ) (Frankel, 2005). Exposure of milk or butterfat to sunlight produces off-flavors that have been described as burnt, light-activated or sunlight flavor (Frankel, 2005).

**Table 1** Threshold values of compounds formed from oxidized oils

Compounds	Thresholds (mg/kg)
Hydrocarbons	90–2150
Substituted furans	2–27
Vinyl alcohols	0.5–3
1-alkenes	0.02–9
2-alkenals	0.04–2.5
Alkanals	0.04–1.0
Trans,trans-2,4-alkadienals	0.04–0.3
Isolated alkadienals	0.002–0.3
Isolated cis-alkenals	0.0003–0.1
Trans,cis-alkadienals	0.002–0.006
Vinyl ketones	0.00002–0.007

Akoi, C.C., Min, D.B., 1998. Food Lipids: Chemistry, Nutrition, and Biotechnology (Food Science and Technology), Marcel Dekker.

In meat products, the oxidized flavors in precooked, stored and reheated meat is often described by the term “warmed over flavor” (WOF), which is mainly caused by oxidation of lipids. Particularly the formation of hexanal, 1-octen-3-one, (E)- and (Z)-2-octenal, (Z)-2-nonenal (E,E)-2,4-nonadienal and trans-4,5-epoxy-(E)-2-decenal seems to play a role for the formation of WOF (Konopka and Grosch, 1991). WOF has been suggested to mainly be the result of oxidation of membrane phospholipids (Gray and Pearson, 1987).

The most important flavor change during frozen storage of fatty fish such as salmon is the formation of train oil, bitterness and metallic tastes (Refsgaard et al., 1998). Milo and Grosch (1995) suggested that the increased concentration of 1-octen-3-one (Z)-1,5-octadien-3-one, hexanal (Z)-3-hexenal (Z)-4-heptenal (Z,Z)-2,6-nonadienal and (E,Z)-2,6-nonadienal observed during storage of cod most likely were important contributors to the train oil odor in the stored cod sample.

Apart from affecting odor and flavor, lipid oxidation may also affect color. Autoxidation of heme iron may decrease the red color of fish muscle (Sannaveerappa et al., 2007), whereas lipid oxidation of the lipids will lead to an increase in a more yellow hue.

## Measurement of Lipid Oxidation

### Accelerated Methods Versus Traditional Storage Experiments

Evaluation of the oxidative flavor deterioration of neat lipids can be performed at ambient temperatures or lipid oxidation can be accelerated by elevating the temperature to 30 °C or above. It is, however, important to bear in mind that already at temperatures above 40 °C oxidation kinetics will change for some oil types as illustrated for fish oil (Sullivan et al., 2011). Therefore, oxidation studies carried out at high temperatures may not be representative for reactions taking place at lower temperature. Regarding emulsified foods such as dressing and mayonnaise temperatures above 30 °C may break the emulsions and therefore it will not be possible to increase temperature above this level. For other food products such as raw meat and fish products higher temperatures than 5 °C will lead to microbial spoilage and storage experiments are therefore carried out at lower temperatures than 5 °C. For neat oils and emulsions storage experiments at ambient temperatures may be accelerated by light or by the addition of metals such as iron or copper, whereas for fish muscle models oxidation is accelerated by addition of heme iron (Jacobsen et al., 2008). It is important to bear in mind that light induced oxidation will give rise to other types of secondary oxidation products and thereby other off-flavors than those produced by autoxidation.

### Analytical Methods for Lipid Oxidation Measurements

Measurement of lipid oxidation can be carried out by a wide range of methods such as peroxide value (PV), anisidine value (AV), thiobarbituric acids reacting substances (TBARS) as well as instrumental methods such as HPLC, GC-MS, NIR, FTIR and DSC. Sensory evaluation of oxidative flavor deterioration is another important method that should always be included at some stage to understand how lipid oxidation has impacted sensory properties of the food product in question. In lipid oxidation studies on meat products there seems to be a fairly good correlation between TBARS and sensory data, although in many cases no attempts have been made to statistically evaluate the correlations (Eckert et al., 1997; Murano et al., 1998; Winne and Dirinck, 1997). However, newer data indicate that even in meat TBARS may be an unreliable method (Summo et al., 2010). This may be related to the fact mentioned above that lipid oxidation have several alternate pathways. Therefore, if lipid oxidation is only followed by measuring formation of TBARS and peroxide values the major proportions of oxidation products may be missed and the extent of lipid oxidation may be significantly underestimated. The same is the case for studies, which only measure peroxide value and hexanal (aldehyde formed from n-6 fatty acids). In complex foods, the situation is even more complicated. This is due to the fact that lipid oxidation radicals and secondary oxidation products (e.g. aldehydes) react with other components in foods, particularly

proteins. This type of co-oxidation will thus consume lipid oxidation intermediates and products and at the same time other substrates in the food system will be affected by oxidation. If only the traditional lipid oxidation measurements are performed, lipid oxidation can be underestimated, when it is in fact spread to other components of the food system, which may have an effect on sensory properties of the food product.

Good correlations data from headspace GC analysis and sensory data have been found for a range of different oxidized products such as fish (Milo and Grosch, 1995), fish oil enriched milk (Venkateshwarlu et al., 2004), mayonnaise and dressing (Hartvigsen et al., 2000; Let et al., 2007a) and boiled potatoes (Blanda et al., 2010). Headspace GC analysis can therefore be recommended as one of the best methods to chemically assess oxidative flavor deterioration. Different headspace methods are available for collection of the volatile oxidation products including static headspace, dynamic headspace, purge and trap and solid phase microextraction. Thomsen et al. (2016) have recently compared the performance of some of these methods in neat oil and two emulsified systems.

## Factors Affecting Lipid Oxidation in Neat Oils Versus Complex Food Systems

### Neat Oils

In neat oils, lipid oxidation is primarily affected by light, temperature, the oxygen level, the presence of minor components such as water, trace metals, free fatty acids (FFA), phospholipids (PL), monoacylglycerides (MAG), diacylglycerides (DAG) and natural antioxidants and pigments. Light will only increase the rate of lipid oxidation if a photosensitizer is present whereby singlet oxygen is formed as described above. If this is the case, lipid oxidation rates can be more than 1000 times faster compared to free radical oxidation with triplet oxygen (Frankel, 2005). Regarding temperature, as a rule of thumb lipid oxidation rates will double every time temperature is increased by 10 °C. The effect of minor components on lipid oxidation has been reviewed by Chen et al. (2011). Some important conclusions from the review are summarised here. Water can affect the rate, extent and oxidation mechanism in neat oils because it may act as a solvent for hydrophilic or amphiphilic antioxidants or prooxidants. Free fatty acids have been suggested to promote lipid oxidation due to their ability to accelerate decomposition of hydroperoxides and bind metals to make them more prooxidative. The effect of PL on lipid oxidation is controversial as some studies have found antioxidative effects of PL, particularly in the presence of tocopherol where PL have been found to have a synergistic effect. In contrast, other studies have shown either no effect or a prooxidative effect of PL. Whether PL has no, antioxidative or prooxidative effect seems to depend on the exact composition of the mixture of PL, the composition of the neat oil including the presence of other minor components as well as the conditions under which the study was performed. Importantly, FFA, PL, MAG and DAG are surface active compounds, which can form physical structures (association colloids) in neat oils in the presence of water (~300 ppm). A variety of association colloids can be formed such as reverse micelles, micro-emulsions, lamella structures and cylindrical aggregates (Chen et al., 2011). It is well known that the physicochemical properties of water–oil interfaces can impact lipid oxidation. Therefore, water–oil interfaces of association colloids can also impact lipid oxidation. How and to which extent the association colloids impact lipid oxidation depends on the exact composition and structure of the water–oil interface. See Chen et al. (2011) for further discussion of this topic.

### Complex Food Systems

In complex food systems, lipid oxidation is obviously more complex because foods consist of many ingredients, which can affect lipid oxidation in different ways. Since many foods are food emulsions, some of the factors that can affect lipid oxidation in emulsions will be summarised in the following. Fig. 5 illustrates an oil-in-water (o/w) emulsion. Milk, yoghurt, mayonnaise

**Figure 5** Factors affecting lipid oxidation in emulsions.

and dressing are examples of oil-in-water food emulsions. When lipids are dispersed as small droplets in an o/w emulsion there is a huge increase in the lipid-water surface area. For example, when the average droplet diameter decreases from 100  $\mu\text{m}$  to 100 nm, the specific surface area increases from 65.2  $\text{m}^2/\text{kg}$  to 65,220  $\text{m}^2/\text{kg}$  (Decker et al., 2017). As mentioned above lipid oxidation is an interfacial phenomenon because it is often catalysed by water soluble trace metals, which reacts with lipids or lipid hydroperoxides located near the oil-water interface. Therefore, lipid oxidation is typically faster in emulsions than in neat oils.

In food emulsions, water soluble ingredients will be located in the aqueous phase, oil soluble compounds in the oil phase and amphiphilic compounds at the interface, where they can interact with the emulsifier. Lipid oxidation in emulsions is affected by factors such as pH, physical structure of the emulsion, composition, microstructure and charge of the interface and partitioning of the emulsifier between the interface and the aqueous phase as discussed in a recent reviews by Berton-Carabin et al. (2014) and Jacobsen (2015) and as illustrated in Fig. 5.

As mentioned above, trace metals present in the aqueous phase may promote decomposition of lipid hydroperoxides located near the interface of the lipid droplets whereby alkoxyl radicals are formed. These radicals will then diffuse inside the oil droplet and react with another lipid whereby lipid oxidation propagates. The oil-water interface should therefore be designed to prevent this interaction between trace metals and lipid hydroperoxides. Factors that can affect the ability of the interface to resist the interaction between lipid hydroperoxides and trace metals include the thickness and physical properties of the interface as well as its charge. If the interface is positively charged it will repel the positively charged trace metal ions (e.g.  $\text{Fe}^{2+}$ ) (Mei et al., 1998). In contrast, if the interface is negatively charged, it will attract trace metal ions and increase lipid oxidation. The charge of the interface is determined by pH and the type of emulsifier used. Furthermore, pH also affects the solubility of trace metals. For example,  $\text{Fe}^{2+}$  is more soluble at low pH than at neutral pH.

Because lipid oxidation is an interfacial phenomenon, the rate of lipid oxidation could be expected to be depending on size of the total interfacial area, i.e. the droplet size as shown in Fig. 5. However, contradicting reports are available on the effect of the droplet size on oxidation in different food systems (Jacobsen et al., 2000; Lethuaut et al., 2002; Let et al., 2007b). The available data thus suggest that other factors than the mere interfacial area are of significance for oxidation.

Fig. 5 also shows that the emulsifier may be present in the aqueous phase. This is the case when there is an excess of emulsifier and the unadsorbed emulsifier will then partition into the aqueous phase. Particularly unadsorbed proteins may strongly interact with water soluble free radicals and metal ions whereby lipid oxidation can be affected (Donnelly et al., 1998; Ponginebbi et al., 1999; Faraji et al., 2004). In many cases, the unadsorbed protein will act as an antioxidant due to its ability to chelate metals or scavenge free radicals as reviewed by Berton-Carabin et al. (2014). Likewise, unadsorbed surfactants present in the aqueous phase in concentrations above CMC can form colloid structures such as micelles, mixed micelles or very small droplets, which has been shown to reduce oxidation rates in some cases (Ponginebbi et al., 1999; Berton et al., 2011).

Viscosity of the surrounding aqueous phase depends on the ingredients used to produce the food emulsion. A high viscosity of the aqueous phase will slow down the diffusion of reactants, which includes trace metals and even some polar lipid hydroperoxides, which may be present in the aqueous phase.

## Prevention of Lipid Oxidation by Antioxidants

### Antioxidant Mechanisms

Antioxidants can retard or inhibit lipid oxidation. Antioxidants are classified as primary or secondary antioxidants based on their mechanism of action. Some antioxidants have more than one mechanism of action and are referred to as multiple-function antioxidants. Primary antioxidants, also referred to as chain-breaking antioxidants, are able to react directly with free radicals and convert them to more stable, non-radical products. In the initiation and propagation steps, antioxidants react with lipid, peroxy and alkoxyl radicals, whereby further decomposition into aldehydes and other volatile oxidation products is prevented (Fig. 6). Phenolic compounds with one or more hydroxyl groups are effective chain breaking antioxidants because they can donate H-atoms to the free radicals. After they have donated their H-atom they form stable and relatively unreactive phenoxyl radicals. Examples on synthetic phenolic compounds are butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), propyl gallate and tertiary butyl hydroquinone (TBHQ). Examples on natural phenolic compounds are tocopherol, ascorbic acid, caffeic acid and rosmarinic acid.

Secondary antioxidants inhibit lipid oxidation by different mechanisms such as chelation of transition metals, oxygen scavenging and quenching of singlet oxygen. Some secondary antioxidants are able to regenerate primary antioxidants in a synergistic manner. In food systems, metal chelators, which prevent the metal ions from decomposing lipid hydroperoxides to reactive radicals, are often very important secondary antioxidants. Examples of metal chelators are synthetic ethylenediaminetetraacetic (EDTA), polyphosphates, phytate, caseinate and lactoferrin. Polyphenols are often multi-function antioxidants with both free radical scavenging and metal chelating properties.

### Factors Affecting Antioxidant Efficacy

Apart from the basic properties of antioxidative compounds mentioned above the efficacy of antioxidants in complex foods is affected by many other factors and is therefore hard to predict. In 1980, Porter proposed the "the polar paradox", which stated that polar antioxidants work best in bulk oils while non-polar antioxidants work best in lipid dispersions such as oil-in-water

- **Primary or chain breaking antioxidants (radical scavengers) (AH)**

- **Metal chelators can chelate transition metals such as  $Fe^{2+}$**

**Figure 6** Antioxidant mechanisms.

emulsions and liposomes (Porter, 1980). For several years, attempts have been made to use the polar paradox theory to predict antioxidant effects in emulsified systems. Unfortunately, in several cases the experimental data did not agree with the predictions made from this theory. Recent research has compared the antioxidative effect of antioxidants esterified to fatty acids with a chain length from 2 to 20 carbon atoms in simple oil-in-water emulsions (Laguerre et al., 2009, 2010). On the basis of these results the so-called cut off theory was proposed. In brief, this theory states that the efficacy of polar antioxidants such as ascorbic acid in emulsions can be increased by lipophilizing the antioxidants up to a certain length of the alkyl group esterified to the polar antioxidant. Beyond the optimal chain length of the alkyl group, the efficacy of the lipophilized antioxidant will collapse. The cut-off theory has been confirmed in simple oil-in-water emulsions with antioxidants such as rosmarinic acid (Laguerre et al., 2010), chlorogenic acid (Laguerre et al., 2009) and dihydrocaffeic acid (Sørensen et al., 2012). In general, it was found that antioxidant esters had maximal activity in the 8–12 carbon chain length with esters with short and longer chain lengths being less effective. However, lipophilisation of protocatechuic acid did not improve their efficacy in simple soy o/w emulsions (Silva et al., 2017).

The absence of AO hydrophobicity effect on the antioxidant efficiency of protocatechuates was explained by their concentrations at the interfacial region of soybean oil emulsions, which is believed to be the site where AOs react with lipid radicals. The distributions of the esters in the emulsions were assessed by using a novel approach based on a pseudophase kinetic model for interpreting observe rate constants ( $k_{obs}$ ) for the reaction between a hydrophobic arenediazonium ion probe ( $16-ArN_2^+$ ) and the antioxidants as also described in previous works by this group. The results obtained for protocatechuates suggested that lipophilization with alcohols of different chain length had a modest effect on their interfacial concentrations, which as a consequence, led to insignificant variations in their antioxidant efficiency.

When ferulic acid and caffeic acid esters were evaluated in fish oil enriched milk other optimal chain lengths than those reported in simple emulsions were found. For both phenolic compounds it was observed that the short chain esters (with chain lengths C1 or C4) were the most efficient antioxidants (Sørensen et al., 2015; Alemán et al., 2015). This suggests that the optimal chain length of an antioxidant in complex food systems cannot be predicted from studies in simple o/w emulsions. This is most likely due to the fact that antioxidants can impact lipid oxidation kinetics in many ways and therefore their efficacy is not only governed by their physical location. Moreover, antioxidants may adsorb and interact with the oil-water interface. A recent review by Decker et al. (2017) discusses the hurdles in predicting antioxidant efficacy in oil-in-water emulsions in more detail. The reader is also referred to another review by McClements and Decker (2018) which discusses the strategy of using antioxidant emulsifiers to prevent lipid oxidation. An antioxidant emulsifier is in this context defined as “a substance that can adsorb to oil-water interfaces, enhance the formation and physical stability of emulsions and inhibit lipid oxidation”.

For more details on the effect of antioxidants in a wide range of food emulsions the reader is referred to Jacobsen (2016).

## Conclusions

Lipid oxidation has significant impact on the sensory properties and the shelf life of foods. Lipid oxidation reactions can proceed through several alternate and parallel pathways. Therefore, one should carefully consider which methods to use for measuring the extent of lipid oxidation. The rate of lipid oxidation can be affected by several different factors, which can have different impact depending on the type of food. Lipid oxidation can be prevented by the addition of antioxidants, but with our current knowledge it is hard to predict the efficacy of antioxidants in different foods.

### Glossary

**Arabinofuranosidases** (EC 3.2.1.55) act on  $\alpha$ -L-arabinofuranosides,  $\alpha$ -L-arabinans containing (1,3)- and/or (1,5)-linkages, arabinoxylans, and arabinogalactans.

**$\beta$ -elimination** in organic chemistry class, one learns that elimination reactions involve the cleavage of a  $\sigma$  bond and formation of a  $\pi$  bond. A nucleophilic pair of electrons (either from another bond or a lone pair) heads into a new  $\pi$  bond as a leaving group departs. This process is called  **$\beta$ -elimination** because the bond  $\beta$  to the nucleophilic pair of electrons breaks.

**Feruloyl esterase** forms a part of the enzyme complex that acts collectively and synergistically to completely hydrolyze xylan to its monomers.

**Homogalacturonans** are linear chains of  $\alpha$ -(1–4)-linked D-galacturonic acid.

**Methylophilic bacteria** are a group of microorganisms that are able to use compounds containing one-carbon as well as multi-carbons as energy and carbon sources.

**Psychrophilic** thriving at a relatively low temperature

**Rhamnogalacturonans** (RGs) are a group of closely related cell wall pectic polysaccharides that contain a backbone of the repeating disaccharide: 4)- $\alpha$ -D-GalpA-(1,2)- $\alpha$ -L-Rhap-(1,.

### Introduction

Pectin is a high-molecular weight, biocompatible, nontoxic, and anionic natural polysaccharide extracted from cell walls of higher plants. It mostly consists of three structurally well-characterized polysaccharide motifs: homogalacturonan (HG), rhamnogalacturonan I (RG I), and rhamnogalacturonan II (RG II) (Chen et al., 2015). Pectic enzymes, pectinases or pectinolytic enzymes, are a heterogeneous group of related enzymes that hydrolyze the pectic substances, present mostly in plants. They have a share of 25% in the global sales of food enzymes (Jayani et al., 2005). The primary source of industrial enzymes is microorganisms. The classification of pectic enzymes is based on their attack on the galacturonan backbone of the pectic substance molecule, and pectic enzymes is broadly classified into three types on the basis of their mode of action: pectin esterase, hydrolases and lyases (Garg et al., 2016). Pectinases are the growing enzymes of biotechnological sector, showing gradual increase in their market. They hold a leading position among the commercially produced industrial enzymes. Pectinases have many applications in various industries, such as pectin treatment in the food industry, wastewater treatment in the paper and pulp industry, and natural fiber treatment in the textile industry. Recent years, pectinases were also used in some new industries, such as bioethanol and oligosaccharides production. This is the review which covers the recent reports on the classification, production, and application of pectinases. Furthermore, it provides a bird's eye view of the possible application of these enzymes in new commercial sector.

### Classification of Pectic Enzyme

In general, pectinases are divided into three groups according to the cleavage site: hydrolases consisting of polygalacturonase, PG (EC 3.2.1.15); lyase/*trans*-eliminases comprising pectin lyase, PNL (EC 4.2.2.10), and pectate lyase, PL (EC 4.2.2.2); pectin esterase, PE (EC 3.1.1.11) (Garg et al., 2016; N. Sharma et al., 2013). Because pectin is an extremely complex polysaccharide, composed of as many as 17 different monosaccharides and more than 20 different linkages. Therefore, there are new classification of pectin degrading enzymes depending on their action sites in the pectic polymer (Bonnin et al., 2014). Briefly, these pectinases including homogalacturonan (HG) and rhamnogalacturonan (RG)-degrading enzymes (Table 1).

### HG-Degrading Enzymes

HG-degrading enzymes consist of esterases, polygalacturonases, and lyases. Esterases include pectin methylesterases (PME; EC 3.1.1.11; CE 8; [www.cazy.org](http://www.cazy.org)) and pectin acylesterases (PAE; CE 12). PME catalyze the release of methanol from methyl-esterified GalpA, PAE remove acylesters from pectin. Polygalacturonases include endo-polygalacturonases (endo-PG; EC 3.2.1.15; GH 28) and exopolygalacturonases (exo-PG; EC 3.2.1.67; GH 28), both endo-PG and exo-PG catalyze the hydrolysis of the  $\alpha$ -(1–4) glycosidic bond between two adjacent D-GalpA units.

Xylogalacturonan hydrolase (no EC number; GH 28) acts on xylogalacturonan by cleaving  $\alpha$ -1,4-D-galacturonan linkages between two xylosylated GalpA units only to predominantly release the disaccharide Xyl-GalpA. Pectin and pectate lyases split the glycosidic linkage between two GalpA units by catalyzing a  $\beta$ -elimination reaction, thus introducing a double bond on the newly

**Table 1** Enzymes involved in pectin degradation

Enzyme	Abbreviation	EC number	CAZy family <sup>a</sup>	Substrate
<b>HG-degrading enzymes</b>				
Endo-polygalacturonase	endo-PG	3.2.1.15	GH 28	Homogalacturonan–LM pectin
Exo-polygalacturonase	exo-PG	3.2.1.67	GH 28	Homogalacturonan–LM pectin

Pectin methylesterase	PME	3.1.1.11	CE 8	Pectin
Pectin acylesterase	PAE	3.1.1.6	CE 12	Pectin
<b>RG-degrading enzymes</b>				
Rhamnogalacturonan hydrolase	RGH	3.2.1.171	GH 28	Rhamnogalacturonan–pectin
RG-galacturonohydrolase	–	3.2.1.173	GH 28	Rhamnogalacturonan–pectin
RG-rhamnoidhydrolase	–	3.2.1.174	GH 28	Rhamnogalacturonan–pectin
$\alpha$ -L-rhamnosidase	$\alpha$ RHA	3.2.1.40	GH 28	Rhamnogalacturonan–pectin
Endo-arabinanase	eA	3.2.1.99	GH 43	Arabinan
Exo-arabinanase	–	3.2.1.-	GH 93	Arabinan
$\alpha$ -L-Arabinofuranosidase	AF	3.2.1.55	GH 3, 10, 43, 51, 54, 62	Oligoarabinosides
$\beta$ -L-Arabinofuranosidase	–	3.2.1.185	GH 127	Oligoarabinosides
Endo- $\beta$ -1,4 galactanase	eG	3.2.1.89	GH 53	Galactan
Exo- $\beta$ -1,4 galactanase	–	3.2.1.-	GH 35	Galactan
$\beta$ -galactosidase	$\beta$ -Gal	3.2.1.23	GH 1,2,35, 42	Oligogalactosides
Rhamnogalacturonan lyase	RL	4.2.2.23	PL 4, 11	Rhamnogalacturonan
RG-acylesterase	RGAE	3.1.1.86	CE 12	Rhamnogalacturonan
Feruloyl esterase	–	3.1.1.73	CE 1	Feruloylated oligosides

<sup>a</sup>CAZy family data from [www.cazy.org](http://www.cazy.org).Data modified from [Garg et al. \(2016\)](#).

formed nonreducing GalpA end. Pectin lyases (EC 4.2.2.10; PL 1) and pectate lyases (EC 4.2.2.2; PL 1,2,3,9,10) act on methylated and non-methylated substrates, respectively.

### RG-Degrading Enzymes

RG-degrading enzymes include endo- and exo-enzymes are involved in the cleavage of the RG-I backbone. Exo-acting enzymes include RG hydrolase (EC 3.2.1.171), RG-galacturonohydrolase (EC 3.2.1.173), and RG-rhamnoidhydrolase (EC 3.2.1.174). All the hydrolases involved in RG-I backbone degradation belong to the family GH 28, as PGs do. Very few RG-lyases (EC 4.2.2.23) are reported, which ensure the endo-type eliminative cleavage of L- $\alpha$ -Rhap-(1–4)- $\alpha$ -D-GalpA bonds of RGI domains. RG acylesterases (EC 3.1.1.86, CE 12) required for the deacetylation of the RG-I backbone were firstly described in *Aspergillus* species.

Degradation of arabinan involves different enzymes that differ by their recognition sites in the polymer: endoarabinanases, exoarabinanases, and arabinofuranosidases. Endo-arabinanases (EC 3.2.1.99, GH 43) randomly cleave the  $\alpha$ -1,5-linkages in the internal region of the arabinan backbone. Exo-arabinanases (no EC number, GH 93) hydrolyze arabinan from the nonreducing end to release arabinobiose. Arabinofuranosidases (EC 3.2.1.55) act on  $\alpha$ -L-arabinofuranosides,  $\alpha$ -L-arabinans containing (1,3)- and/or (1,5)-linkages, arabinoxylans, and arabinogalactans. They are found in several GH families: 3, 10, 43, 51, 54, and 62.

Similarly to arabinan, the complete degradation of galactan requires different enzymes. Endo- $\beta$ -1,4 galactanases (EC 3.2.1.89, GH 53) act randomly on the galactan core of AGI. Exo- $\beta$ -1,4 galactanases (no EC number, GH 35) release galactose or galactobiose from the nonreducing end of  $\beta$ -1,4-galactan.  $\beta$ -Galactosidases (EC 3.2.1.23) release the terminal nonreducing galactose from various substrates of low molar mass.

22 pectic enzymes were listed in **Table 1**, these enzymes belong to endo/exo-hydrolases, lyases, and esterases, respectively. Among the 15 hydrolases involved in pectin degradation, 8 enzymes belong to GH 28 family. By comparison, lyases and esterases are less than hydrolases, there were only 3 lyases and 4 esterases in **Table 1**.

### Microbial Pectinases

Pectinases are one of the most widely distributed enzymes in bacteria, fungi and plants. The primary source of industrial enzymes is microorganisms, out of which, 50% originate from fungi and yeast, 35% from bacteria, while the remaining 15% are either of plant or animal origin. The pectinases are being produced by various kinds of microorganisms, and almost all the commercial preparations of pectinases are produced from fungal sources. *Aspergillus niger* is the most commonly used fungal species for industrial production of pectinolytic enzymes ([Jayani et al., 2005](#)).

### Acidic Pectinases

Acidic pectic enzymes used in the fruit juice industries and wine making often come from fungal sources, especially from filamentous fungi. An acidic endo-polygalacturonase (EPG4) from a mutant strain of *Penicillium oxalicum* displayed optimal pH and temperature at 5.0 and 60–70 °C towards polygalacturonic acid (PGA), respectively, and was notably stable at pH 2.2–7.0 (Cheng et al., 2016). Wang et al. (2017) showed that the optimal pH and temperature of the recombinant PGA-ZJ5A from *A. niger* were 4.5 and 40 °C, respectively, and this make PGAZ-J5A potentially effective in juice clarification without pH adjustment.

### Alkaline Pectinases

Fungi and yeasts produce mainly acidic PGases, whilst alkaline pectinases are mainly produced by bacteria. The highest reported values for PGase production (from 3600 to 23076 IU/g) were obtained by alkalophilic strains of *Bacillus* spp. and *Streptomyces* spp. under SSF conditions (Favela-Torres et al., 2006). Recently, alkaline thermostable pectin lyase from *A. niger* strain\_WHAK1 was produced, and the optimum pH and temperature values of pectin lyase were 8.0 and 40 °C at 60 min, respectively (Poturcu et al., 2017).

### Thermostable Pectinases

Thermal stability and activity of pectinases are of great significance in biotechnological processes. Recently, a thermo-alkaline pectate lyases (BacPelA) gene from an alkaliphilic *Bacillus clausii* strain was cloned and overexpressed in *Escherichia coli*, and the mature BacPelA exhibited maximum activity at pH 10.5 and 70 °C and showed high cleavage capability on methylated pectins (Zhou et al., 2017).

### Psychrophilic Cold-Active Pectinases

Recently, there has been a new trend in the food industry to adopt low-temperature processing. The reason behind this change in trend is driven by certain economic and environmental advantages, such as, energy saving, retention of labile and volatile flavor compounds, prevention of contamination and elimination of any residual enzyme activity, which is inactivation of enzyme when temperature is raised (Adapa et al., 2014). Merin and de Ambrosini (2015) reported that cold-active and acid-tolerant pectinases from non-*Saccharomyces* yeasts were able to remain active at glucose, ethanol and SO<sub>2</sub> concentrations usually found in winemaking. Five strategies have been suggested to promote proper expression and folding of cold-active enzymes expressed in heterologous host, increasing their solubility, activity, and yield. These strategies include the use of: (i) molecular chaperones; (ii) cold-active promoters; (iii) fusion partners; (iv) psychrophilic hosts, and (v) a combination of these strategies (Santiago et al., 2016).

### Production of Pectinases

There are two fermentation techniques we can use for pectinases production, as many other enzymes these techniques are Solid State Fermentation (SSF) and submerged fermentation (SmF). Usually, the pectinases can be produced via fungal SSF particularly by using *Aspergillus* strains. Industrially, pectinases can be produced from pectin-containing wastes, such as citrus and orange wastes, apple pomace, grape pomace or other fruit residues without any harsh pre-treatment owing to the nature of these substrates and the low moisture content (Kiran et al., 2014). Orange peel wastes are the most suitable candidate for production of pectinase and/or polygalacturonase because they contain more pectin content besides the fermentable sugars (Table 2). Demir and Tari (2014) found that wheat bran, among various agro-industrial wastes, was the most suitable substrate for the production of polygalacturonase using *Aspergillus sojae*. Li et al. (2015a,b,c) compared the typical agricultural residues for production of multi-enzyme complexes (pectinase, CMCase, and xylanase) by *Aspergillus japonicus* PJ01 in SmF and SSF. Compared to SmF, SSF presents unparalleled advantages, such as higher productivity per reactor volume, lower capital and operating costs, lower space requirements, simpler equipment and easier downstream processing. However, there were still some obstacles needed to overcome, such as unsatisfactory reproducibility of the results, difficulty in scale-up, regulating and monitoring of biomass concentration, and complicated methods of product purification (Hölker and Lenz, 2005).

### Applications of Pectinases

#### Food Industry

Pectinase has been used in many fields of food industry, such as fruit and vegetable processing, wine industry, extraction of vegetable oil, tea and coffee processing. Enzymatic treatment for juice extraction is most commonly used nowadays (Fig. 1). Enzymatic treatment prior to mechanical extraction significantly improves juice recovery compared to any other extraction process. Enzymatic hydrolysis of the cell walls increases the extraction yield, reducing sugars, soluble dry matter content and galacturonic acid content and titratable acidity of the products. Furthermore, cellulolytic and pectolytic enzymes mixtures are having wide application to enhance pulp liquefaction and provide a higher yield of juice with high soluble solids content (Sharma et al., 2017b).

**Table 2** Pectic enzymes production using agricultural wastes as the main substrate

Microorganisms	Substrate <sup>a</sup>	Enzyme	Fermentation	References
<i>Aspergillus</i> spp.	WB & OPW	Pectinolytic enzymes	SSF	Heerd et al. (2012)

**Figure 1** Applications of pectinases in various industries.

The use of pectolytic enzymes, in this case preferably alkaline, allows the extraction of vegetable oils in an aqueous process by degradation of cell wall components. Aqueous enzymatic process (AEP) for oil extraction is undoubtedly an emerging technology in the fats and oil industry since it offers many advantages such as cost saving, environmental friendliness, and healthful nutrition. *A. giganteus* pectinases improved oil yield and rheological features without altering chemical composition of olive oil (Ortiz et al., 2017). Cavitation-accelerated aqueous enzymatic extraction (CAEE) of seed oil from *Cucurbita pepo* was performed, an enzyme cocktail comprised of cellulose, pectinase and proteinase can work synergistically in releasing the oil (Li et al., 2016c).

Pectinase treatment accelerates tea fermentation by breaking down the pectin which is present in the cell walls of tea leaves and also destroys the foam forming property of instant tea powders by destroying the pectins (Garg et al., 2016). Pectinase from *A. niger*, *Byssochlamys fulva* and *Mucor circinellus* used for fermentation of tea leaves from *Camellia sinensis* plant, increased production of phenolic compounds increases tea quality (Thakur and Gupta, 2012).

### Animal Feed

The use of pectinases in production of ruminant feed decreases the feed viscosity and increases the absorption of nutrients by ruminants, liberates nutrients by enzymatic action which also reduces the amount of faeces (Kumar and Suneetha, 2014).

### Processing of Textile Material

Retting and degumming are important in processing of textile material. Fibres containing gum should be degummed for its usage in textile industry. Pectin cements the fibres together and this pectin should be degraded. As chemical degumming causes pollution, an alternative use of pectinases and xylanases mixture serves as an eco-friendly and economical solution for pollution with non biodegradable pollutants (Rebello et al., 2017). Recently, a thermo-alkaline pectate lyases gene (*pelA*) from an alkaliphilic *B. clausii* strain S10 was cloned and overexpressed in recombinant *E. coli*, and this pectate lyases have potential application in bioscouring of the textile industry (Zhou et al., 2017). Abdulrachman et al. (2017) expressed a recombinant acidic endo-polygalacturonase from *Aspergillus aculeatus* in methylotrophic yeast *Pichia pastoris* using high cell density fermentation, the recombinant enzyme was evaluated in eco-friendly textile processing in comparison to the conventional alkaline scouring process.

### Paper and Pulp Industry

Pectinases in combination with xylanases are primarily used in the paper industry as a bio-bleaching agent. Unlike the conventional chemical bleaching agents, the use of enzymes is found to be eco-friendly, less harsh and good in improving the quality of the paper (Rebello et al., 2017). Recent studies indicate that ultra filtered concoction of pectinase and xylanase give better result than crude enzyme (Sharma et al., 2017a). Agrawal et al. (2016) reported xylano-pectinolytic synergism from *Bacillus pumilus* AJK was used in bleaching of plywood veneer SAQ pulp.

### Waste Water Treatment

Current deinking process depends upon the use of large amount of environment damaging chemicals. Deinking using enzymes is less polluting, energy saving, gives better performance to achieve the desired deinked pulp properties and results in lower disposal problems (Rebello et al., 2017). Recently, a combination of xylanase and pectinase has been used for deinking of school waste paper (Singh et al., 2012).

### New Applications

The first generation bioethanol (1G) consists in fermenting sucrose from the juice. Sucrose is extracted from large vacuoles present in cells of the stem. Sucrose is then used in fermentation tanks to produce ethanol using *Saccharomyces cerevisiae* (Amorim et al., 2011). The raw material employed in 2G technologies is the plant cell wall, a complex conglomerate of three polysaccharide domains (pectins, hemicelluloses, and cellulose) which are cross-linked with lignin. Hydrolysis of the fibers for production of monosaccharides is the most important and critical step because monosaccharides serve as a base material for production of value-added products such as ethanol, vitamins and organic acids. Li et al. (2016b) investigated the saccharification of orange peel wastes with crude enzymes from *A. japonicus* PJ01. John et al. (2017) review on the potential of citrus waste for bioethanol production, and pectinase enzyme will help in complete degradation of peel by breaking the polysaccharide pectin from cell wall to galacturonic acid in hydrolysis period.

Pectin-degrading enzymes and -modifying enzymes may be used in a wide variety of applications to modulate pectin properties or produce pectin derivatives and oligosaccharides with functional as well as nutritional interests. Many pectin-rich agro-residues such as orange peel waste (OPW), apple pomace, sugar beet, and olive pomace could serve as feedstocks for pectic oligosaccharides (POS) production. Since OPW contain a lot of insoluble polysaccharides, synergistic action of pectinase, cellulase, and xylanase for its depolymerization is required. Production of POS from pectin-rich biomass using commercial pectinase, cellulase, and beta-glucosidase has been reported by some teams (Combo et al., 2013; Concha Olmos and Zúñiga Hansen, 2012; Martínez Sabajanes et al., 2012). Martínez Sabajanes et al. (2012) assessed the effects of the enzyme loadings (polygalacturonases and cellulases) and reaction time on the conversion of polysaccharides into monosaccharides and oligomers using an empirical model. Li et al. (2016a) studied the production of POS from OPW by using multi-enzyme complexes from *A. japonicus* PJ01, and evaluated the prebiotic and antimicrobial potentials of these POS.

# Phospholipases

Angeliki Bourtsala and Dia Galanopoulou, National and Kapodistrian University of Athens, Athens, Greece

## Introduction

Phospholipases (EC 3.1) are enzymes present in all animal, plant, lower eukaryotic and bacterial cells studied so far; they hydrolyze ester bonds of plasma or internal membrane structural lipids (glycerophospholipids and sphingophospholipids, [Fig. 1](#)) to produce simpler metabolites. These are either lipid molecules, which diffuse in the membrane where they exert their further action, or they are water-soluble molecules. The water-soluble metabolites leave the membrane and play their role, in many cases as parts of signal transduction pathways, in a different cellular compartment.

The main classes of phospholipases, hydrolyzing glycerophospholipids, are shown in [Table 1](#), together with their mode of function.

Phospholipases of the A type (PLA) remove one of the two fatty acids from their substrate molecule to produce a lyso (monoacyl) phospholipid, therefore they are acyl hydrolases (EC 3.1.1, a fourth number in the EC numbering system refers to the enzyme substrate). The remaining fatty acid is removed by lysophospholipases, which prevent high concentration of lytic lysophospholipids in the membrane. PLA<sub>1</sub>s are not very specific as some of them degrade neutral lipids as well (acting as lipases) or remove also the acyl chain from the *sn*-2 position, thus showing additional lysophospholipase activity (phospholipases B, PLBs). Where the enzyme appears to have low selectivity for the *sn*-1 and *sn*-2 positions, the term PLA is used. The term PLB should be restricted to enzymes that produce minimal accumulation of lysophospholipids. Phospholipases C and D are phosphodiesterases (EC 3.1.4). PLC removes the *sn*-3 associated phosphobase group to produce 1,2-diacylglycerol (DAG). PLD produces PA, an important intermediate of lipid metabolism, together with the base group associated at the *sn*-3 position. PA has a cone-shaped geometry and negative charge and, therefore, it induces negative membrane curvature promoting vesicle formation ([Kooijman and Burger, 2009](#)). In the presence of short-chain primary alcohols, PLDs exchange the base group of membrane lipids with the alcohol group and this transphosphatidyl reaction produces lipids not normally existing in membranes ([Jenkins and Frohman, 2005](#)). Accordingly, this reaction is used for PLD activity identification. Besides their specificity concerning ester bonds,

**Figure 1** Structures of membrane lipids. Glycerophospholipids may contain, besides choline, H (phosphatidic acid, PA), ethanolamine (PE), serine (PS), *myo*-inositol (PI) or phosphatidylglycerol (cardiolipin) attached to phosphate group esterified at the *sn*-3 position of the glycerol molecule.

**Table 1** Hydrolysis of glycerophospholipids by phospholipases

phospholipase A <sub>1</sub> (PLA <sub>1</sub> )	
phospholipase A <sub>2</sub> (PLA <sub>2</sub> )	
phospholipase C (PLC)	
phospholipase D (PLD)	

there are phospholipases acting only on specific members of the different phospholipid groups. For example, PAF acetylhydrolase (PAF-AH) is a PLA<sub>2</sub> which removes the ester-linked acetic acid from the *sn*-2 position of a PC molecule containing an ether-linked fatty acid at the *sn*-1 position (Fig. 1). Similarly, the phosphoinositide-specific PLC (PI-PLC) hydrolyzes preferentially PIP<sub>2</sub> (Fig. 1).

Sphingophospholipids are ceramide derivatives: sphingomyelins, which are present mainly in the myelin sheath, contain phosphocholine (Fig. 1) or phosphoethanolamine as a base group, thus resembling glycerophospholipids in their three-dimensional structure and general properties. Specific sphingomyelinases hydrolyze phosphocholine group of sphingomyelins by a mechanism resembling that of a glycerophospholipid PLC. The metabolism of sphingolipids is prone to genetic defects of enzymes involved in their degradation; a rare defect in lysosomal acid sphingomyelinase induces accumulation of sphingomyelin in brain, spleen and liver causing mental retardation and early death in infants (Niemann-Pick disease, a sphingolipidosis).

### Interaction of Phospholipases With Lipid–Water Interfaces

As most phospholipases are soluble proteins, they act in lipid–water interfaces. These enzymes are more active *in vitro* on aggregated substrates, becoming fully active above critical micellar concentration (cmc) of the substrate. The soluble nature of phospholipases suggests that their interaction with cellular membranes is possibly a regulatory mechanism which controls membrane lipid degradation. The interaction involves the creation of an enzyme interfacial binding which precedes productive binding in the lipid surface and actual catalysis. Both polar and non-polar interactions are involved in the interfacial binding, while surface charge and perturbations in the interface (like those from factors affecting membrane fluidity, phospholipid packing density or polymorphism of the aggregate) affect phospholipase activity. The membrane surface charge is also influenced by ions present in the aqueous environment. However, although binding of PLA<sub>2</sub>s to membrane phospholipids is enhanced by 10-fold in the presence of Ca<sup>2+</sup>, in its absence binding of the highly cationic human secreted sPLA<sub>2</sub> is promoted by the presence of anionic PA in the bilayer (Kinkaid et al., 1998). PI, also an anionic phospholipid, may have a similar role. Additionally, phospholipase activity is affected by possible conformational changes in the enzyme structure upon its binding in the lipid aggregate (van den Berg et al., 1995) and by the diffusion rate of the enzyme product. This is important especially for the A type phospholipases, as both their products are hydrophobic.

### Classification of Phospholipases

Phospholipases are further classified into different types which are presented in Tables 2 and 3 (mammalian PLA<sub>1</sub>/PLA<sub>2</sub> and PLC/PLD, respectively) and Table 4 (plant phospholipases). This classification is based on their distribution, sequence similarity, structure characteristics and requirements for optimum activity *in vitro*, which is connected to the differential activation of these enzymes.

Although food industry faces phospholipases mainly as hydrolytic tools, their physiological functions show that they are indispensable for cellular metabolism and homeostasis (structural lipids undergo constant metabolic turnover, the rate of their synthesis being counterbalanced by an equal rate of degradation by phospholipases), membrane remodeling and, also, for environmental signal regulation. A good example of membrane remodeling is PAF production in hypersensitivity reactions: PAF is synthesized from alkylacylphosphocholine after *sn*-2 acyl chain removal by a PLA<sub>2</sub> (and not by de novo synthesis). PAF can then be inactivated by PAF-AH.

### Structure and Biological Functions of Mammalian Phospholipases

#### PLAs

Mammalian PLA<sub>1</sub>s are classified into intra- and extra-cellular enzymes based on their cellular localization (Table 2). Besides they all possess a GxSxG lipase motif, the extracellular PLA<sub>1</sub>s contain also the catalytic SHD triad and lipid binding surface loops (β9, lid domain) which affect their specificity, whereas conserved intracellular disulfide bonds provide stability (Bamji-Mirza and Yao, 2017). PLA<sub>2</sub> is the most varied class of phospholipases: it is consisted of 16 groups of enzymes, subdivided into six main types: secreted PLA<sub>2</sub> (sPLA<sub>2</sub>), cytosolic PLA<sub>2</sub> (cPLA<sub>2</sub>), Ca<sup>2+</sup>-independent PLA<sub>2</sub> (iPLA<sub>2</sub>), PAF-AH PLA<sub>2</sub> and the lipoprotein-associated PLA<sub>2</sub> (LpPLA<sub>2</sub>, a subtype of PAF-AH PLA<sub>2</sub>), lysosomal PLA<sub>2</sub> (LPLA<sub>2</sub>) and adipose-specific PLA<sub>2</sub> (AdPLA<sub>2</sub>) (Mouchlis and Dennis, 2016). The main structural characteristics and functions of PLA<sub>2</sub>s are presented in Table 2. The sPLA<sub>2</sub>s are highly disulfide-

**Table 2** Mammalian phospholipases A<sub>1</sub> and A<sub>2</sub>

Classes	Types	Groups	Substrates	Domains	Regulators/cofactors	Functions
PLA <sub>1</sub>	Intracellular		Non-specific	GxSxG lipase motif		- Spermiogenesis - Vesicular transport
	Extracellular	- PS-PLA <sub>1</sub> - mPA-PLA <sub>1</sub> - Lipases	- PS - PA - Phospholipids, triacylglycerols	- GxSxG lipase motif - Catalytic SHD triad (x3) - C residues for disulfide bonds - $\beta$ 9 loop - Lid domain - Catalytic HD dyad (x2) - 6–8 disulfide bonds - Ca <sup>2+</sup> binding in the active site		Regulation of: apoptosis, blood coagulation, PKC signaling (PS-PLA <sub>1</sub> ), platelet aggregation, motility, cell proliferation (PA-PLA <sub>1</sub> )
PLA <sub>2</sub>	Secreted (sPLA <sub>2</sub> )	I–III, V, IX–XIV	Higher activity with anionic phospholipids (PE, PG, PS) or PC vesicles	- Catalytic HD dyad (x2) - 6–8 disulfide bonds - Ca <sup>2+</sup> binding in the active site	Ca <sup>2+</sup>	- Non-catalytic role (aggregates with vesicles acting as ligands for specific cellular targets) - Antibacterial, antiviral functions - Role in inflammatory and autoimmune diseases
	Cytosolic (cPLA <sub>2</sub> )	IVA–F	- Highly AA-specific - Additional PLA <sub>1</sub> , lysophospholipase, transacylase activity	- Catalytic HD dyad (x3) - $\alpha/\beta$ hydrolase domain - C2 domain - PIP <sub>2</sub> binding site - Lid domain	Ca <sup>2+</sup> , also activated by PIP <sub>2</sub> , C1P	Generation of eicosanoids, role in inflammation
	Ca <sup>2+</sup> -independent (iPLA <sub>2</sub> )	VIA–F	- Low specificity for <i>sn</i> -2 AA - Additional PLA <sub>1</sub> , lysophospholipase, transacylase, lipase activity	- 7–8 ankyrin repeats - S in the active site - Catalytic SD dyad	- Ca <sup>2+</sup> -independent - ATP-regulated	- Constitutive low release of fatty acids - Role in insulin release
	PAF-AH PLA <sub>2</sub> secreted or intracellular	VIIB, VIIIA–B	Specificity for PAF, PAF analogues (short <i>sn</i> -2 acyl chain)	- Catalytic SHD triad (x3) - GxSxG lipase motif - $\alpha/\beta$ hydrolase domain		- Response to oxidative stress - Involved in spermatogenesis
	Lipoprotein-specific (LpPLA <sub>2</sub> ) (PAF-AH PLA <sub>2</sub> subgroup)	VIIA	- Specificity for oxidized phospholipids (monomers or small aggregates) - Additional PLA <sub>1</sub> DAG/triacylglycerol hydrolase activity		Ca <sup>2+</sup> -independent	- Associated with LDL, HDL - Role in atherosclerosis, cardiovascular diseases
	Lysosomal (LPLA <sub>2</sub> )	XV		- Catalytic SHD triad (x3) - GxSxG lipase motif - N-terminal signal sequence - N-glycosylation sites - Secreted	Ca <sup>2+</sup> -independent	Major enzyme in pulmonary surfactant metabolism
	Adipose-specific (AdPLA <sub>2</sub> )	XVI	- AA-specific - Additional PLA <sub>1</sub> , acyltransferase activity	- Catalytic HC dyad - Intracellular	Ca <sup>2+</sup> -independent	- Found in adipocytes - Induced by insulin - Antilipolytic agent - Role in peroxisome biogenesis, tumorigenesis

mPA-PLA<sub>1</sub>, membrane phosphatidic acid-specific PLA<sub>1</sub>; C1P, ceramide 1-phosphate.

bonded and Ca<sup>2+</sup>-dependent phospholipases. The cPLA<sub>2</sub> is specific for *sn*-2-associated arachidonic acid (AA), while it contains a lid domain in the catalytic region that regulates substrate uptake (Bamji-Mirza and Yao, 2017). The release of AA leads to the generation of eicosanoids and subsequent inflammatory response. On the contrary, iPLA<sub>2</sub> has low specificity for *sn*-2 AA and it is responsible for the constitutive, low-level release of fatty acids that is necessary for membrane homeostasis. As shown by its name, iPLA<sub>2</sub> does not require Ca<sup>2+</sup> for activity. Instead, it is regulated by ATP and, only indirectly, by Ca<sup>2+</sup> (Mouchlis and Dennis, 2016). Structurally, the ankyrin repeats discriminate the iPLA<sub>2</sub> from the rest PLA<sub>2</sub>s and facilitate protein–protein interactions. Finally, the LPLA<sub>2</sub> and AdPLA<sub>2</sub> are the less studied types, known by their role in lung surfactant metabolism (Bamji-Mirza and Yao, 2017) and AA release in white adipose tissue (Wolf, 2009), respectively.

An additional non-specific acylhydrolase has been recently studied, namely the patatin-like PLA<sub>2</sub> (PNPLA<sub>2</sub>). The mammalian patatin-like enzymes have an active site similar to that of cPLA<sub>2</sub> and they are highly expressed in adipocytes, while their functions are under investigation (Bamji-Mirza and Yao, 2017).

## PLCs

According to their substrate specificity, mammalian PLCs are classified into PC- and PI-PLCs. PC-PLCs are not extensively studied. However, it is well-documented that they rapidly translocate, upon stimulation, from the cytosol to the plasma membrane to regulate cellular functions like those presented in Table 3 (Cocco et al., 2015). PI-PLCs act mainly on PIP<sub>2</sub> to yield, also upon stimulation, the membrane-associated DAG and the soluble inositol triphosphate (IP<sub>3</sub>). Both these molecules are important second messengers, activating protein kinase C (PKC) and regulating Ca<sup>2+</sup> release from internal stores, respectively. PI-PLC group is consisted of enzymes divided into six subgroups ( $\beta$ - $\eta$ ). They are intracellular enzymes, present mainly in plasma but also in nuclear membrane and they are regulated by direct binding to G protein subunits, small GTPases, receptor and non-receptor tyrosine kinases and also by membrane lipids (Balla, 2013; Bunney and Katan, 2011).

**Table 4** Plant phospholipases—cont'd

<i>Classes</i>	<i>Types</i>	<i>Substrates</i>	<i>Domains</i>	<i>Regulators/cofactors</i>	<i>Functions</i>
PLD	PLD $\alpha$	PC, PE, PG	- 2 catalytic HKD motifs - C2 domain	Ca <sup>2+</sup> (~100 mM)	Role in: - H <sub>2</sub> O balance - Response to pathogens, wounding, drought, salinity, freezing stress - ROS production - Seed aging
	PLD $\beta$	- Main phospholipids, NAPE - Active in the presence of phosphoinositides and PE	- 2 catalytic HKD motifs - C2 domain - K/R-rich PIP <sub>2</sub> binding motif	- Ca <sup>2+</sup> (50 $\mu$ M) - PIP <sub>2</sub>	Role in early responses to pathogens
	PLD $\gamma$ PLD $\delta$	see PLD $\beta$ - Mainly PC, PE - Active in the presence of oleic acid	- 2 catalytic HKD motifs - C2 domain	- Ca <sup>2+</sup> (100 $\mu$ M, $\mu$ M-mM) - Oleic acid	Role in: - Response to freezing, drought, pathogens - ROS regulation - Cytoskeletal organization
	PLD $\epsilon$	Main phospholipids	- 2 catalytic HKD motifs - C2 domain	- Ca <sup>2+</sup> - No distinction from PLD $\alpha$ - $\delta$	Role in: - Nitrogen signaling - Root development
	PLD $\zeta$	Mainly PC	- 2 catalytic HKD motifs - PX domain - PH domain	Ca <sup>2+</sup> -independent	Role in: - Regulation of phosphate levels - Vesicular trafficking - Response to auxin
	PLD $\phi$ (SP-PLD)	Not defined	- 2 catalytic HKD motifs - N-terminal signal peptide	Not defined	Not defined

DGDG, digalactosyldiacylglycerol; MGDG, monogalactosyldiacylglycerol; ABA, abscisic acid; NAPE, N-acylphosphatidylethanolamine

## PLDs

Mammalian PLDs belong to either PLD1 or PLD2 types. PLD1 exerts low basal activity, being stimulated by PIP<sub>2</sub>, IP<sub>3</sub>, PKC $\alpha$  and GTP-binding proteins. PLD2 is stimulated also by PIP<sub>2</sub> and negatively regulated by cytoskeletal proteins (Bamji-Mirza and Yao, 2017). They both contain the conserved domains shown in Table 3, while the existence of a negatively regulating loop region in PLD1 discriminates the two types. Mammalian PLD involvement in cellular processes has been attributed mainly to the PA formation. In addition, PLD activity implication in disease-related signaling pathways (for example, those related to cancer invasion and metastasis) makes PLDs prominent therapeutic targets. A specific mammalian lysoPLD (autotaxin) acts on lyso-phospholipids and it is the main source of lysoPA in blood. This enzyme does not include an HKD motif (for PLD functions and autotoxin, see Further Reading).

## Structure and Biological Functions of Plant Phospholipases

### PLAs

Plant PLAs are classified, based on sequence similarity and biological functions, into four classes, namely PC-hydrolyzing PLA<sub>1</sub> (PC-PLA<sub>1</sub>), PA-specific PLA<sub>1</sub> (PA-PLA<sub>1</sub>), secreted low-molecular-weight PLA<sub>2</sub> (sPLA<sub>2</sub>) and patatin-like PLA (pPLA). Concerning PLA<sub>1</sub>s, they show high specificity for their substrate (PC or DGDG for PC-PLA<sub>1</sub> and PA for PA-PLA<sub>1</sub>), while they are involved, besides cell homeostasis, in wound responses and the regulation of vesicular trafficking in plant cells (Table 4). sPLA<sub>2</sub> shows preference for unsaturated fatty acid-containing membrane lipids, while its structure resembles mammalian sPLA<sub>2</sub>. Finally, pPLA exerts both PLA<sub>1</sub> and PLA<sub>2</sub> (but not lipase) activity and it is involved in oxylipin or jasmonic acid (JA) biosynthesis and in responses to several environmental stresses (Wang et al., 2012).

### PLCs

As in mammals, plants possess two different types of PLC, the non-specific PLC (NPC) and the PI-PLC. The first is low-expressed and hydrolyzes mainly PC, PE and lysoPA, but not other lysophospholipids (Hong et al., 2016). NPC is responsible for phospholipid degradation in case of phosphate deficiency and it is also involved in responses to hormones and abiotic stresses (Wang et al., 2012; Pokotylo et al., 2013). PI-PLC, which resembles mammalian PI-PLC $\zeta$ , acts selectively on PIP<sub>2</sub> in a Ca<sup>2+</sup>-dependent manner. Plant PI-PLC is implicated in cytoskeletal organization, root hair and pollen tube growth, as well as in stress-induced responses (Table 4) (Wang et al., 2012; Hong et al., 2016).

### PLDs

PLDs were first discovered in plants. Twelve PLD genes exist in *A. thaliana* when there is only one in *S. cerevisiae* and two in animal cells. Plant PLDs are divided into seven main types, PLD $\alpha$ - $\zeta$ , and the newly-discovered PLD $\phi$  (Wang et al., 2012; Hong et al., 2016; Tang et al., 2016). They all hydrolyze common membrane phospholipids, mostly PC and PE in the presence of Ca<sup>2+</sup>, with the exception of PLD $\zeta$  which shares more homology to yeast and mammalian isoforms. These enzymes respond to several environmental stresses and regulate cytoskeletal organization and reactive oxygen species (ROS) production (Wang et al., 2012; Hong et al., 2016; Bourtsala et al., 2017). PLD $\alpha$  is the constitutive plant PLD. PLD $\beta$  and  $\gamma$ , apart from Ca<sup>2+</sup>, require also PIP<sub>2</sub> as cofactor. Likewise, oleic acid is indispensable for PLD $\delta$  activity.

## Bacterial Phospholipases

In bacteria, besides their role in cellular homeostasis and membrane remodeling, phospholipases have additional functions serving also extracellular nutrition and host penetration. This is the reason why phospholipases, mainly of Gram-negative bacteria, are involved in several diseases. In *E. coli*, the presence of two PLA<sub>1</sub>-type phospholipases has been demonstrated. One is a detergent-resistant protein in the outer membrane of the cell, which acts more as a PLB-type enzyme, showing also lysophospholipase activity. The second is a detergent-sensitive enzyme present in plasma membrane and soluble fractions. sPLA<sub>2</sub>s have also been found in both Gram-positive and Gram-negative bacteria, but they differ in structure from the most eukaryotic sPLA<sub>2</sub>s. In addition, plant-type sPLA<sub>2</sub>s and PLA<sub>2</sub>s containing patatin-like domains (p.e. ExoU from *Pseudomonas aeruginosa*, which is activated by ubiquitin) have been identified in bacteria (Mansfeld, 2017). PLCs are mainly secreted by pathogenic bacteria and, therefore, play important roles in cytotoxicity. Bacterial enzymes have various specificities as they are either PLCs acting on PC/sphingomyelin or PI-PLCs acting on PI (but not on phosphatidylinositol phosphates) and, also, on glycosylphosphatidylinositol (GPI)-anchored mammalian proteins. Microbial PLDs are also involved in cell penetration like those secreted by *Streptomyces* strains. Some of them are the best characterized PLDs and the only microbial PLDs commercially used for the production of natural and synthetic phospholipids. This is favored by their high transphosphatidylase activity (Mansfeld, 2017).

### Phospholipases in Fungi and Protozoa

Phospholipases are also present in lower eukaryotes. PLA<sub>1</sub>s have been found in several fungi strains, like *Aspergillus* and the plant-associated *Fusarium*, and also in protozoa. Genes encoding sPLA<sub>2</sub>s and cPLA<sub>2</sub>-like proteins have been identified in the genomes of various fungi, including the *PLaA* of *A. nidulans* and several *Neurospora* genes. In contrast to bacteria, PI-specific PLCs are present in many lower eukaryotes like yeasts, slime molds (*Dictyostelium discoideum*) and protozoa (Heinz et al., 1998; Leondaritis and Galanopoulou, 2011). Finally, a PC-specific PLD from *S. cerevisiae* (SPO14/PLD1), involved in cell sporulation and maintaining membrane trafficking events, has been extensively studied (Rudge and Engebrecht, 2012).

### Phospholipases in Food Processing

Based on the presence of phospholipids in most foods, the industrial use of phospholipases serves the improvement of food quality and the production of novel foods with improved properties. In addition, because of the recent interest for cleaner technologies, they are used as biocatalysts, often after genetic modification of existing enzymes to create desirable properties, i.e. higher stability. A similar high stability is also shown by extremophile enzymes and this explains their recent use in industry (Song et al., 2005). There are already commercially available enzymes, mainly of microbial origin which have a lower cost, serving edible oil processing or baking and dairy product manufacture. The first phospholipase to be commercialized was the thermostable Lecitase® Ultra (Novozymes A/S, Denmark), a PLA<sub>1</sub> from *Thermomyces lanuginosus*/*Fusarium oxysporum* expressed in *Aspergillus oryzae*, used for the degumming of vegetable oils (Casado et al., 2012). There are also several examples of commercial PLA<sub>2</sub>s, like Lecitase® 10 L (Novozymes), a secreted enzyme of animal origin, also for the degumming of vegetable oils, and LysoMax® (Genencor, USA) of bacterial origin which releases lysophospholipids with emulsifying properties but not fatty acid which are transferred to the hydroxyl group of sterols present in the oil. Industrial application of PLC is rather limited, while PLDs from different plant and microbial sources are commercially available: their application is mainly based on their transphosphatidylolation potential (Ulbrich-Hofmann et al., 2005).

#### Degumming

Vegetable oils separated from either oilseeds or oil-bearing fruits contain, regardless the separation procedure, variable amounts of undesirable material, which may affect the quality of the final product. The major purification process is refining, either chemical which neutralizes fatty acids with alkaline solutions, or physical (usually a distillation process). Degumming, a process converting phospholipids to hydrated gums which can be separated accordingly by filtration or centrifugation, is an essential preliminary step. However, the relative inefficacy of traditional water or acid degumming methods introduced phospholipases in the field for the removal of non-hydratable compounds. Using phospholipases, an effective separation of the aqueous phase containing the hydrolyzed phospholipids is an easy next step (Casado et al., 2012). The main commercial enzymes for degumming purposes, mainly PLA<sub>1</sub> and PLA<sub>2</sub>, have been reviewed recently (Dijkstra, 2010). The aqueous mixture of the degumming product, containing lysophospholipids, can be used in animal feed industry, while the fatty acid fraction can be removed during the subsequent deodorization step. One additional advantage of phospholipases involvement in degumming is the fact that they can be reused. Furthermore, the use of PLCs, leading to the formation of DAG which stays in the oil on refining (instead of fatty acids which must be removed), is recently considered for oil degumming.

#### Bakery Industry

Bread making includes mixing of flour, water and yeast, fermentation of dough and baking of the fermented dough. All these steps are characterized by complex physical, chemical or biochemical changes of the dough main components, namely starch and gluten (the protein network responsible for trapping carbon dioxide during fermentation) which affect the quality and the volume of the final product. To achieve good quality, emulsifiers and enzymes (amylases, oxidases, proteases) are widely used in the bakery industry. It is interesting that, among the enzymes used in food processing, those used in bakery industry constitute one-third of the market (Casado et al., 2012). Although lipid fraction is a minor component of wheat (and flour), the presence of phospholipids is important for bread making: they form monolayers in the gas/liquid interface, stabilizing gas cells and increasing gas retention in the dough. Therefore, their function results in the improvement of bread volume. However, due to the low levels of lipids in flour, exogenous phospholipids must be added during bread making to act as emulsifiers instead of traditional emulsifying agents. The use of phospholipases in bread making is quite recent and it is related to the modification of endogenous or exogenously added phospholipids: the lysophospholipid released improve dough rheological properties. Usually, phospholipases with broad specificity are used in the bakery industry. A good example is the commercially available lipase from *F. oxysporum* (Lipopan F®, Novozymes) which shows both lipase and phospholipase activity (de Maria et al., 2007).

#### Dairy Industry

Milk fat consists mainly of triacylglycerols (>95%) present in the form of fat globules dispersed in the aqueous phase of milk. Triacylglycerols are localized in globule core, while globules are surrounded by a milk fat globule membrane (MFGM), rich in

phospholipids, sphingolipids and cholesterol, which is derived from the membrane of the secreting mammary epithelial cells and act by stabilizing the dispersion. Phospholipid fraction of MFGM consists mainly of sphingomyelin, PC and PE. Depending on the dairy product, MFGM has a different technological role (Casado et al., 2012). For example, in aerated products like ice-cream, milk phospholipids reduce the effect of ice crystals while, during butter manufacture, they influence phase separation and fat crystallization (Fedotova and Lencki, 2008).

Lipolytic enzymes, mainly lipases, have been traditionally used in the cheese industry for enhancing ripening process, including flavor improvement. Recently, phospholipases are used during cheese processing, but with a different purpose, that of increase in cheese yield. Normally, 85%–95% of milk fat is entrapped in the cheese curd, while the rest is lost in the whey. Phospholipases release lysophospholipids which, compared to phospholipids, have better emulsifying potential and promote increased fat retention in the final product. Novozymes proposed the general use of PLA<sub>1</sub>, PLA<sub>2</sub> and PLB for milk fat pretreatment during cheese production (Bourlieu et al., 2009). Apart from the A type phospholipases, the use of PLC and PLD has also been suggested for cheese production, as these enzymes eliminate PC and PE during the procedure.

### Modification of Egg Yolk Properties

Whole eggs and egg yolks are widely used in food industry, as they act as very effective emulsifying agents during the manufacture of bakery products and mayonnaise. Egg yolk is an emulsion containing 32% phospholipids, mainly PC. These phospholipids are present in the layer that surrounds lipoproteins of yolk plasma fraction. As these lipoproteins are the main factor responsible for the emulsifying properties of egg yolk, any modification of the phospholipids, including treatment with phospholipases, leads to the modification of lipoproteins which, in turn, changes emulsifying properties of egg yolk (Casado et al., 2012). Enzymes used in the bakery industry are also used in mayonnaise and sauce industries. One additional advantage in this case is the improvement of heat stability of products, which facilitates pasteurization. In addition to PLAs, PLD has also been used for the modification of egg yolk properties. By using this enzyme, the production of unsaturated fatty acids by PLA<sub>2</sub>, possibly inducing bitter taste to the final product, is avoided (Jaekel and Ternes, 2009).

### Phospholipases in Human Nutrition

Dietary triacylglycerols are absorbed through the intestinal wall after fine dispersion induced by biological emulsifiers (bile acids) and are subsequently degraded by water-soluble lipases in the intestine. Degradation products diffuse into intestinal epithelial cells, where they are reconverted to triacylglycerols and packaged to chylomicrons for transfer to tissues. Similarly, dietary phospholipids are degraded to lyso (1-acyl) phospholipids by an intestinal PLA<sub>2</sub>. Therefore, development of novel lipids by linking fatty acids of biological interest (p.e. omega-3 fatty acids) at the *sn*-1 position of dietary phospholipids is an interesting new approach in human nutrition (Casado et al., 2012). In a similar attempt, yolk suspension was hydrolyzed by a PLA<sub>2</sub> (Lesitase 10 L, Novozymes) before omega-3 fatty acids being linked to egg lysophospholipids.

Phospholipase-produced lysophospholipids have also been used for better absorption of nutrients since they form smaller micelles in the intestinal track compare to phospholipids. Furthermore, hydrolysis of egg yolk PC by cabbage or *Streptomyces chromofuscus* PLD yields a lipid mixture rich in PA (Shnigir and Kisel, 2004), which has been used for medical purposes. Another example of phospholipases involved in human nutrition is the production of PS whose availability from natural sources is limited. Clinical trials have indicated that PS supplementation in the diet may improve mental functions. Therefore, methods for the PLD-catalyzed conversion of PC to PS have been developed (Hokosawa et al., 2000).

## Enzyme Fundamentals

Enzymes are proteins with a biological function. They are highly selective biological catalysts involved in many metabolic processes in all organisms (Bugg, 2012). Enzymes accelerate, or catalyze, chemical reactions by converting substrates into products. Enzymes consist of one or more polypeptide backbones of a defined amino acid sequence, arranged in a specific folding. The shape of natural folding is known as native state. Enzyme activity is related with its three-dimensional structure. The deteriorative enzyme activity is not desirable in food since it causes the loss of quality during storage.

As shown in Fig. 1, four distinct levels of structure characterize the enzyme globular protein. The primary structure consists of a unique sequence of amino acids in polypeptide chain. The folding of the polypeptide chain gives rise to the secondary structure, which are the  $\alpha$ -helix and  $\beta$ -sheet structures. The structures are held by the hydrogen bonds of the amino acids. Tertiary structure is defined by the unique three-dimensional arrangement of the polypeptides. It describes the relationship and interaction of secondary structures and usually governed by the hydrogen bonding, hydrophobic interactions, electrostatic interactions and van der Waals forces. The structure formed by the union of more than one protein molecule is known as quaternary structure. Enzymes usually shift between several similar structures in order to function. These functional arrangements which are the tertiary and quaternary structures are called conformations. Thus, the changes in the native conformation are addressed as conformational

**Figure 1** The four level of protein structure. Retrieved from National Institutes of Health, National Human Genome Research Institute. Talking Glossary of Genetic Terms: Protein. <https://www.genome.gov/glossary/>.

changes. Enzyme conformational changes can result in partial or total inactivation of enzyme, no change in the activity or even enzyme activation. The enzyme conformation is affected by the pH, temperature (T), pressure (P), salt concentration and chemical or physical processes, which can cause denaturation of the protein. Sometimes denaturation can be reversible because the primary structure of the polypeptide is conserved in the process and after the denaturing factor is removed, the protein regenerates and resumes its function. Other times the denaturation is irreversible leading to partial or total enzyme inactivation. With respect to thermal treatment, high pressure processing (HPP), ultrasound (US), thermosonication (TS) and pulsed electric fields (PEF) of apple juice and strawberry puree, [Sulaiman et al. \(2017a, 2017b\)](#) demonstrated PPO did not recover the lost activity since the residual activity of PPO obtained after the process remained constant during 1 month at ambient temperature and refrigerated storage at 3 °C.

Enzymes are categorized in six groups according to the reactions they catalyze: oxidoreductases (1), transferases (2), hydrolases (3), lyases (4), isomerases (5), and ligases (6). In addition, every enzyme is classified with Enzyme Commission number (EC). The EC number consists of a sequence of four numbers, where the first number specifies the enzyme group.

### Food Endogenous Enzymes

While some commercial enzymes are added to foods to promote important reactions, most of endogenous native enzyme in foods can degrade nutrients and cause quality deterioration. The undesirable enzymatic reaction occurs when the cells contained in the foods of plant (e.g. fruit, vegetable) or animal origin are disrupted during processing and get in contact with its substrates. Fruit and vegetable often contain endogenous enzymes, which sometimes are more heat resistant than microorganisms ([Silva and Gibbs, 2004, 2009](#)). Although the microbes are first considered in the design of new thermal and non-thermal processes to pasteurize food products, spoilage enzymes should also be inactivated to a minimal level, to avoid deteriorative chemical reactions during storage and allow a longer shelf-life of the food ([Silva and Sulaiman, 2017](#)). The activity of deteriorative enzymes naturally present in foods such as polyphenoloxidase or polyphenol oxidase (PPO), peroxidase (POD), pectinmethylesterase (PME), polygalacturonase (PG),  $\beta$ -glucosidase (BGL) and lipoxygenase (LOX), can affect food color, flavor, texture and nutritional quality ([Ludikhuyze et al., 2003; Vernwal et al., 2006; Zhang et al., 2005](#)).

## Polyphenoloxidase (PPO) and Enzymatic Browning in Fruit and Vegetable Products

### Food Browning

Browning reactions occur in food during processing and storage. There are two types of browning reactions, the non-enzymatic browning (e.g. Maillard and caramelization) and the enzymatic browning. It is well known that fruits, vegetables and certain crustacean seafood (e.g. shrimp) experience enzymatic browning when plant tissues are exposed to air during handling, processing and storage. This undesirable reaction is due to the activity of polyphenoloxidase (PPO) endogenous enzyme, which is naturally present in the plant tissues. PPO catalyses the degradation of phenolic fruit constituents to o-quinones in the presence of oxygen. The resulting o-quinone will subsequently polymerize with other o-quinone, protein or amino acids producing undesirable brown compounds ([Golagoldhirsh et al., 1984; Vámos-Vigyázó, 1981](#)). The enzymatic browning of fruit and vegetable tissues has been an on-going concern in the industry with economic losses due to the negative impact on the colour, appearance, flavor, nutritive properties of food and subsequent consumer's acceptability ([Mayer and Harel, 1991; Dauthy, 1995; Whitaker and Lee, 1995; Lee, 1999](#)). Enzymatic browning can occur due to mechanical injuries in whole fruits/vegetables during postharvest handling and storage, and is also common in processed food products such as juices, purees/smoothies, cut fruits/vegetables (e.g. cubes, slices, etc).

### PPO Enzyme

Polyphenoloxidase or polyphenol oxidase or PPO (EC 1.14.18.1) is an oxidoreductase copper-containing metalloprotein that is responsible for the browning of fruits and vegetables (e.g. apple, pear, peach, potato, lettuce, mushroom), and certain seafoods such as crustaceans ([Martinez and Whitaker, 1995](#)). Catechol oxidase, tyrosinase, phenolase, catecholase, o-diphenol oxidase and are some of the names of PPO. PPO catalyzes the hydroxylation of monophenols to o-diphenols and the oxidation of o-diphenols to o-quinones. Then the quinones may condense and react non-enzymatically with other phenolic compounds, amino acids, proteins and other cellular constituents to produce brown melanoidin pigments ([Rouet-Mayer et al., 1990; Whitaker and Lee, 1995](#)). PPO enzyme can be active in a range of pH from 3.5 to 9 and temperatures from 15 to 60 °C ([Dalmadi et al., 2006; Navarro et al., 2014; Siddiq et al., 1993; Wu et al., 2013; Yang et al., 2000](#)). [Fig. 2](#) shows an example of PPO structure from grape berry which has been successfully crystalized and modelled ([Virador et al., 2010](#)). The crystal structure is a monomeric protein of 38.4 kDa mass with an ellipsoidal shape and dimension of  $57 \times 48 \times 48$  Å ([Virador et al., 2010](#)). The secondary structure is primarily  $\alpha$ -helical with four helix bundle which are composed of  $\alpha$ -helices  $\alpha 4$ ,  $\alpha 5$ ,  $\alpha 12$  and  $\alpha 14$  ([Fig. 2](#)). The active site is the dicopper in the centre of the four helix bundle ([Fig. 2](#)). Removal or distortion that causes the conformational changes of the overall ellipsoidal shape will inactivate the enzyme. The active site of grape PPO was found to be similar to the sweet potato PPO described by [Klabunde et al. \(1998\)](#).

**Figure 2** Ribbon model of PPO grape (*Vitis vinifera* L., cv. Grenache) showing the overall ellipsoidal shape, two  $\beta$ -shape and the dicopper center within a four-helix bundle. Adapted from Virador et al. (2010).

## PPO Control and Inactivation in Fruit and Vegetable Products

### PPO Inhibition in Foods by Chemical Agents

Anti-browning agents such as sulphites, sodium chlorite, cysteine, kojic acid, ascorbic acid and cinnamic acid are used for food preservation to control enzymatic browning (Lambrecht, 1995; Vámos-Vigyázó, 1995; Guerrero-Beltrán et al., 2005; Queiroz et al., 2008). These anti-browning compounds have different mechanisms in inhibiting PPO activity. Ascorbic acid reduces o-quinones to monophenols or diphenols (McEvily et al., 1992); cysteine produces colourless adducts when reacting with o-quinones (Walker and Reddish, 1964); kojic acid inhibits PPO and bleached melanin due to chemical reaction of the browning pigment to colorless compound (Iyidogan and Bayindirli, 2004); benzoic and cinnamic acids make a complex with copper at the active site of PPO and sodium chlorite as a strong oxidizing agent which generates chlorine dioxide under acidic condition reduce the pH of the food thus inhibit PPO (Lu et al., 2006). Natural compounds such as honey also have inhibitory effects on PPO (Chen et al., 2000). Honey from different floral sources reduced PPO activity (range of 2% to 45%) in fruit and vegetable homogenates (Chen et al., 2000).

### PPO Inactivation by Thermal and Non-thermal Processes

Consumers have been choosing preservative free foods and there is a global trend to reduce the use of chemical additives that have adverse effect towards human health. Thermal processing is the most reliable method for controlling fruit/vegetable browning, often referred to by the industry as blanching or pasteurization. However, heat employed in thermal processing negatively affects the fruit flavor (Silva et al., 2000) and can degrade some nutrients such as vitamin C, polyphenols and other antioxidants (Castro et al., 2008; Volden et al., 2008). There is an increasing consumer demand for convenient, healthy and ready-to-eat fruit/vegetable products such as canned baby foods, fruit juices, fruit puddings, fruit jams, and so forth. These products should maintain the original characteristics flavor, texture, color, nutrient and aroma of the fruits/vegetables (Landl et al., 2010) and offer a reasonably extended shelf life. Due to the demand for fresh and minimally processed, preservative free fruit/vegetable products, the study and potential of emerging non-thermal food preservation technologies alone and combined with mild heat to inactivate PPO enzyme in foods is an active area of research. The following technologies and their impact on PPO inactivation were reviewed in the next sections: ultrasound (US), high pressure processing (HPP), and pulsed electric fields (PEF). As the enzyme inactivation and kinetics might be affected by the medium or food in which the enzyme is processed (Rapeanu et al., 2006), the studies reviewed have processed the fruit/vegetable product containing the enzyme. Also, in terms of industrial application, it is desirable to process the real fruit/vegetable product instead of an extract containing the enzyme.

## PPO Inactivation in Fruit and Vegetable Products by Thermal Processing/Blanching

### Thermal Processing Fundamentals

Heat is the common method used by food industry to inactivate endogenous fruits and vegetables' enzymes. Thermal processing is an ancient and established technique for stabilizing and preserving foods, as heat inactivates the microbes (Silva and Gibbs, 2009;

Silva et al., 2014) and denatures permanently deteriorative enzymes. Heat from steam is usually applied indirectly by heat exchangers to juices and purees. As enzymes can be active at freezing temperatures (Arighi et al., 1936) and spoil whole/pieces of frozen fruits and vegetable during storage, blanching is usually carried prior to the freezing process. Blanching involves the direct contact of steam or hot water with the whole or cut pieces of fruit and vegetables for a certain period of time. The biggest drawback of using heat to preserve foods is the destruction of thermosensitive nutrients, which include vitamins, flavors, color, texture, carbohydrates and other water-soluble components (Queiroz et al., 2008). In addition, blanching is an energy and water intensive technology, thus economically unfavorable. The thermal stability of PPO is dependent on the fruit/vegetable species, and within one species on the cultivar. Depending on the fruit/vegetable, exposure to 70 to 100 °C partially or completely inactivates PPO (Dimick et al., 1951; Ludikhuyze et al., 2003; Silva and Gibbs, 2004). The thermal inactivation kinetics of PPO was described with simple first order model (Dimick et al., 1951; Sulaiman et al., 2015a) and first order biphasic model.

### Effect of Thermal Processing/Blanching on PPO Enzyme

A review of recent works focusing on the effect of thermal processing and blanching of fruit and vegetable products and its effect on endogenous PPO enzyme was carried out and is presented on Table 1. The results vary from 45% residual activity (RA) on slices of red cabbage blanched at 100 °C for 10 min (Bernstein and Noreña, 2016) to <5% RA in Boskoop cloudy apple juice exposed for 1 min to 70 °C (Buckow et al., 2009), and 0.3% RA in Camarosa strawberry puree exposed for 5 min to 70 °C (Sulaiman and Silva, 2013). The variability within the same fruit is also very high, depending on the fruit cultivar or variety. Taylor's Gold pear puree processed for 10 min at 85 °C resulted in 0.3% RA (Sulaiman et al., 2015a), whereas Packam pear puree RA was 53% after 100 °C for 0 min (Zhou et al., 2018). Regarding strawberry puree, 90 °C for 15 min had no effect on Festival PPO enzyme and minor effect on PPO in Aroma strawberry puree (Terefe et al., 2010) as opposed to 0.3% RA in Camarosa puree after 5 min at 70 °C. Other very resistant PPO enzymes include pumpkin, mushroom, mango and pineapple.

## PPO Inactivation in Foods by High Pressure Processing (HPP) and High Pressure Thermal Processing (HPTP)

### HPP Fundamentals

Although Hite described first the application of HPP to preserve milk long time ago (Hite, 1899), not until 1980s more interest on the HPP technology was observed, leading to several studies and developments on various aspects of this novel pasteurization treatment, and the introduction of the first HPP pasteurized foods in Japan in the early 1990s (Van Loey et al., 2003). In 2013 units with 525 L capacity and 3000 kg/h throughput were launched by Hiperbaric, and in 2015, 315 HPP industrial units were already installed worldwide, mostly in the USA and Europe, and (Balda, 2018).

High pressure processing (HPP) or high hydrostatic pressure (HHP) is a cold pasteurization technology by which vacuum packed food products are introduced in a vessel containing a pressure transmitting liquid (usually water), and submitted to a high level of isostatic pressure (300 to 600 MPa). The pressure builds up to a desired maximum pressure which is held for a certain time, followed by a quick decompression to end the HPP cycle. The product is removed and stored generally under refrigerated conditions. HPP is a commercial pasteurization considered as an alternative to conventional heat treatment, because of its ability to inactivate pathogenic and spoilage microorganisms at room or mild temperatures (Evelyn and Silva, 2018; Silva and Evelyn, 2018). Thus, the nutritional and sensory characteristics of the original fresh fruit/vegetables are better retained compared to an equivalent thermal process (Houška and Silva, 2018). Cold pressed HPP fruit juices have been the drivers of this technology, but smoothies, guacamole, oysters, ham and fresh meat products are also available in the supermarkets worldwide (Balasubramaniam, 2003). Several studies have been demonstrating that room temperature HPP has limited effectiveness towards the inactivation of certain microbial spores and enzymes associated with food quality degradation (Silva and Evelyn, 2018; Terefe and Buckow, 2018). Therefore, the combination of HPP with mild heat (60–90 °C) also referred to as high pressure thermal processing (HPTP) has been investigated for more effective spore and enzyme inactivation.

### Effect of HPP on Enzymes

With respect to enzymes, HPP at ambient temperature typically breaks the non-covalent bonds (e.g. hydrogen bonds, in the enzymes), but does not break covalent bonds (e.g. peptide bond in enzyme) (Hendrickx et al., 1998; Mozhaev et al., 1996). Therefore, HPP mainly affects tertiary and quaternary structure of the enzymes (Terefe and Buckow, 2018). The hydrogen bond maintaining the helical secondary structures is also ruptured at HPP > 400 MPa (Hendrickx et al., 1998). Since HPP disrupts the enzyme secondary, tertiary and quaternary structures, the enzyme may be activated or inactivated (Mozhaev et al., 1996), depending on the levels of pressure treatments. The factors influencing the effect of HPP process on the enzyme includes the origin of the enzyme (fruit/vegetable cultivar), the level and duration (time, t) of pressure (P) treatment, and for heat assisted pressure processing (HPTP), the temperature (T) of the treatment. Generally, it is expected a higher enzyme inactivation or lower enzyme residual activity (RA) when higher T, P and t are used for processing.

### Effect of HPP and HPTP on PPO Enzyme

A few modeling studies of PPO inactivation by HPTP revealed non-linearity, best described by a first order biphasic model (Weemaes et al., 1998; Rapeanu et al., 2005; Sulaiman et al., 2015b). This model was applied successfully to HPTP inactivation of PPO in Taylor's Gold pear and Camarosa strawberry purees (Sulaiman et al., 2015b). Tables 2 and 3 show a review of HPP/HPTP processes applied to fruit and vegetable products, respectively, and its effect on PPO residual activity (RA). Except for whole strawberry PPO which was fully inactivated by 15 min at 600 and 800 MPa at room temperature (Garcia-Palazon et al., 2004), room T HPP only partially inactivate PPO enzyme in Scirose apple puree (40% RA after 600 MPa - 15 min), whole raspberry (70% RA, 800 MPa - 15 min), strawberry puree from Ruby Gem, Festival, Camarosa and whole Pajaro strawberry varieties (19%–83% RA, 600 MPa), peach puree (5% after 22 min at 517 MPa), and Hass avocado puree (16% after 30 min at 689 MPa) (López-Malo et al., 1998; Garcia-Palazon et al., 2004; Guerrero-Beltrán et al., 2004; Terefe et al., 2013; Sulaiman et al., 2015b). Therefore several authors attempted HPTP, which still seems to have only partial inactivation of the enzyme. For example RA of Nashi pear puree was 88% after 15 min exposed to 600 MPa-62 °C, apple juices/purees from Boskoop, Scirose, Royal Gala, and Amasya exposed to 450–700 MPa and 50–71 °C resulted in RA in the range of 11%–60% (Bayindirli et al., 2006; Buckow et al., 2009; Sulaiman et al., 2015b). Camarosa strawberry puree was fully inactivated after exposure for 15 min to 600 MPa-71 °C (Sulaiman et al., 2015b). The increase of T in HPTP reduced the RA of the PPO enzyme of Royal Gala apple puree and Queen pineapple puree (Chakraborty et al., 2015). The combination of a very high P with a very high T was still incapable to fully inactivate PPO enzyme in pumpkin puree (54% RA after 900 MPa - 121 °C - 3 min) and red plum puree (50% RA, 900 MPa - 95 °C - 1 min) (García-Parra et al., 2014, 2018). The differences between the results published might be just due to different fruit cultivars, growing conditions and ripening stage which can have different isoenzymes (Terefe et al., 2014). In addition fruit composition (pH, soluble solids, etc.) could also be the reason for different PPO inactivations in different cultivars. For example, Rapeanu et al. (2006) concluded PPO resistance from Victoria grape was higher in the grape must than the buffer solution at the same pH.

Undesirable fruit enzyme activation was registered under certain processing conditions: 600 MPa HPP at RT for 15 min caused PPO activation in Taylor's Gold and Nashi pear purees, and Royal Gala apple puree (Sulaiman et al., 2015b); 1 cm slices of Bartlett pear submitted to 400 MPa for 10 min activated PPO enzyme by a factor of 5 (Asaka and Hayashi, 1991). Activation at room temperature 600 MPa was also observed in the vegetables sweet potato and mushroom (Matser et al., 2000; Tribst et al., 2016).

					22	5	
Avocado	Hass	Puree	HPP at RT	689 MPa	30	16	López-Malo et al. (1998)
		acidified					
Avocado	Hass	Paste	HPP at RT	60 <sup>a</sup> MPa	3	51	Jacobo-Velázquez and Hernández-Brenes (2010)

<sup>a</sup>HPP at RT means high pressure processing at room temperature non-thermal conditions (T < 30 °C).<sup>b</sup>For HPTP, temperature is the average during constant pressure phase of the HPP cycle.<sup>c</sup>The fruit and vegetable products were vacuum packed before HPP and HPTP processing.

Furthermore, activation was observed after a HPTP treatment of Taylor's Gold pear puree (600 MPa – 71 °C-15 min) and pumpkin puree (900 MPa – 58 °C-5 min) (Sulaiman et al., 2015b; García-Parra et al., 2018). The increase in enzyme activity with HPP or HPTP is unacceptable as this can result in undesirable browning, and changes in flavour and nutritional quality of the juices during product processing and storage (Terefe and Buckow, 2018).

### Comparing Thermal With HPTP Inactivation of PPO

For certain fruit/vegetable cultivars, there is no extra benefit in using the thermal assisted HPP technology (HPTP) to potentiate and increase the inactivation of PPO. For example, thermally treated pumpkin puree at 90 °C for 10 min resulted in 55% residual activity. The same authors attempted 900 MPa combined with 121 °C for 3 min and obtained a similar RA of 54% (García-Parra et al., 2018). So, for pumpkin puree, an exclusively thermal process seems to be a better option. The PPO RA of plum puree containing peel after 85 °C for 5 min was approximately 50%. Using HPTP at 600 MPa-85 °C for 1 min resulted in 65% RA (García-Parra et al., 2014). This might indicate that HPTP is not suitable for PPO inactivation in Crimson Globe plum puree, being preferable to use a higher temperature thermal process alone. The Royal Gala apple puree PPO RA of 23% after a thermal treatment of

**Table 3** Residual activity of polyphenoloxidase in vegetable products after non-thermal high pressure processing (HPP) and high pressure thermal processing (HPTP)<sup>c</sup>

Vegetable	Cultivar	Medium	Type of treatment <sup>a</sup>	Treatment conditions <sup>b</sup>	Time (min)	Residual Activity (RA, %)	Reference
Pumpkin	nr	Puree	HPTP	900 MPa - 121 °C	3	54	García-Parra et al. (2018)
				900 MPa - 58 °C	5	111	
Sweet potato	nr	Puree	HPP at RT	600 MPa	30	380	Tribst et al (2016)
		0.5 cm cubes			30	200	
Mushroom	nr	Whole	HPP at RT	950 MPa	5	10	Matser et al. (2000)
				800 MPa	5	25	
				600 MPa	5	153	
Cocoyam	nr	Puree	HPP at RT	600 MPa	30	60	Tribst et al (2016)
		0.5 cm cubes			30	75	
Carrot	Peruvian	Puree	HPP at RT	600 MPa	30	10	Tribst et al (2016)
		0.5 cm cubes			30	25	
Coriander leaves	nr	Paste	HPP at RT	600 MPa	5	38	Nath et al. (2016)

<sup>a</sup>HPP at RT means high pressure processing at room temperature non-thermal conditions ( $T < 30\text{ }^{\circ}\text{C}$ ).

<sup>b</sup>For HPTP, temperature is the average during constant pressure phase of the HPP cycle. For pumpkin puree the temperature is after the compression phase/adiabatic heating (García-Parra et al., 2018).

<sup>c</sup>The vegetable products were vacuum packed before HPP and HPTP processing.

15 min at  $75\text{ }^{\circ}\text{C}$  is lower than 40%, the residual activity value obtained after 15 min HPTP at 600 MPa-  $71\text{ }^{\circ}\text{C}$  (Sulaiman et al., 2015a, 2015b). For Taylor's Gold pear puree while 600 MPa -  $71\text{ }^{\circ}\text{C}$  for 15 min activated the enzyme (RA = 127%), a great inactivation is observed at  $85\text{ }^{\circ}\text{C}$ -10 min (RA<1%) (Sulaiman et al., 2015a, 2015b). The heat processing of Boskoop cloudy apple juice at  $70\text{ }^{\circ}\text{C}$  for 1 min resulted in <5% RA of PPO, whereas a 15 min HPTP at 700 MPa- $70\text{ }^{\circ}\text{C}$  resulted in a higher RA of 11%, revealing HPTP was not acceptable for PPO inactivation in this apple cultivar juice (Buckow et al., 2009). This could be possibly due to the protective effect of pressure against temperature. Hydrogen bonds in proteins are generally stabilized by pressure and destabilized by heat (Damodaran, 1996; Heremans, 1982).

## PPO Inactivation in Foods by Ultrasound Processing (US) and Thermo-sonication (TS)

### Ultrasound Fundamentals

Ultrasound is composed of sonic waves with frequencies higher than human ear audible sound. Power ultrasound or high intensity ultrasound uses lower frequencies (kHz) than medical applications, and are characterized by sound intensity or acoustic intensity ranging between 10 and  $1000\text{ W/cm}^2$  (Feng and Yang, 2011). Sonication refers to the power ultrasound processing of liquid foods or beverages for microbial and enzyme inactivation to increase shelf life. Thermo-sonication (abbreviated TS) is the combined use of power ultrasound with moderate temperatures to process the food and improve the efficiency of thermal process alone. The application of an external mild pressure during sonication (e.g. 2 atm =  $2 \times 101.3\text{ kPa}$ ), referred as manothermo-sonication (abbreviated MTS), is one step further in terms of microbial and enzyme inactivation. The sonication generates bubbles in the liquid food as the wave energy propagates and this phenomenon is called acoustic cavitation. The formation and collapse of tiny bubbles can occur in few microseconds and the cavitation is increased with acoustic energy (power). Vigorous mixing of gas bubbles and liquid food occurs which accelerate heat and mass transfer. In addition to the mechanical effects of cavitation, chemical effects can also occur during sonication, with the formation of reactive free radicals.

The ultrasound unit consists of a generator which converts electricity into high frequency alternating current and a transducer for converting the current into mechanical vibrations. The probe is the most efficient method to sonicate liquid food because of its direct contact with the food. The probe is also referred as sonotrode, ultrasonic tip, horn or finger. Food research ultrasound units are available with a selection of sonotrodes with different geometries for different applications, which present different maximum amplitude (energy). Some of the units available for research are equipped with a flow cell which allows continuous mode ultrasound experimentation (Milani and Silva, 2017), one step further close to industrial application. The flow cell is surrounded by a jacketed vessel where cold water (or other cooling liquid) is circulated to better control the temperature of the liquid food product during the ultrasound treatment, avoiding the increase of temperature. The flow cell with controlled temperature can also be used in batch process for kinetic experiments (Evelyn and Silva, 2016; Milani et al., 2016; Milani and Silva, 2017). The probe conveys the sonic vibrations to the treated food and the energy transmitted to the food medium can be expressed as sound intensity ( $\text{W/m}^2$ ), which is proportional to the amplitude of the wave ( $\mu\text{m}$ ). Usually the amplitude/energy can be adjusted in the settings of the ultrasound unit. The specific acoustic energy/power or volumetric acoustic energy/power density (AED/AEP, in  $\text{W/ml}$  of processed liquid sample) is also very useful to quantify the energy requirements of the process for a given volume of treated food. The higher the sound intensity/energy/power, the higher will be the mechanical and sonochemical effects. The energy supply for the ultrasound

treatment can be set in continuous or in pulses. Wave frequency is given in kHz and ultrasound units usually present a fixed frequency and varying amplitude, the last directly proportional to the energy or power consumed and energy delivered to the food. The frequency of most units used for food research is around 20–24 kHz. Higher food medium temperature (T) and/or pressure (P) increase the efficiency of the TS/MTS process.

### Ultrasound Effect on Enzymes

Ultrasound is known to break up proteins, starches and other large biopolymers (Weiss et al., 2011) such as enzymes, and can affect the protein and enzyme functionality. The damage of protein structure by ultrasound is desirable since it results in enzyme inactivation. Changes in enzyme biological activity are due to changes in the folding of the proteins, the secondary and tertiary structures of the enzyme. The rapid formation and collapse of bubbles change the enzyme's environment, such as temperature, pressure, shear stress and pH, which can cause the enzyme inactivation (Feng and Yang, 2011; Sala et al., 1995; Terefe et al., 2015a). Under these extreme changes, hydrogen bonds and van der Waals bonding in the enzyme polypeptide chains can be broken down (Islam et al., 2014), resulting in loss of enzyme activity (Zhong et al., 2004). Additionally, the formation of high energy free radicals due to sonication could lead to the sonolysis of water molecules (O'Donnell et al., 2010). The free radicals can react with the amino acids of the enzyme structure, subsequently affecting the enzyme activity and its catalytic function (Barteri et al., 2004; López et al., 1994; Potapovich et al., 2003).

The sonication processing conditions can cause partial or total inactivation of enzyme activity, depending on the type and the fruit/vegetable source of the enzyme. Often room temperature sonication has minor effects on enzyme activity (O'Donnell et al., 2010), so it is necessary to use TS or MTS for effective enzyme inactivation (Silva and Sulaiman, 2017). The effect of ultrasound treatment on enzyme depends on ultrasonic intensity (acoustic energy), duration of process (t), temperature (T), pressure (P), food pH and ionic strength. The medium in which the enzyme is suspended for ultrasound processing affects hugely the inactivation of enzymes (Özbek and Ülgen, 2000; Terefe et al., 2015a). For example, the extracted thermostable orange pectinmethylesterase (PME) was suspended in orange juice and citrate buffer with the same pH (3.5) and processed by MTS (117  $\mu$ m, 72 °C, 200 kPa) and thermal treatment alone. The MTS reduced the  $D_{72^{\circ}\text{C}}$ -value of PME suspended in orange juice from 500 min (only thermal process) to 1.24 min, and when suspended in citrate buffer, the  $D_{72^{\circ}\text{C}}$ -values were very different and reduced from 20 to 0.8 min (Vercet et al., 1999). The methodology used to extract the enzyme and the different media submitted to TS affect the enzyme inactivation rate. Therefore, the review showed in the following section will focus on studies of enzymes processed in their natural food environment. This approach will reproduce better real-case-scenario conditions (Table 3) (Table 3).

### Effect of Ultrasound (US) and Thermosonication (TS) on PPO Enzyme

The TS inactivation of PPO in Taylor's Gold pear puree, Royal Gala apple puree, Camarosa strawberry puree and Golden Delicious apple juice was linear and followed the first order kinetics model (Başlar and Ertugay, 2013; Sulaiman et al., 2015a). Table 4 shows the residual activity of PPO in several juices/purees after TS and US processing. The TS process was much more efficient than sonication at room temperature (US), yielding the following RA after 10 min treatment: 1%–4% at 72 °C in Taylor's Gold pear, Royal Gala apple and Camarosa strawberry purees (Sulaiman et al., 2015a); 2% at 65 °C for *Pyrus bretschneideri* pear juice (Saeeduddin et al., 2015); 5%–6% at 60 °C for Fuji apple juice (Abid et al., 2014) and carrot juice (Jabbar et al., 2015). On the other hand, the values of RA after a 10 min sonication process without heat were 89% for *P. bretschneideri* pear juice, 58% for Taylor's Gold pear puree, 59% for Royal Gala apple puree, 85% and 97% for juices of 2 apple cultivars, 84% for pineapple diluted juice (Costa et al., 2013) and 25% for strawberry puree. From the studies analyzed it is also obvious the higher the TS temperature, the higher is the PPO inactivation with lower RA values. Surprisingly, Cheng et al. (2007) registered 80% increase in activity of guava juice PPO after a 30 min ultrasound treatment at 15–20 °C.

### Comparing TS With Thermal Inactivation of PPO

The comparison of TS with thermal treatment alone at similar temperatures demonstrated the potential of power ultrasound to assist thermal pasteurization processes aiming enzyme inactivation. The best example is Taylor's Gold pear puree PPO, while 90% RA was obtained after 10 min – 75 °C thermal process, only 4% was registered after a 10 min TS at 72 °C (Sulaiman et al., 2015a). For *Pyrus bretschneideri* pear juice thermally treated for 10 min at 65 °C resulted in 59% RA, and TS (10 min at 65 °C) resulted in 2% RA (Saeeduddin et al., 2015). Royal Gala apple puree submitted for 10 min at 75 °C resulted in 24% RA vs. 4% RA after TS for 10 min at 72 °C (Sulaiman et al., 2015a).

## PPO Inactivation in Foods by Pulsed Electric Fields (PEF)

### PEF Fundamentals

Pulsed electric fields (PEF) is a non-thermal preservation method that uses high voltage at extremely short processing time (milliseconds) and relatively low temperature to inactivate enzymes and produce microbiologically safe foods. It retains the fresh-like

nr = not reported.

<sup>a</sup>T is the process average temperature which was controlled during treatment with a surrounding water bath or a jacketed vessel.

flavor without significant loss of nutrients. PEF involves the application of a short burst ( $\mu\text{s}$  or  $\text{ms}$ ) of high voltage (15–80 kV/cm) to foods flowing between two electrodes (Butz and Tauscher, 2002; Qin et al., 1996; Milani et al., 2015). The main important components of PEF are the impulse generation systems and the treatment chamber (Alkhafaji and Farid, 2007). Most PEF is done in a continuous mode where the liquid food is pumped into the chamber at room temperature, refrigerated temperature or even at elevated temperature. The pre-cooling or pre-heating might be required to maintain the temperature of the supplied food product to the desired temperature of processing and packaging. The continuous mode operation is an advantage for the high throughput required for industrial production of beverages. There are several studies about the inactivation of enzymes by PEF within the last two decades which demonstrate no inactivation to full inactivation of enzyme, depending on the food origin of the enzyme and suspending medium (Terefe et al., 2015b). Commercial PEF treatment of orange juice was carried out (Min et al., 2003).

### PEF Effect on Enzymes

The mechanism of enzyme denaturation is still unclear. The application of electric fields may cause association or dissociation of functional groups of protein, movement of charged chains and changes the alignment of the helices (Tsong and Astumian, 1987). The structure of proteins is stabilized by a sensitive balance of various covalent and non-covalent bonds/interactions (electrostatic forces, Van Der Waals, hydrogen bonds, and interaction hydrophobic effect). Also, the application of external electric field may effect the local electrostatic fields in proteins and disrupt the electrostatic interaction of peptide chains leading to conformational changes (Barsotti and Cheftel, 1999; Zhao and Yang, 2009). The electro-chemical and thermal effects associated with PEF solely or in combination as mentioned above may cause changes in the structure and conformation of enzymes (Tsong, 1990; Yeom et al., 1999; Van Loey et al., 2001; Zhong et al., 2007; Zhao and Yang, 2009).

### Effect of PEF on PPO Enzyme

Table 5 summarizes the results of a few studies carried out with apple and white grape juices. It seems the resistance of PPO to PEF is higher in Parellada white grape juice, followed by Jonagold Red apple juice, then Royal Gala apple juice and finally Golden Delicious apple juice. The increase of electric field intensity causes higher treatment temperature ( $T_{\text{max}}$ ), thus higher PPO inactivation. Ertugay et al. (2013) fully inactivated PPO activity in Golden Delicious apple juice using a thermal assisted PEF treatment at 40 kV/cm-55 °C for 200  $\mu\text{s}$ . So PEF combined with moderate heat was slightly more effective for enzyme inactivation than non-thermal PEF treatment. For example an electric field intensity of 30 kV/cm and 100  $\mu\text{s}$  real PEF treatment time applied to Jonagold Red apple juice resulted in 43% RA when using heat (65 °C) as opposed to 59% RA for PEF alone ( $T_{\text{max}} = 38$  °C) (Riener et al., 2008). The increase in treatment time also reduces the PPO RA. Ertugay et al. (2013) applied a non-thermal PEF process (30 kV/cm,  $T \leq 45$  °C) for 100 and 400  $\mu\text{s}$  to Golden Delicious apple juice and obtained 32% and 1.6% RA, respectively. In another non-thermal PEF study carried out with white grape juice at 35 kV/cm ( $T_{\text{max}} = 40$  °C) the RA was reduced from 94% when applying 1000  $\mu\text{s}$  treatment to 16% after 5000  $\mu\text{s}$  PEF treatment (Marsellés-Fontanet and Martín-Belloso, 2007).

### Other Non-thermal Food Preservation Technologies for PPO Inactivation

High pressure carbon dioxide, cold plasma and ultraviolet processing are other emerging non-thermal food technologies under investigation with potential to inactivate PPO enzyme.

### Ultraviolet Light Processing

Within the optical radiation spectrum, broad-spectrum ultraviolet (UV) is the strongest and most damaging to living microorganisms. UV light (200 to 400 nm wavelength) is a commercial non-thermal technology used for decontamination of water (e.g. supply drinking water, pool water), air and surfaces, which can be applied for food and beverage processing. UV is divided into wavelength ranges identified as UV-A (315 to 400 nm), UV-B (280 to 315 nm), UV-C (200 to 280 nm) and UV-vacuum (100 to 200 nm) (NTP, 2018). UV-C has shown effectiveness in eliminating microbial contamination at the surface of meat, poultry and fish, and also extending the shelf life of beverages such as apple cider and fruit juices (Choi and Nielsen, 2005; Guerrero-Beltrán and Barbosa-Canovas, 2006; Huang and Toledo, 1982; Kaess and Weidemann, 1973; Nakayama and Shinya, 1981; Stother, 1999; Tran and Farid, 2004; Wallner-Pendleton et al., 1994). As opposed to water disinfection, the UV light has a very low penetration effect on turbid and coloured liquid beverages. Despite the effectiveness for microbial disinfection, enzyme inactivation by UV-C is still under study. One of the proposed mechanisms of PPO inactivation is that the photo-oxidation by UV can affect the native structure of protein, thus resulting in loss of enzyme functionality (Davies and Truscott, 2001; Rhim et al., 1999). A RA of 19% in mango nectar has been reported after a 30 min UV treatment with light intensity of 25 mW/cm<sup>2</sup> (Guerrero-Beltrán and Barbosa-Cánovas, 2006). The irradiation of Starking Delicious cloudy apple juice by combined rays of UV-C and UV-A with UV-LED for 40 min resulted in 33% PPO RA (Akgün and Ünütürk, 2017).

**Table 5** Residual activity of polyphenoloxidase in fruit juices after pulsed electric fields (PEF) processing

Fruit or vegetable	Cultivar	Medium processed	Treatment details	Electric field intensity (kV/cm)	Type of treatment	$T_{max}^a$ (°C)	Treatment time (μs)	Residual activity (RA, %)	Reference
White grape	Parellada	Juice	200 Hz, 4.0 μs pulse	35	Non-thermal	40	5000	16	Marsellés-Fontanet and Martín-Belloso (2007)
				35			1000	94	
				25			1000	96	
Apple	Jonagold	Juice	15 Hz, 1.0 μs pulse	40	PEF + heat	72	100	29	Riener et al. (2008)
	Red			40	Non-thermal	45	100	40	
				30	PEF + heat	65	100	43	
				30	Non-thermal	38	100	59	Sulaiman et al. (2017a)
Apple	Royal Gala	Juice	721 Hz, 2.8 μs pulse	24.8	PEF + heat	54	169	18	
Apple	Golden Delicious	Juice	200 Hz, 2.0 μs pulse	40	PEF + heat	55	200	0	Ertugay et al. (2013)
				40	PEF + heat	54	100	6.2	
				30	Non-thermal	45	400	1.6	
				30	Non-thermal	44	200	7	
				30	Non-thermal	43	100	32	

<sup>a</sup>The PEF treatment increases the juice temperature. Therefore,  $T_{max}$  is the maximum temperature measured after processing in the outlet of the PEF unit.

### Cold Plasma

Cold plasma, plasma or non-thermal plasma is the partially or wholly ionized gas that is essentially composed of photons, ions and free electrons as well as atom in their fundamental or excited state owing a net neutral charge (Misra et al., 2011). Cold plasma is generated through the non-equilibrium of temperature between electrons and ion. The fundamental of cold plasma technology and the application on food disinfection has been reviewed by Misra et al. (2011) and Niemira (2012). Being a recent technology, few studied the effect of cold plasma on enzyme inactivation. Peroxidase has been inactivated by cold plasma in a model food system and crude extract from tomato (Pankaj et al., 2013; Surowsky et al., 2013). Surowsky et al. (2013) postulated that cold plasma induced modification of the secondary structure of the enzyme as the possible inactivation mechanism.

### High Pressure Carbon Dioxide

HPCD which is also known as dense phase carbon dioxide (DPCD) processing involves the use of carbon dioxide (CO<sub>2</sub>) at it subcritical or supercritical phase, to process a food material by having CO<sub>2</sub> to contact with the food. The supercritical CO<sub>2</sub> is achieved by processing sample at the CO<sub>2</sub> critical temperature (31 °C) and pressure (4.7 MPa). The sensory quality and nutritional component of the food is not affected by this processing (Damar and Balaban, 2006). Cloudy Fuji apple juice treated with supercritical carbon dioxide at 30 MPa and 55 °C for 60 min resulted to 38.5% residual activity (RA) (Gui et al., 2006). PPO RA 12% was registered for carrot juice treated with HPCD at 8 MPa for 3 min at room temperature, while peach PPO revealed to be more resistant as 33% RA was obtained after a HPCD of 8 MPa room temperature for 60 min (Zhang et al., 2010). The inactivation of enzyme under HPCD was suggested to be caused by the decrease in pH of the media and alteration of ionic equilibrium (Ortuño et al., 2013).

### PPO Stability Versus Regeneration During Storage

There are only few studies assessing the possible regeneration of PPO during storage after processing. This is related with reversible or irreversible inactivation of the enzyme with the processing. The 15 min treatments of Camarosa strawberry puree at 65 °C alone, 600 MPa-48 °C and 1.3 W/g - 33 °C reduced PPO activity to <18%. No changes were observed throughout 30 days storage (at room temperature and 3 °C) on PPO residual activity (Sulaiman et al., 2017b). Likewise, no change in PPO was observed during 23 days storage at 14 °C of peeled green banana (cv. Enana) after blanching for 11 min in boiling water (~4% RA) (Cano et al., 1990). Stable PPO activity has also been reported for guava (cv. Chung Shan) puree treated at 88 to 90 °C for 24 s, presenting PPO RA of 16% and 14% after processing and 60 days storage respectively (Yen and Lin, 1996). Similarly, TS (1.3 W/mL, 58 °C, 10 min) and thermal treatment alone (75 °C, 20 min) of Royal Gala apple juice reduced the PPO RA to 15% and 3%, respectively, which remained unchanged during 30 days storage at room temperature and 3 °C (Sulaiman et al., 2017a). The RA of 18% obtained after PEF treatment of the same apple juice (26.4 kV/cm, 53.4 °C, 169 μs) decreased slightly to 14% during 30 days storage at 3 °C and to 12% after 30 days storage at room temperature. An increase of PPO RA was registered after 60 days storage at 4 °C from 63% to 81% RA for HPP treated (600 MPa, 15 min) guava puree (Yen and Lin, 1996).

## Processing Effects on Meat Flavor

**Siripong Kanokruangrong, John Birch, and Alaa El-Din Ahmed Bekhit,** Department of Food Science, University of Otago, Dunedin, New Zealand

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Aging** Process of breaking down the protein by endogenous enzymes.

**Dry aging** Process of aging unpacked meat or packaged meat with highly permeable material through exposing the meat to a controlled environment.

**Dynamic headspace extraction** Extraction method involves entrapping volatiles onto a matrix

**Heterocyclic compounds** Cyclic compounds that are generated from the Maillard reaction. The structure contains nitrogen, oxygen or sulfur atoms.

**Lipid oxidation** Oxidative degradation of lipid in meat. The process where free radicals damage the lipid compounds.

**Simultaneous distillation extraction** Solvent extraction method that is performed inside a special apparatus using two different solvents.

**Solid phase micro extraction** Extraction method involving adsorption of compounds onto a special chemical matrix.

**Wet aging** Process of aging meat by sealing the meat under vacuum and storing it for certain time (from 7 to 28 days) at chilled conditions.

### Introduction

Meat is an important source of high quality and bioavailable protein in our diet. The main composition of meat comprises proteins, water and fat. Meat is normally eaten after being seasoned and cooked but sometimes can be eaten raw (e.g. beef tartare). Meat is a rich reservoir of compounds that can contribute to Maillard reactions (MR) during heat treatment. Flavor of meat is one of the most important eating quality attributes that complements the dining and eating experience. There are many factors that can affect the flavor of the meat such as breed, sex, feed, muscle types, aging, cooking treatment, novel technologies and so on. Therefore, it is important to benchmark the impact of these factors on flavor formation.

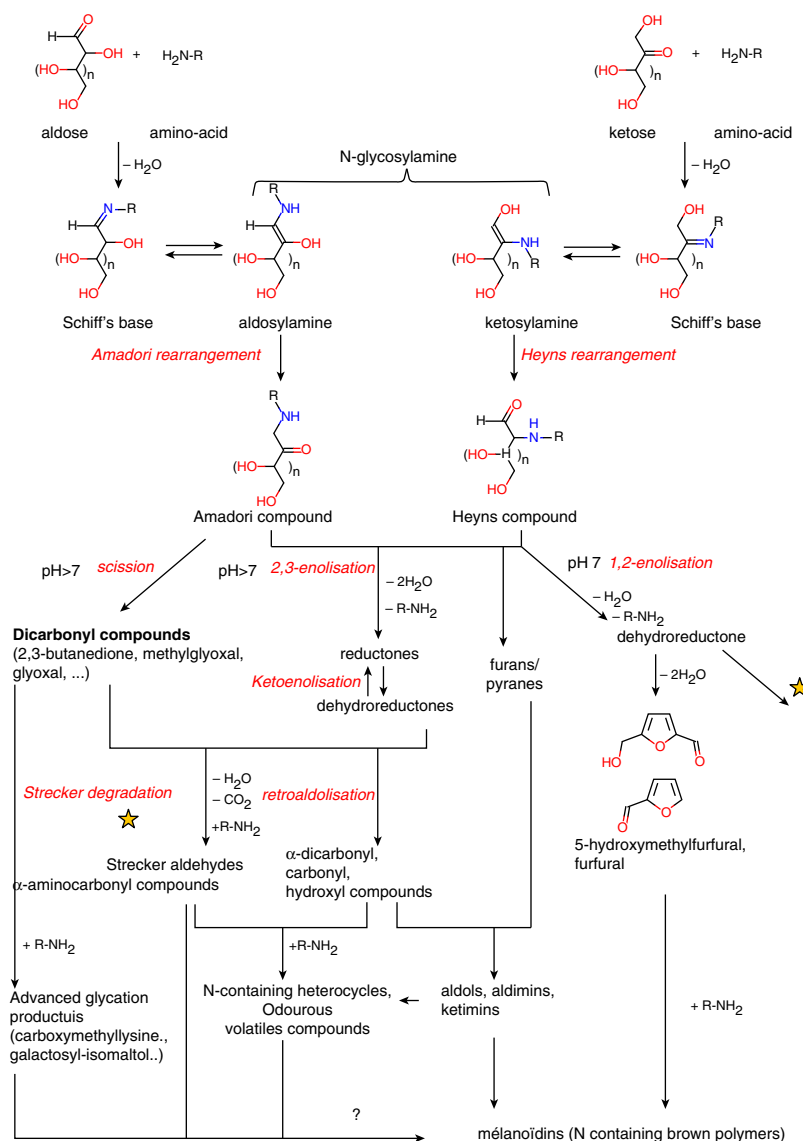

### Meat Flavor

The majority of meat flavor precursors can be divided into two groups; water-soluble components and lipids. During the heat treatment, many reactions such as Maillard reactions, lipid oxidation, and thiamine degradation contribute to the formation of these compounds. Meat flavor and palatability are influenced by fat content, especially in Intra-muscular fat. Lipid oxidation is a major cause of meat quality deterioration during storage and processing due to generation of rancid and off-flavors but low levels of lipid oxidation can enhance the flavor of the cooked meat. Heterocyclic compounds have been reported to be the main contributors to the volatiles of cooked meat.

The Maillard reaction is a reaction between the carbonyl group of a reducing sugar and the amine group of amino acids. It produces the desirable flavor in the cooked meat, baked bread, coffee and chocolate. In the Maillard reaction, a cascade of reactions occur, and this creates numerous compounds. Primary compounds such as furfural, furanone derivatives, hydroxyketones, and dicarbonyl compounds are created initially. Further reactions with other amines, amino acids, aldehydes, hydrogen sulphide, and ammonia through the Amadori rearrangement, Strecker degradation, and Schiff bases pathways lead to more complex products. The reaction also leads to the formation of melanoidins, brown and high molecular weight polymers, from the condensation of cyclic compounds. The overall reaction scheme is shown in Fig. 1. Different classes of compounds contribute their own characteristics to the meat flavor. The summary and compound examples are shown in Table 1.

The final stage of the MR (Fig. 2) is the most important step for flavor formation and it is often called the Strecker degradation. The intermediate carbonyl compounds react with each other, amino compounds, and amino acid degradation products such as hydrogen sulphide and ammonia. This final stage produces heterocyclic compounds such as pyrazines, pyrroles, furans, oxazoles, thiazoles and thiophenes.

The Strecker degradation is very important in flavor generation, as it provides routes by which nitrogen and sulphur can be introduced into heterocyclic compounds in the final stage of the Maillard reaction. The Strecker degradation is initiated by reaction between carbonyl compounds and amino acid forming two important intermediate compounds;  $\alpha$ -aminoketones and Strecker aldehyde. The Strecker aldehyde itself contributes to the flavor of the meat. The  $\alpha$ -aminoketones are key precursors for heterocyclic

**Figure 1** Schematic illustration of volatile compounds generated by the Maillard reaction between sugars and amino acids; heat degradation of lipids and thiamin, \* refers to Strecker's degradation. Source: Bertrand, E., El Boustany, P., Faulds, C.B., Berdagué, J.-L., 2018. The Maillard reaction in food: an introduction. Reference Module in Food Science. Elsevier.

**Table 1** Flavor compounds generated from the Maillard reaction

Flavor class	Characterized flavor/aroma notes	Compound example
Alkane	Fatty, burnt, pungent	Hexane
Aldehyde	Green, fatty, sweet, pungent, smoky	Hexanal, Butanol, Undecanal
Ketone	Musty, fruity, fatty, mouldy	2-Octanone, 1-octen-3-one
Alcohol	Roasted, woody, fatty, oily	1-Octen-3-ol
Pyrazine	Nutty, roasted, meaty	Dimethylpyrazine
Pyridine	Cereal-like	2-Isobutyl-3,5-diisopropylpyridine
Furan	Sweet, burnt, pungent, caramel-like	Pentafuran
Oxazoles	Green, nutty, sweet	2,4,5-Trimethyl-1,3-oxazole
Thiophene	Meaty	2-Formyl-5-methylthiophene

**Figure 2** Strecker degradation. Source: Mottram, D.S., 2007. The Maillard reaction: source of flavour in thermally processed foods. Flavours and Fragrances. Springer.

**Figure 3** Strecker degradation of cysteine compounds. Source: Mottram, D.S., 2007. The Maillard reaction: source of flavour in thermally processed foods. Flavours and Fragrances. Springer.

compounds, such as pyrazines, oxazoles and thiazoles. In the case of alkylpyrazines, the most direct and important route for their formation is thought to be via self-condensation of  $\alpha$ -aminoketones or condensation with other aminoketones.

The Strecker degradation can lead to the production of hydrogen sulphide, ammonia and acetaldehyde if the amino acid is cysteine, whereas methionine will yield methanethiol. These compounds, together with carbonyl compounds produced in the Maillard reaction, provide intermediates for reactions giving rise to important aroma compounds, including sulphur-containing compounds such as thiophenes, thiazoles, trithiolanes, thianes, thienothiophenes and furan thiols and disulphides. The reaction scheme is shown in Fig. 3.

## Lipid Oxidation

Fatty acids and lipids contribute greatly to the generation of the volatile flavor compounds that are characteristic of cooked meat. The fatty acids in meat are influenced by several factors such as diet, life style and breeds. The levels of fat content and fatty acid profiles in meats plays an important role in the formation of volatiles. Intramuscular fat and adipose tissues contain different proportions of saturated and unsaturated fatty acids. Both types can be degraded and oxidized, which create a prolific number of volatile flavor compounds. Examples of volatile flavor compounds derived from lipid degradation that have been found in cooked meat include aliphatic hydrocarbons, aldehydes, ketones, alcohols, carboxylic acids and esters. The significance of lipid-derived compounds is not as high as the relatively low concentrations of the heterocyclic compounds because the odor detection threshold values for the lipid-derived compounds are much higher. The oxidation of adipose tissues and intramuscular fat occur in raw meat and continues under the catalytic conditions such as in the presence of metals, oxygen, light, and heat. Lipid has a significant role in meat flavor, when adipose tissue is added to lean meat, it does not affect the lipid-derived flavor compounds (Mottram and Edwards, 1983). Mottram and Edwards (1983) studied the effect of intramuscular fats and phospholipids removal from beef and found significant impact on flavor compounds formed and sensory characteristics of the cooked meat. Thus, the intramuscular (i.e. marbling fat) and membrane lipids are thought to be the main source of volatile flavor components and generate species-specific flavors. High levels of polyunsaturated fatty acid contents (PUFA) can cause undesirable aromas and flavors as they are prone to oxidation and inhibit of some MR products (Mottram and Edwards, 1983).

## Feed

Animal feed affects the carcass composition, fatty acid profile, tenderness and color but feed mainly affects the fatty acid profile of the meat (Khan et al., 2015; Van Ba et al., 2012). Grass-fed beef could be less prone to lipid oxidation than grain-fed beef as there is a higher level of vitamins A, C and E, carotenoids, and flavonoids. However, steaks from grass/forage-fed beef were reported to be less tender compared to steak from grain-fed animals, but no difference in juiciness was observed. Feeding animals with vitamins improves the overall quality of the meat. For example, vitamin E in feed is deposited in lipid tissues and membranes and acts a strong antioxidant during storage, which enhances the shelf life and color of the meat. Mutton aroma found in cooked sheep meat was reported to arise from the presence of short branched-chain fatty acids (BCFAs) (Young et al., 2003). Animals with grain-based diet contains a high value of BCFAs compared to pasture-based diet. Diet high in polyunsaturated fatty acids such as fish oils, raw soybeans or canola oil can result in off-flavors in beef. An increase in unsaturated fatty acids increases oxidation during storage. Palm-oil and whole linseed supplements increases muscle levels of alpha-linolenic [C18:3] and EPA (eicosapentaenoic acid [C20:5]); fish oil increases EPA and DHA (docosahexaenoic acid [C22:6]). Meat flavor can be influenced by the diet, which means that diet can be used to tailor desirable flavor to some degree.

## Heat Treatment

Heat and cooking techniques (grilling, roasting or boiling) do have a massive effect on the flavor of the meat. Grilling, roasting and boiling create different volatile profiles due to the mode of heat transfer and the direct or lack of exposure to the heat source. The Maillard reaction is influenced by many factors such as heat, pH and water content. Dry heat cooking methods encourage the Maillard reaction and wet cooking methods hinder the reaction. This is seen when meat is cooked in a frying pan as it develops stronger color and flavor compared to boiled meat. The effect of different cooking methods (frying, boiling, roasting and microwaving) on the formation of volatiles profile and lipid oxidation was investigated by Domínguez et al. (2014). Ester compounds were reported to be the most abundant for fresh foal meat. Aldehydes were the main compounds present in the headspace of the cooked foal meat, representing between 53 and 65% of total volatiles. Alkanes were also reported to have a higher concentration in cooked foal meat. Meat cooked under boiled and lightly roasted conditions was found to be dominated by lipid oxidation products (aldehydes, alcohols, ketones and lactones) (Mottram, 1985).

It is known that there is a higher rate of pyrazine formation when the cooking temperature is about 120 °C. Therefore, cooking methods such as roasting and grilling would produce pyrazines at a higher yield compared to boiling. A lower yield of heterocyclic compounds was found when pork is cooked by light grilling, roasting or boiling (Mottram, 1985). The concentration of pyrazines produced was higher under dry heating conditions compared to boiling. Boiling does not allow a high temperature to be reached and low water activity to be obtained, so that MR is not promoted. The caramelization process is also eliminated during boiling which reduces its contribution to flavor production. Reheating food has an impact on the volatiles because during cooking the membranes get disrupted and dehydrated making the phospholipids more prone to oxidation contributing to warm off flavor.

## pH

pH is one of the important factors that influence the volatile flavor compounds formed in the MR, and determines the final flavor characteristics of cooked meat. Numerous studies have revealed that pH plays a significant role in the formation of pyrazines (Yeo and Shibamoto, 1991; Koehler and Odell, 1970; Madruga and Mottram, 1995). These authors investigated the effect of pH by experimenting with glucose-protein and meat related systems. The formation of pyrazines is promoted when the pH level is high in the food system. The greatest number of pyrazine compounds was detected at pH 9. The authors stated that basic conditions enhanced the reactivity of the amino groups toward the carbonyl groups of glucose and increased rearrangement and fragmentation of sugars. Pyrazines were the most abundant class for all conditions (54%–79% of total volatiles) and were at their highest concentration under basic conditions.

## Aging Process

The aging process is a storage process under defined conditions (temperature, mass transfer and permeability of oxygen and moisture) to improve the tenderness and palatability of meat. Biochemical reactions such as lipolysis, proteolysis and oxidation occur during the aging process (Khan et al., 2016). The breakdown of myofibrillar proteins during aging releases peptides and amino acids. Also, the degradation of fats during aging creates free fatty acids and peroxides that contribute significantly to the flavor of the meat upon cooking. Breakdown products and metabolites form more precursor compounds that react during the cooking process. The concentrations of ribose, methionine and cysteine increase significantly during 21 days of the wet aging period (Koutsidis et al., 2008). These compounds were reported to be very important for flavor formation. After aging for 21 days, the increase in the total free amino acid pool was greater than that observed for the reduced sugars and related substances. Kim et al. (2016) reported that tryptophan, phenylalanine, valine, tyrosine, glutamate, isoleucine and leucine were more abundant in the dry-aged beef

samples than in the wet-aged samples, whereas inosine monophosphate was more abundant in the wet-aged group. Such changes are likely to result in an increase in MR-derived flavor compounds, such as pyrazines and Strecker aldehydes.

Two types of aging techniques are wet and dry aging. Both methods include storage in controlled temperature but for wet aging, the meat is vacuum sealed which prevents water loss and does not affect the overall yield. Dry aging, on the other hand, involves storing the meat in breathable sealed bags or when the meat is fully exposed to the air. The control of humidity is important for dry aging because if humidity is too high, microbial activity will occur but if too low, the meat yield will suffer greatly. Both methods were reported to improve the tenderness of meat. Dry aging resulted in a lower yield of the meat due to the water loss and the outer layer must be trimmed off after aging. Dry aging can be done to a whole carcass since it does not require sealing of the meat.

A significant difference in the overall flavor of cooked dry and wet aged beef loins was noted by consumers who rated dry aged beef higher than wet aged (Kim et al., 2016), and dry aged beef had a significantly higher score for the overall likeness. The development of musty and putrid flavor was reported in dry aged meat which was stronger closer to the exterior surface (Smith, 2012). An evaluation of beef flavor after aging using traditional dry aging, dry aging bag and vacuum aging using sensory panels revealed were no differences for most of the sensory attributes between samples (Dikeman et al., 2013). However, specific notes such as umami and butter fried meat taste were more noticeable in the dry-aged steaks compared with the vacuum-aged steaks. Both bag (dry aging bag and vacuum aging) methods had higher metallic flavor than traditional dry aging. Aging time affected most of the sensory traits in that study, and significant improvement occurred after 8 days of storage. In a consumer test, meat aged for 21 days in dry aging bags was preferred than the samples aged in a vacuum.

The volatile compounds of wet-aged beef (30 days) cooked at 180 °C was reported by Watanabe et al. (2015). The results showed that there was a significant increase in pyrazine, 2,6-dimethylpyrazine and 2,3-dimethylpyrazine with wet aging. The aging process increases the concentration of free amino acids which leads to an increase in total yield of pyrazine compounds. Research that compares the volatile profile between the two aging types is very limited but exposure of the meat to air during dry aging allows oxidation and this can contribute directly to the overall flavor of the meat.

## Irradiation

Irradiation is a technology designed to eliminate disease-causing germs from foods. Applying irradiation on the raw meat or processed meats can eliminate pathogenic bacteria such as *Escherichia coli*, *Salmonella* and *Listeria*, viruses and parasites. Irradiating fresh meat can result in the formation of off-flavors which have been described as rotten egg, bloody, fishy, barbecued corn, burnt, sulfury, metallic, acetic acid, liver-like, alcohol, and serummy). Irradiation can promote autooxidation, which can create undesirable flavor compounds. The effect of irradiation on meat flavor is dependant on the treatment dose, the presence of oxygen, temperature and pH of the treated meat, which mainly affect the rate of lipid oxidation. Methods to decrease the unwanted changes in meat are; oxygen exclusion, irradiation under vacuum or in the presence of an inert gas. Aldehydes such as propanal and hexanal were reported to be a good indicator of lipid oxidation in irradiated meat. Vacuum packaging will retain the irradiated sulfur-containing compounds but re-packaging meat in a permeable barrier allows for dissipation of these flavor compounds.

## Pulsed Electric Field

Pulsed electric field (PEF) is a non-thermal processing technology that uses high voltage short electric pulses to preserve food (Bekhit, 2017). The technology is very suitable for preserving liquid foods such as honey, juices and milk. Even though PEF treatment is considered to be a nonthermal process, it can still cause a slight temperature increase in the treated product due to the electric current flow. The advantages of pulsed electric field are small treatment time, low treatment temperature, increase in shelf life, increased yield (in juice), use of both batch and continuous processes and improved metabolite extraction. Pulsed electric field may improve the tenderization of meat by electroporation and enhance proteolysis however there is no agreement in the literature (Bhat et al., 2018). Study on meat volatiles with application of PEF is very limited. Ma et al. (2016) investigated the volatile profiles of PEF cooked lamb and non-PEF cooked lamb. There were some significant increases in volatile compounds between them. The compounds showing differences were mostly lipid oxidation related compounds; aldehydes, ketones, furans and pyrazines. The PEF sample had more livery and oxidized brown flavor and an increase in the overall volatile profile in lamb. PEF appears to have some potential tenderization effect which may find a commercial application in future provided further research comes up with optimized technological inputs for different muscles, cuts and species. There is no scientific evidence regarding the toxic or hazardous effects of the technology.

## High Pressure Processing

High pressure technology is another non-thermal technology as it allows microbial inactivation at low temperature (Cheftel and Culioli, 1997). The changes leading to lipid oxidation in pressure processed meat start around 300 MPa at room temperature. Suitable packaging or antioxidants must be used as these pressure induced oxidations will limit the potential of this technology for meat-based products (Cheah and Ledward, 1996).

High-pressure carbon dioxide (HPCD) is a pasteurization method that inactivates microorganisms and enzymes through molecular effects of CO<sub>2</sub> under pressures below 50 MPa without exposing foods to the effects of heat. Since thermal pasteurization can cause undesirable changes on nutritional quality of the foods (i.e. development of cooked flavors as well as causing denaturation of proteins) can reduce the product quality and consumer acceptance of foods. HPCD is a novel nonthermal processing technology that retains flavor, avoids loss of nutrients, as well as changes in physical, mechanical, and optical properties of the food materials involved in food processing. When HPCD is applied to meat, both the pressure and temperature could affect molecular interactions and protein conformation, leading to protein denaturation. The solubility of the sarcoplasmic and total protein in porcine longissimus dorsi muscle was decreased after HPCD (Choi et al., 2008), and the major denatured proteins were phosphorylase b, creatine kinase, and triosephosphate isomerase. HPCD had no significant effect on the myofibril fragmentation index value of chilled pork, and thus does not appear to affect texture.

## Flavor Extraction and Detection of Compounds

### Solid Phase Micro-extraction (SPME)

SPME is a simple, quick, solvent-free and inexpensive extraction technique that is now widely used in flavor analysis of foods such as wine, honey, fruits, drinks and meat (Balasubramanian and Panigrahi, 2011). This method is also commonly used for analyzing non-volatile compounds such as pesticides and pharmaceuticals. SPME requires an SPME fiber that looks like a needle. Fused silica fibers coated with a thin polymer film (such as polydimethylsiloxane (PDMS)) are now the more commonly used SPME devices used in meat volatile studies.

The two typical SPME applications are Head-space (HS-SPME) and Direct-immersion (DI-SPME). The HS-SPME is when the device is inserted through a septum-type cap into the headspace of a sample solution in a vessel. The fiber is exposed to the surroundings, which allows analytes to be absorbed and adsorbed onto the coated fiber. After a certain period, the fiber is then removed and inserted directly into either gas chromatography or liquid chromatography instruments. To release the analytes from the fiber, the fiber is heated (thermal desorption) for gas chromatography. A mobile phase is used for eluting the analytes in liquid chromatography. The fiber is immersed in the solution directly for DI-SPME. SPME is often used with a gas chromatography process as it does not require any solvents, which is convenient. The DI-SPME produces good reproducibility, but it does not allow changes to the sample matrix, such as changing the pH.

### Dynamic Headspace Extraction (DHE)

Dynamic headspace entrainment is regularly known as the “purge and trap” method. The process involves passing an inert gas carrier over the interested food complex trapping the volatile analytes onto a sorbent and then desorbed into the analytical instrument (Snow & Slack, 2002). It is a suitable method for analyzing a very low concentration of an analyte as a study reported that SPME is suitable for a straightforward analysis of major volatile compounds, but the dynamic headspace trapping is more suitable for trace analysis. Madruga et al. (2009) compared three extraction methods, DHE, SPME and simultaneous distillation extraction (SDE), and they concluded that the DHE (tenax) extracted a higher number of Maillard-derived compounds, such as pyrazines, pyrroles, pyridines, and alkyl sulphides.

### Simultaneous Distillation Extraction (SDE)

It is widely accepted that the SDE method was established in 1964 when Likens and Nickerson (1964) designed an apparatus to analyze hop oil. SDE is an old method but it still has a great value in isolating volatile fraction from the matrix before analysis. The apparatus contains two flasks attached to it; one for the solvent used for extraction and the other one is for the food to be extracted in water. The process involves boiling both the extraction solvent (such as dichloromethane) and a slurry of the food and allowing the steam to travel up the column and condense on the condenser surface where the extraction process happens at that point. Both the solvent and water are collected back into the separator part and due to density differences, they flow back into their respective flasks. The process can be done under an atmosphere (A-SDE) or under vacuum (V-SDE) (Chaintreau, 2001).

The advantages of this method are that the extract does not contain high-boiling point and non-volatile materials making it less potent to the GC liners and columns. The extract can be concentrated enabling the enhancement of a trace level detection. The main disadvantage of this method is that since the matrix is heated for a long time (about an hour), artefacts could form and some heat sensitive compounds might be destroyed whereas highly polar or hydrophilic compounds such as acids and alcohols are poorly extracted. A study by Farkaš et al. (1997) found that a number of compounds were formed in the SDE method but not in high vacuum distillation (EVD) method concluding that they were artefacts.

The most reported drawback in A-SDE is the presence of artefacts in the extracts because of the harsh condition and exposure to air. Many compounds can be sensitive to oxidation, including benzaldehydes, terpenes and unsaturated fatty acids.

Common solvents used for extraction of meat volatiles are pentane, dichloromethane and diethyl ether. Dichloromethane appears to be the best solvent for extraction as it provides the widest variation. Different compounds have different affinity to different solvents which means there is no best solvent for everything. A study by Jayatilaka et al. (1995) investigated the recovery rate for five different compounds; cinnamaldehyde, eugenol, cinnamyl acetate, 2-methoxycinnamaldehyde, cinnamyl alcohol and

coumarin using five different solvents, pentane, dichloromethane, chloroform, ethyl acetate and methyl ter-butyl ether. The recovery rate for dichloromethane was the highest on average but each solvent has its own preference to each compound. Adding salt to water can increase the recovery of polar compounds. The extraction time for SDE process is usually between 1–2 h. It had been reported that the maximum yield for honey flavor compounds reached maximum yield at after 30–45 mins mark and followed a slow decrease profile (Bouseta and Collin, 1995).

Cha et al. (2006) compared the volatile profile for blue crab using V-SDE and SPME extraction methods, the V-SDE was able to extract more aldehyde, ketone and alcohol compounds and SPME did better in the aromatic compounds. The SPME method extracted less low-molecular-weight compounds and the SDE extracted more high-molecular-weight compounds. The same trend is found in the goat meat's volatiles in which Tenax is reported to have the best extraction for low boiling point aldehydes, low boiling point alcohol, pyrazines and pyridines (Madruga et al., 2009).

### Glossary

**Actin** A small globular protein important in the cytoskeleton of all eukaryotic cells and forms the major component of the thin filaments of myofibrils.

**Aging** The process where meat held at refrigerated temperatures becomes more tender as a result of proteolysis.

**Apoptosis** A controlled process of cell death mediated by caspases.

**Calpains** A family of calcium-dependent, cytoplasmic cysteine proteases found in most animal cells.

**Calpastatin** A protein which is a specific, reversible inhibitor of calpain

**Caspases** A family of proteases important in apoptosis

**Cathepsins** The proteases located in the lysosomes which are active under acid conditions.

**Collagen** Most abundant family of structural proteins in the connective tissue of animals.

**Glycogen** Storage form of glucose found in the muscle and liver of animals.

**Myofibrils** The elongated structural elements of muscle cells which are responsible for contraction.

**Myosin** An ATP-dependent enzyme which makes up the thick filaments in myofibrils and acts as a molecular motor to cause contraction following binding of actin.

**Proteases** The enzymes which break down other proteins by hydrolysis of peptide bonds

**Proteasome** A large structure in the cytoplasm with a set of proteases which are responsible for ATP-dependent proteolysis of ubiquitin-labeled proteins.

**Rigor or rigor mortis** Stiffening of muscles after death due to the irreversible binding of myosin to actin after ATP levels have declined in post-mortem muscle.

**Sarcomere** The repeating subunit of myofibrils in striated muscle.

**Ubiquitin** Small cytoplasmic proteins which binds to unwanted proteins and presents them to the proteasome.

### Muscle to Meat

People have cooked and consumed muscles from mammals, birds and fish for thousands of years. Meat continues to be an important source of protein and other micronutrients in the human diet. The characteristics of the meat we eat are the result of the composition of the muscle it was and the processes that occur to it after the death of the animal. Meat is derived from skeletal muscle and meat quality varies with the composition of those muscles. All the muscles have long myofibrils consisting of repeating sarcomere which are responsible for the contraction function of muscles (Ertbjerg and Puolanne, 2017). Surrounding these myofibrils is a variable amount of connective tissue principally made up of collagen.

The process of muscle turning to meat begins as the animal is slaughtered and the circulation ceases (Bate-Smith and Bendall, 1947). In the absence of oxygen and external fuel, the muscle metabolizes its glycogen reserves to maintain homeostasis and preserve its ATP level. This anaerobic glycolysis leads to an increase in lactic acid and a decline in pH. Typically when the pH drops to around 5.5, glycolysis stops and the ATP levels fall. At this stage the sarcomere lengths are fixed as myosin binds to actin and the muscle enters rigor (Matarneh et al., 2017).

### Tenderness

The texture or tenderness of meat is one of the most important quality attributes for consumers (Miller et al., 2001) and is largely dictated by the physical and biochemical status of proteins in the meat. Tenderness is a particular issue with the meat from mammals such as cattle, pigs and sheep. Customers are willing to pay a premium for meat that is more likely to be tender. Tenderness is measured on cooked meat either subjectively with consumer panels (Boleman et al., 1997) or objectively by measuring the shear force to cut through a defined cross-section of meat (Shackelford et al., 1995). These measurements have shown a high level of variability with high proportions of unacceptably tough beef but also lamb and pork (Bickerstaffe et al., 2001). The overall shear force consists of a background component, which is directly related to the proportion and type of collagen (Purslow, 2014), and another variable component resulting from the myofibrillar proteins. This second component increases to a maxima as the muscle goes into rigor and then decreases over time as the rigor is resolved

in a process known as aging or tenderization (Wheeler and Koohmaraie, 1994). The peak toughness is related to the sarcomere length which is determined by the conditions, temperature, pH and restraint, at the time the muscle goes into rigor (Marsh and Leet, 1966). The increase in tenderness with aging is the result of the breakdown of key structural proteins in the myofibrils by endogenous proteases and varies with species and muscles (Kemp et al., 2010). Although there is agreement on the importance of enzymes in aging there is still controversy over the contribution of individual proteases. A candidate enzyme must be found in the muscle, have access to the myofibrils, be active post-mortem and should be able to reproduce the *in vivo* pattern of proteolysis *in vitro* (Koohmaraie and Geesink, 2006).

## Calpains

The family of proteases that best fits the above criteria is the calpains (Goll et al., 2003). These proteases were originally found in skeletal muscle (Dayton et al., 1976) but are now known to be ubiquitous in animal cells. Their defining characteristic is that they require calcium for activation. Fourteen genes for calpain have been identified in the human genome (Ono et al., 2016) and three of these, calpain 1, 2 and 3, have been thought to have a role in tenderization. Calpain 1 and 2 have similar structures with an 80 kDa large subunit which contains the active site and a 28 kDa small subunit. They vary in the amount of calcium required for half maximal activity of approximately 50  $\mu$ M for calpain 1 and 500  $\mu$ M for calpain 2 which gave them their earlier names of  $\mu$ -calpain and *m*-calpain respectively (Goll et al., 2003). These values are considerably greater than the physiological levels of calcium which are of the order of 0.1  $\mu$ M. An initial autolysis step lowers the calcium requirement of both calpains with autolyzed calpain 1 having a half maximal activity near 3  $\mu$ M (Goll et al., 2003). There is also evidence that this autolysis makes the calpain 1 less stable and leads to further autolysis and denaturation (Geesink and Koohmaraie, 2000). Measurement of autolyzed calpain is used to indicate calpain activity (Raser et al., 1995). The calpains have a complex specificity (Shinkai-Ouchi et al., 2016) and often modify the activity of their substrates by making single cuts. Many of the substrates of calpains are cytoskeletal proteins and they are involved in changes in cell structure such as the development of muscle fibers (Sorimachi and Ono, 2012).

The calpain hypothesis for aging of meat begins with the decrease in ATP levels post mortem (Koohmaraie and Geesink, 2006). The cell cannot maintain low sarcoplasmic calcium as the active pumps in the sarcoplasmic reticulum and mitochondria require ATP. With the rise in calcium calpain 1 is activated (Hopkins and Thompson, 2001) and this operates on specific cytoskeletal proteins which are involved in maintaining the structure of the myofibrils. The most important of these are thought to be titin, the giant protein which connects the m-line to the z-disk, desmin, which connects bundles of myofibrils to each other, and vinculin in the costameres, the structures which attach myofibrils to the sarcolemma (Taylor et al., 1995). Nebulin and troponin T, key components of the thin filaments, are also calpain substrates. This proteolysis destabilizes the myofibrils and leads to tenderness. Importantly actin and myosin, the most abundant proteins in the myofibrils are neither good calpain substrates nor extensively proteolysed in post mortem meat.

The pattern of proteolysis when myofibrils were incubated with purified calpain 1 or 2, is similar to what is seen in aged meat (Huff-Lonergan et al., 1996). It was also found that infusion with calcium tenderised meat (Koohmaraie, 1990) while zinc and other more specific calpain inhibitors inhibited aging (Uytterhaegen et al., 1994). Calpain 1, rather than calpain 2, is considered the key enzyme, based on its lower requirement for calcium and its autolysis pattern (Koohmaraie et al., 1987). Calpain 1 is autolyzed in the first few days post-mortem where more proteolysis occurs while most calpain 2 can be intact weeks after death (Morton et al., 1999). This was confirmed by experiments in mice where knocking out the calpain 1 gene prevented post-mortem proteolysis of the muscle (Geesink et al., 2006). There is however evidence that calpain 2 may be important in the later stages of aging in some muscles (Colle and Doumit, 2017).

An important part of the calpain system is calpastatin, a protein with the sole known function of reversible, calcium-dependent inhibition of calpain. The inhibitory region of calpastatin binds to either side of the active site of calpain and blocks access to substrates (Moldoveanu et al., 2008). The importance of calpastatin is evident from the strong correlation between calpastatin levels and the rate of aging both between (Ouali and Talmant, 1990) and within species (Shackelford et al., 1991). Increasing the expression of calpastatin either in transgenic animals (Kent et al., 2004) or with  $\beta$ -agonists (Koohmaraie et al., 1991) leads to reduced post-mortem proteolysis and tougher meat. Increased calpastatin can be the mechanism when changes to increase animal growth sometimes lead to tougher meat as in the callipyge sheep (Koohmaraie et al., 1993). Genetic variation in calpastatin is linked to tenderness in cattle (Casas et al., 2006) and is the basis of commercial testing for tenderness potential.

A third isoform, calpain 3, is found in large amounts in muscle and is bound to titin, one of the key target proteins in aging (Sorimachi et al., 1995). Mutations in the calpain 3 gene are responsible for a muscle wasting disease in humans, limb girdle muscular dystrophy type 2A. Calpain 3 levels were correlated with aging in lamb (Ilian et al., 2004) but not in pork (Parr et al., 1999). However it is unlikely that calpain 3 plays a dominant role in aging as knocking out the calpain 3 gene did not affect post-mortem proteolysis in mice (Delgado et al., 2001) and it is not inhibited by calpastatin (Ono et al., 2004).

## Other Endogenous Proteases

Calpains are not the only proteases in muscle and there is evidence that other proteases have either a direct role in aging or interact with calpain. The cathepsins are the proteases which digest cellular components in the lysosome and are active at the acid pH of

meat (Sentandreu et al., 2002). However they would only have access to the myofibrils under conditions where the lysosomal membranes have been ruptured. They also proteolyse actin and myosin and there is only very limited breakdown of these proteins during aging (Mikami et al., 1987). The proteasome is another candidate protease. This is found in large amounts in the muscle and normally works by an ATP-dependent process involving recognition and proteolysis of ubiquitin-labeled proteins (Robert et al., 1999). In the absence of ATP, as in post-rigor muscle, the proteasome is no longer ubiquitin dependent and has been shown to maintain activity for at least one week post-mortem (Lamare et al., 2002). It can reproduce some of the characteristics of aging and proteolysis in chilled meat is slowed by proteasome inhibitors (Houbak et al., 2008) but the overall pattern of proteolysis differs from normal aging.

Recent theories of early aging have considered it as a process of apoptosis or controlled cell death (Becila et al., 2010). The caspases are the key enzymes activated in apoptosis and there is evidence that caspase 3 can reproduce many of the characteristics of post-mortem proteolysis in myofibrils (Kemp and Parr, 2008). Caspases have also been suggested to be the target of the serine peptidase inhibitors or SERPINs which have correlated with toughness in beef (Herrera-Mendez et al., 2009). There is considerable evidence that the caspases interact with calpains and are able to proteolyse calpastatin (Wang et al., 1998). Thus the current view of post-mortem aging is centered on calpains but involves interactions with several other groups of proteases.

Proteomic approaches have identified several groups of proteins which affect aging. These suggest that the extent of proteolysis is determined by the action of other proteins which protect either the proteases or their substrates (Lana and Zolla, 2016). These include heat shock or chaperone proteins and enzymes involved in metabolism (Gagaoua et al., 2015). There is also a strong correlation of tenderness with proteins which protect against oxidation (Lana and Zolla, 2015) and it is known that calpain is very susceptible to oxidation (Lametsch et al., 2008). The activity of proteases can also be affected by post-translational modification. Calpain 1 activity is changed by phosphorylation either of the protease or its substrates (Li et al., 2016).

The rate and extent of aging is greatly impacted by the changes in temperature, pH and ionic strength within the muscle cells during the hours immediately in following slaughter (Marsh et al., 1987). There is also a relationship with ultimate pH with muscles of intermediate pH 5.8–6.1 being toughest (Purchas, 1990). Many of these changes can be explained by the effect of the conditions on the balance of calpain 1 activity, autolysis and denaturation (Geesink and Koohmaraie, 2000; Mohrhauser et al., 2014).

## Exogenous Proteases and Tenderisation

The highest value muscles on a carcass are those that can be used for grilling but only a small proportion of the muscles become that tender even with optimal aging (Sullivan and Calkins, 2011). The remaining muscles typically have higher levels of connective tissue which cannot be cleaved by the endogenous enzymes. These tough cuts of meat have been successfully tenderised by the use of plant proteases principally papain from papaya, bromelain from pineapple, ficin from figs and actinidin from kiwifruit (Bekhit et al., 2014). The proteases can be infused or injected into the meat or used as a marinade. These plant preparations are often crude extracts with a variety of proteases with low specificity and digest all meat proteins both from the myofibrils and connective tissue. They are very effective at decreasing the shear force of meat but some of them, for example papain, tend to over-digest the meat and leave it with a mushy texture unlike normally aged meat (McKeith et al., 1994). Others, such as actinidin (Lewis and Luh, 1988) and some of the microbial enzymes (Ryder et al., 2015), are more specific and lead to a more controlled tenderness development. The proteolysis following application of infusion of kiwifruit juice to lamb was partly due to activation of calpain 2 (Han et al., 2009).

## Conclusions

Aging or tenderization of meat occurs in refrigerated conditions and is the result of interactions between endogenous proteases and muscle proteins. Calpain 1 is believed to be the main protease responsible for meat tenderization during post-mortem aging, however, there is evidence for the involvement of other proteolytic system either direct or indirectly in the aging process. Calpastatin, the specific calpain inhibitor, modulates the activity of calpain 1. The extent of aging is also affected by other proteins and the temperature and pH of the meat. Aging alone cannot tenderize certain meat cuts and interventions, such as the use of exogenous proteases, could improve the tenderness level.

### Glossary

AN-PEP *Aspergillus niger*-derived prolyl endoprotease;

CD Celiac disease

Endoprotease Enzymes which catalyze the cleavage of peptide bonds within the polypeptide chain

Exoprotease Enzymes which catalyze the cleavage of the terminal (or the penultimate) peptide bond

EPI Exocrine pancreatic efficiency

GI Gastrointestinal

HLA Human leukocyte antigen

IBD Inflammatory bowel disease

IBS Irritable bowel syndrome

PEP Prolyl endopeptidase;

PERT Pancreatic enzyme replacement therapy

POP Prolyl oligopeptidases

### Overview

Proteases hydrolyze peptide bonds in proteins generating peptide fragments and amino acids. These enzymes have primary roles in protein catabolism. For example, in the small intestine, proteases digest dietary proteins to allow the absorption of amino acids. They are also involved in control of biological processes within the body through highly specific cleavage of substrates (López-Otín and Bond, 2008). Proteases are responsible for maturation of prohormones to generate active proteins or peptides that are intimately involved in thermoregulation, reproduction, appetite and many other critical functions. As such, proteases control the fate and activity of proteins. Proteases have also been implicated with various types of pathophysiological conditions such as cancer, inflammatory, cardiovascular and digestive disorders (Drag and Salvesen, 2010).

Our understanding of the role of proteases has to a large extent focused on nutrient digestion. The most well-known proteases are the serine protease family of enzymes that comprise pepsin, an enzyme produced in the stomach, as well as trypsin and chymotrypsin, primarily secreted from the pancreas. Together these enzymes are the principal proteases involved in the human digestive system.

The sequencing of genomes from a diverse range of organisms has revealed the structural and catalytic diversity that exists within the protease family. These data have illuminated the critical role that proteases play in the biology and pathology of diseases, especially digestive disorders (Puente et al., 2003). In recent years, the use of proteases as drug therapies has received attention, in particular for treatment of gastrointestinal (GI) disorders (Drag and Salvesen, 2010; Sollid and Khosla, 2005). By regulating peptide and amino acid production, controlling protein–protein interactions, catalyzing, processing and transducing molecular signals in the GI tract, protease enzymes offer a unique opportunity for targeted drug delivery and treatment options for GI disorders (López-Otín and Bond, 2008).

Most proteases are synthesized as inactive zymogens that become activated through a number of mechanisms, including cleavage by upstream proteases, changes in pH, or dimerization. Fig. 1 shows the site of protease production in the human GI tract and their mode of action in the stomach and small intestine. Once the protease is in the active conformation, substrates can enter the active site and be cleaved. However, protease activity can be altered by the presence of endogenous and exogenous protease inhibitors. As a result, keeping the balance between inhibitors and enzymes is a challenge but also represents a path for exploitation in the design of novel drug therapies.

Proteases have differing roles in animals, plants and microbes (Sollid and Khosla, 2005; Sipos, 1995; Nair et al., 1974). In plants, proteases play a vital role in the processing, maturation, or destruction of specific proteins in response to developmental cues or variations in environmental conditions (García-Lorenzo et al., 2006). Additionally, proteases have become important tools in the biotechnology and biopharmaceutical industries because of their efficient digestion of proteins. Examples include the use of alkaline protease to remove hair from hides, the use of pancreatic protease extracts as detergents in leather processing, the use of proteases in rennet from unweaned calves in cheese production and the use of papain for tenderizing meat (Li et al., 2013).

This chapter will provide an overview of the proteases found in humans, the types and their roles in digestion and digestive disorders. In addition to these endogenous enzymes, we will also discuss currently available protease supplements for GI disorders,

**Figure 1** The human digestive system showing the site of protease production and their mechanism of action: (A) location of protease enzymes in digestive tract; (B) initiation of digestion by pepsin in the stomach; (C) interior surface of the stomach; (D) enzymatic action of proteases in the duodenum; and (E) absorption amino acids through the small intestine.

the current status of and prospective for protease-based drug discovery. Finally, we will discuss protease-based drug therapy as an example for two major digestive disorders: celiac disease (CD) and pancreatic insufficiency.

## Types of Proteases

Proteases have been classified based on their specificity and catalytic types (Garcia-Carreón, 1997). Depending upon their specificity, proteases have been divided into two broad groups: exopeptidases and endopeptidases. Exopeptidases break the peptide bonds adjacent to the N- or C-termini trimming the protein or peptide, while endopeptidases act on internal peptide bonds. Based on the exopeptidase site of action or specificity, they can be divided further into subclasses, i.e. the aminopeptidases release the N-terminal amino acid, while the carboxypeptidases hydrolyze peptide bonds at the C-terminus, and di/tri-peptidyl peptidases release a di/tri-peptide from the N-terminus. Unlike exopeptidases, endopeptidases cleave peptide bonds within the protein sequence and cannot break down peptides into monomers i.e. amino acids. In addition to endoproteases, a family of endopeptidases exist whose substrates are size limited. For example, oligopeptidases cleave oligopeptides instead of proteins.

Based on their catalytic mechanism, endoproteases are classified into the following six types: aspartic, cysteine, glutamic, metallo, serine, and threonine proteases (Rawlings et al., 2015; Garcia-Carreón, 1997). The mechanism of peptide bond cleavage involves making the amino acid residue (cysteine and threonine proteases) or a water molecule (aspartic acid, metallo- and acid proteases) nucleophilic so that it can attack the peptide carboxyl group. The generation of a nucleophile can occur via a catalytic triad, where a histidine residue is used to activate serine, cysteine, or threonine as a nucleophile. Endoproteases can be highly specific, for instance the serine protease trypsin cleaves the carboxyl side of Arg and Lys, while chymotrypsin cleaves after the hydrophobic amino acids, Phe, Trp and Tyr, and with lower affinity at Leu and Met.

## Enzyme-Based Therapies

The human diet is typically composed of protein, fat and carbohydrate. Digestive enzymes (proteases, lipases and carbohydrases) act to break these components down aiding in nutrient absorption. Enzyme-based therapies have been successfully applied to the treatment of some metabolic disorders wherein there is an insufficiency in particular class of enzyme. Lactose intolerance arises due to an insufficiency of the enzyme  $\beta$ -galactosidase (lactase). Yeast, fungal and bacterial-derived  $\beta$ -galactosidase enzyme supplementation therapy are commonly used in the management of lactose intolerance (Swallow, 2003). It has been proposed that similar enzyme-based therapies may be used for the treatment of protease-based insufficiencies. For example, combinations of proteases with other digestive enzymes such as lipases, are being used as a treatment option for pancreatic enzyme insufficiency resulting from conditions such as cystic fibrosis and pancreatic cancer (Littlewood et al., 2006).

## Protease Deficiency and Natural Sources of Protease Supplements

Proteases are also known as systemic enzymes because of their vital role in digestion. They are essential in the digestive system as they break down the protein molecules into small pieces and supply the amino acids required by the body for new protein metabolism. Without proteases, the GI tract cannot process proteins leading to serious health problems, including nutrient malabsorption. In addition to digesting food, proteases can help to kill harmful microorganisms in the intestine and break down unwanted waste products such as toxins and cellular debris (Turk and Stoka, 2007). By killing pathogens and degrading waste products, proteases help to reduce the load on the immune system.

Under normal physiological conditions, the body produces a sufficient quantity and diversity of proteases to digest the proteins present in the everyday diet (López-Otín and Bond, 2008). However, protease deficiency may occur due to pancreatic or genetic disorders, illness, injury/trauma, excessive exercise, ageing or a combination, and may require protease supplementation or therapy to restore proper GI function. Protease supplements can be an option to treat or alleviate GI-related disorders. At present, these enzymes are sourced from animals, plants and microbes.

### Animal-Based Protease Enzymes

Animal-derived pancreatic enzyme supplementation has been widely accepted for the treatment of several digestive disorders. For example, trypsin and chymotrypsin either individually or combination, are the most commonly used supplements for pancreatic disorders. These enzymes are extracted from either porcine or bovine pancreas glands. The activity and concentration of these enzymes are determined by multiple factors, including the animal's species, age and sex. The enzyme complement derived from hogs pancreas is most similar to human and primarily contains amylase and lipase enzymes, whereas the bovine pancreas is enriched with proteolytic enzymes such as trypsin and chymotrypsin (Wooldridge et al., 2009). US pharmacopoeia grade trypsin and chymotrypsin are collected from the ox pancreas gland (Ross and Kang, 2008).

### Plant-Based Protease Enzymes

Plant-based proteases have long been used as health supplements in various forms of therapy. Some fruits contain proteases, for instance, actinidin from kiwifruit (Boland, 2013), papain from papaya (Berti and Storer, 1995) and bromelain from pineapple (Maurer, 2001) that can serve an important role in protein digestion.

Actinidin, the main proteolytic enzyme in kiwifruit, can aid the digestive process. Studies have reported that dietary actinidin fed in the form of fresh green kiwifruit increased the rate of gastric emptying and the digestion of several beef muscle proteins in the growing pig (Montoya et al., 2014). The presence of actinidin in a beef muscle protein-based diet significantly enhanced the gastric disappearance of the higher-MW proteins (>32 kDa) during the first three-hours of ingestion, but had little effect on the smaller proteins (<32 kDa) (Montoya et al., 2014).

Papain is a proteolytic enzyme found in green papaya and has been proven to loosen necrotic and encrusted waste material from the intestinal walls (Nair et al., 1974). Traditionally, papain has been used as meat tenderizer, but also in skin burn treatment, as an antiseptic, and as an anti-inflammatory agent (Wagner, 2005). Papain has proposed to be used in controlling dyspepsia and digestive disorders and malfunction in the GI tract (Perry, 2001a). For instance, the commercially available papaya preparation (Caricol®) is used for the maintenance of GI tract physiology and has proven to alleviate various functional disturbances, like symptoms of IBS (Muss et al., 2013). The papaya latex-derived enzyme caricain has also been used to reduce the gliadin content in wheat dough with an aim to develop a bread suitable for celiacs and gluten intolerants (Buddrick et al., 2015). However, the gliadin content in the bread produced was still above 1500 ppm and structure of the bread was poor. A combination therapy of alcalase from *Bacillus licheniformis* and papain has shown a greater efficiency in reduction of gliadin levels in wheat flour in comparison to single enzyme treatment (Li et al., 2016).

Bromelain is an enzyme extract from pineapples that has been noted to have high proteolytic activity (Harrach et al., 1995) and has been reported as a supplementary aid for IBS. Bromelain comprises a number of cysteine proteases that aid in protein digestion and also acts to decrease inflammation (Onken et al., 2008). Studies have reported that this enzyme increases the permeability of the digestive tract, providing better absorption of nutrients (Nair et al., 1974; Perry, 2001b). Several patents have been submitted based on the preparation of bromelain in combination with other enzymes such as papain, trypsin, and chymotrypsin to treat digestive disorders, impaired liver function, cystic fibrosis and as a digestive aid (Gross et al., 1971; Sipos, 1978, 1994, 1995; Ozlen, 1995; Ross and Kang, 2008). Due to its strong proteolytic activities, there has been interest in using it in a diverse range of industries, including baking, meat tenderization, fish protein hydrolysis, alcohol production and so on (Arshad et al., 2014).

The commercial uses and development of proteases in both industry and for scientific research have been reviewed extensively by Li et al. (2013). These findings imply that the afore-mentioned plant-based proteases may assist in gastric digestion of proteins after having a high-meat meal, amino acid absorption in the GI tract and cleaning of the intestinal wall.

### Microbe-Derived Protease Enzymes

Microbial enzymes represent a greater proportion of the worldwide protease enzyme production due to their varied catalytic activities, the ease of genetic manipulation, their high production capacity, inexpensive media for their growth and absence of

time-dependent or seasonal production (Gurung et al., 2013). These enzymes are also more stable than plant and animal enzymes (Singh et al., 2016; Gurung et al., 2013). The production of microbial proteases is considered more convenient and safer, and well suited for industrial-scale production of animal or plant-derived enzymes in the microbial system (Hasan et al., 2006; Luniak et al., 2017).

## Uses of Proteases in Treating Digestive Disorders

The gut epithelium controls the digestive, absorptive and secretory functions, and coordinates with the mucosal immune, vascular and nervous systems (Artis, 2008). Proteases regulate the availability and activity of growth factors, cytokines, and extracellular matrix proteins (Antalis et al., 2007). To maintain a proper balance in the intestine, protease enzyme activity is highly regulated along with other digestive enzymes such as amylase and lipase. Uncontrolled proteolysis may cause GI problems as observed in IBS or IBD. Thus understanding how proteases maintain balance and regulatory function in the healthy digestive system and the role they play in the pathophysiology of diseases will facilitate the use of these enzymes as a therapeutic leads for GI disorders. In this section, two disease conditions: CD and pancreatic insufficiency are discussed because protease-based therapy has shown potential as a treatment option.

### Celiac Disease

CD is a lifelong disorder affecting the small intestine that is triggered by the ingestion of gluten proteins present in the wheat, barley and rye (Green and Cellier, 2007). Currently, the only available treatment is complete exclusion of gluten from the diet. There is need for preventative or therapeutic treatment of this condition. In CD (Fig. 2A), people that are genetically predisposed (carry the HLA-DQ 2/8 alleles) may mount an inappropriate immune response to gluten-derived peptides. Gluten refers to a family of proline- and glutamine-rich proteins that are recalcitrant to GI digestion. Gluten proteins also contain fewer basic amino acids (Lys, Arg) which are the sites of cleavage by trypsin. Their unique amino acid composition renders these proteins with a resistance to gastric and intestinal digestion. Thus instead of being degraded to monomers (amino acids) or small oligomers (di-/tripeptides), larger peptides derived from gluten persist after gastrointestinal digestion. These peptides may contain stretches of amino acids, or epitopes that trigger an inflammatory response and are immunotoxic to those with CD (Sollid, 2002).

Aside from hindering digestion, proline plays a crucial role in directing tTG-mediated deamidation of the glutamine residues and thereby increasing the peptides affinity to bind to HLA DQ2 and DQ8 and hence increasing the immunotoxicity (Stoven et al., 2012). Many researchers have investigated the role of transglutaminase as a means for detoxification of  $\alpha$ -gliadin, the main elicitor of CD (Gianfrani et al., 2007; Mazzealla et al., 2012; Mazzeo et al., 2013). These studies have revealed that transamidation of wheat flour resulted in decreased T cell response as evidenced by lower levels of inflammation-related markers. This approach aimed at

**Figure 2** Pathophysiology and treatment targets for coeliac disease (A) and exocrine pancreatic insufficiency/pancreatitis (B).

detoxifying gluten and inhibiting the binding of gluten-derived peptides to tissue transglutaminase represents a complementary approach to oral therapies aimed at gluten digestion (Sollid and Khosla, 2005; Plugis and Khosla, 2015; Sulic et al., 2015).

In the area of CD, microbe-derived proteases can be used indirectly to reduce the toxicity of prolamins epitopes found in the gluten proteins from wheat, barley and rye. For example, the use of selected sourdough lactobacilli-derived proteases has been proposed as a means to minimize the toxicity of gluten-derived peptides without removing the gluten from wheat, barley and rye (De Angelis et al., 2006a,b; Di Cagno et al., 2004; Di Cagno et al., 2002). The use of selected lactic acid bacteria and fungal proteases, which are routinely used in bakery, caused the degradation of gluten and one study reported a concentration of 12 ppm gluten after sourdough fermentation (Rizzello et al., 2007). The lactic acid bacteria *Lactobacillus plantarum* CRL 775 and *Pediococcus pentosaceus* CRL 792 showed proline-specific activity resulting in partial hydrolysis of  $\alpha$ -gliadin substrates (Gerez et al., 2008). As a result, food processing by selected sourdough lactobacilli or fungal proteases may be considered an approach to reduce gluten toxicity prior to ingestion (Mandile et al., 2017). Although, *in vitro* protease treatment shows promise as an option to reduce intact gluten content during sourdough preparation, gluten-derived peptides may remain in the finished product. Moreover, questions remain over the accuracy of the currently used gluten quantitative methods for the analysis of hydrolyzed and/or fermented products (Panda et al., 2015; Slot et al., 2015; Thompson and Méndez, 2008).

Akin to the use of lactase in lactose intolerance, oral therapy by exogenous prolyl endopeptidases (PEPs) that could cleave these proline-rich peptides has been proposed as an alternative therapeutic option (Sollid and Khosla, 2005). Several studies have investigated the possibility of enzymatic defects in the intestinal mucosa of patients with CD and have tried to establish treatment options employing proteases (Bruce et al., 1984; Cornell et al., 2005; Shan et al., 2002). Oral enzyme supplementation is designed to accelerate GI degradation of proline-rich gluten, especially the proteolytically stable antigenic peptides (Cerf-Bensussan et al., 2007). Oral therapy, by exogenous prolyl endopeptidases (PEPs) which act to degrade ingested gluten, was proposed as an alternative treatment to the diet (Monod and Grouzmann, 2010). Shan and co-workers have shown that lack of PEP in the gastric and pancreatic enzymes, and in the human intestinal brush border, prevents efficient digestion of gluten peptides (Shan et al., 2002). Thus, undigested peptides can cross the intestinal barrier and trigger the adaptive immune system, ultimately causing inflammation in the gut. Both *in vitro* and *in vivo* assays by using bacterial prolyl endopeptidase have shown the potential use of PEP in detoxifying immunogenic gluten peptides in CD patients (Shan et al., 2002). Sollid and Khosla showed that addition of PEP in *in vitro* or *in vivo* rat model reduced the ability of toxic peptides to stimulate gliadin-specific T-cells (Sollid and Khosla, 2005). Recently two endopeptidases, KumaMax™ and KumaWT, showed high levels of activity and specificity towards the PQ dipeptide motif present in gluten proteins, with activity retained at pH 4 (Siegel et al., 2017). Although oral-enzyme therapies are currently under development for CD, oral administration of therapeutic enzymes remains challenging due to proteolysis and unfolding (of the therapeutic proteases) in the GI tract.

As discussed above, a range of microorganisms have been investigated as a source of oral enzyme therapies. The ability to degrade gluten has led to these proteases being given the generic name glutenases. The range of glutenases include prolyl oligopeptidases from *Flavobacterium meningosepticum* (FM-POP) (Stepniak et al., 2006) and from *Myxococcus xanthus* (stan-1) (Shan et al., 2002), prolyl endoprotease from *Aspergillus niger* (AN-PEP) and *Sphingomonas capsulata* (SC-PEP) (Stoven et al., 2012), and *A. niger*-derived aspergillopepsin with dipeptidyl peptidase IV (López-Otín and Bond, 2008; Stoven et al., 2012; Bethune et al., 2006). POP is generally a soluble, 76–80 kDa protein (Polgar, 1994) while members of PEPs sub-family are ~75 kDa in size (Gass and Khosla, 2007). AN-PEP has been shown to be active in the conditions found in the GI tract and be capable of degrading intact gluten molecules to remove T cell stimulatory epitopes from gluten and turn them into non-toxic peptides. FM-POP is inactive in the acidic environments, i.e. the stomach, and its structure limits access of larger peptides to the active site, thus FM-POP preferentially cleaves short peptides (Polgár, 1992). As a result oral supplementation of FM-POP is insufficient to breakdown gluten before it reaches the proximal part of duodenum (Matysiak-Budnik et al., 2005).

Plant-derived enzyme supplementation approaches have been used to reduce the peptide size in the key antigenic regions that bind to HLA and initiate inflammation. The glutamine-specific endopeptidase from barley EP-B2 has been shown to degrade gluten (Bethune et al., 2006). A commercial preparation known as ALV003 is a combination of EP-B2, SC-PEP and AN-PEP is currently under Phase 2B clinical trials (Lähdeaho et al., 2014). A recent study has shown that prolyl endoprotease isolated from carnivorous pitcher plant (*Nepenthes* spp.) can increase gliadin solubilization rates which also reduces T cell recognition (Rey et al., 2016).

### Pancreatic Insufficiency

The pancreas produces hormones, for instance, insulin and glucagon from the endocrine gland, and digestive enzymes such as lipases (pancreatic triacylglycerol lipase), proteases (trypsin and chymotrypsin), and amylases ( $\alpha$ -amylases) from the exocrine glands. Exocrine pancreatic efficiency (EPI) may occur as a result of multiple clinical conditions, including cystic fibrosis, chronic pancreatitis, pancreatic cancer, blockage or narrowing of the pancreatic or biliary duct, pancreatic or duodenal tumors and pancreatic surgeries (Littlewood et al., 2006; Nair et al., 1974) (Fig. 2B). EPI can present with varied symptoms such as malabsorption of nutrients, feelings of indigestion, inconsistency in stool production, flatulence, weight loss and more. Pancreatic enzyme replacement therapy (PERT) or enzyme supplementation are used to alleviate the symptoms caused by EPI. In some conditions, people need to take enzyme supplements for life, whereas other conditions may only require a short-term treatment.

In cystic fibrosis, patients suffer from severe intestinal malabsorption that is caused by a deficiency of pancreatic enzymes (Littlewood et al., 2006). High level of bile salts, bicarbonate deficiency and other factors contribute to the problem. Research has found that most patients with cystic fibrosis benefit in terms of nutrient absorption by using PERT that includes a combination

of proteases, lipases, and amylases commercially available as Zenpep® (Eurand) or pancrelipase (Wooldridge et al., 2009). These enzymes can be found in a wide variety of animal, plant, and fungal sources, but all current prescription enzymes are prepared from porcine (pig) sources. There are six FDA approved pancreatic enzymes that are currently available in the market, CREON® capsules, Pancreaze® capsules, Pertyze® capsules, Viokace® capsules, Ultresa® capsules and Zenpep® capsules (FDA).

## Challenges in the Use of Proteases in Digestive Disorders

The therapeutic use of exogenous protease therapies over the past several decades has provided substantial clinical evidence that implicates their use in digestive disorders. However, some challenges need to be overcome before application of these enzymes as a medication for GI-related disorders. For instance, all enzymes must be tested *in vitro* and *in vivo* clinical models to proof their efficacy, safety and determine any potential side effects before patient administration. Investigation of the site-specific action in the digestive tract and efficient pathways for delivering the proteases to the site of action. Moreover, determining the dosage rates and appropriate formulation of proteases and testing their utility in the different food matrices are necessary to ensure their efficacy. The stomach pH is lower than the intestine and pancreas and as such enteric coated enzyme preparations help retain the protease efficacy by preventing its dissolution and disintegration in the gastric environment (Domínguez-Muñoz et al., 2006). Although enteric coated tablets and capsules have been used to treat gastric acidity issues, further work is needed to prepare enteric coated enzyme preparations in the treatment of digestive disorders.

PERT is the standard treatment for EPI-derived malabsorption conditions. To date, this therapy is well tolerated and has satisfactory (>80%) efficacy. However, some challenges remain to be addressed for this therapy: (1) determining the full spectrum of efficacy in a wider group of patients; (2) considering other factors, for instance, disease conditions or genetic differences; (3) oral enzyme therapy development with unprotected enzymes in combination with enteric coated enzymes; and (4) developing a standardized monitoring system for this treatment.

A major challenge for oral protease therapy in GI disorders such as CD is the ability to measure their safety and efficacy in patients across a broad phenotypic spectrum. Because CD is a complex genetic disorder, using a single enzyme or even a cocktail of enzymes may not be effective in treating this disorder. The GI tract represents a complex system, wherein consideration of the pathobionts and commensal bacteria and their role is required. Appropriately designed clinical trials will be required to ensure that protease therapy is suitable for all patients with CD as well as those that suffer from gluten intolerance.

## Conclusions and Future Perspectives

Proteases play a critical role in normal digestion and are often deficient in digestive disorders like IBD, IBS, CD and EPI. The therapeutic use of enzymes over the past five decades has provided clinical results that suggest their utility in GI disorders. As research reveals the pathologies of various GI diseases and finds potential roles for proteases in disease treatment, comprehensive *in vivo* and *in vitro* trials to assess the efficacy and safety of these preparations will be required. Through basic research new candidate proteases from plants or microbes will be revealed, which can be used as a digestive aids in GI disorders. Translational studies, including novel approaches like gene or cell therapies and drug formulation studies are also required to make significant progress in this area (Ellis et al., 2017). Novel enzymes from natural sources and the use of enzyme cocktails combined with probiotics show promise in the treatment of digestive disorders. Oral enzyme therapy may not be a suitable lifelong treatment option, for example, to replace the 'gluten-free diet' for CD, but it might be suitable as a supplemental treatment to avoid accidental ingestion of gluten when dining out. With the advent of gene editing/therapy technology, better-tolerated protease enzyme therapies can be developed by considering the function of the native pancreas to treat EPI. In conclusion, protease enzyme therapies offer promise as digestive aids in the treatment of disorders of the gastrointestinal tract.

### Glossary

**Allostery** The behavior of some proteins for which binding of a compound one site of a protein regulates the ability of a substrate to bind at a different site of the same protein. This reveals the conformational dynamics of some enzymes.

**Cofactor** A molecule (such as flavin adenine dinucleotide (FAD)) or an atom (typically a metal such as iron or copper) that an enzyme requires to be active; that is, to be able to catalyze a reaction.

**Electrostriction of water** It is the result of ion–water interactions that causes water molecules oriented around the ion which is mainly due to the high electric field of the ion. This results in the water molecules more densely packed around the ion than in the bulk water, leading to the decrease of the volume of the whole system (Barciszewski et al., 1999).

**Far-UV circular dichroism spectra** Spectra used to understand the secondary structure of proteins, like the fractions of alpha-helix, beta-sheet, or beta-turn conformations.

**Hydrophilicity** It refers to the affinity of a surface to water. A material is considered hydrophilic if a droplet of water dropped on the surface spreads, making wet a large area of the surface. instead of forming a sphere.

**Hyperthermophile** A microorganism, archaea or bacteria, that thrives at elevated temperature in excess of 80 °C.

**K<sub>M</sub>** In enzyme kinetics, it is known as Michaelis–Menten constant and is equal the concentration at which the rate of a simple enzyme-catalyzed reaction is equal to half the maximum rate as defined by the Michaelis–Menten equation:

$$V = \frac{V_{max}C_S}{K_M + C_S}$$

where C<sub>S</sub> represents the substrate concentration.

**Oligonucleotide** Short sequence of nucleotides, that is, fragments of single- or double stranded DNA or RNA that code for the synthesis of one or multiple amino acids

**SDS-PAGE** Sodium dodecyl sulfate polyacrylamide gel electrophoresis. This is a molecule (mostly proteins) separating method depending on the difference of molecular weight.

**V<sub>max</sub>** Is the maximal rate of an enzyme-catalyzed reaction.

### Introduction

Enzymes are sustainable catalysts widely used in the food industry. They have many advantages such as being very specific with respect to the substrate, being biodegradable, being active in relatively low concentrations, mild pH and temperature conditions (Sheldon and Van Pelt, 2013). Moreover, some commonly used enzyme preparations are considered generally recognized as safe (GRAS) by FDA (Simpson et al., 2012). Environmental factors that can destabilize enzymatic activity are temperature, pH and water activity. Stabilization of enzymes is important because they are costly and if they are too labile or have a low activity at the processing conditions (temperature, pH, water activity) then they are not cost effective to be used in food processing. Enzymes have an optimum temperature range at which they display their maximum activity and as temperature increases enzymes become deactivated. Food processes using enzymes operate at 5–20 °C below the temperature with the maximum enzyme activity to have a high activity without inactivating the enzyme before the process is completed (Parkin, 2008). Thermal stability of enzymes is especially important in processes that require the use of relative high temperatures such as production of HFCS. The strategies for thermal stabilization of enzymes covered on this review are mutagenesis, immobilization, chemical modification and high hydrostatic pressure (HHP). Table 1 shows examples of the stabilization strategies mentioned on this review.

### Mutagenesis

Mutagenesis consists of producing mutants by replacing one or multiple oligonucleotides in a gene that codes for a given enzyme. Such mutations alter the sequence of amino acids of the target enzyme for the purpose of altering one of several of its characteristics such as K<sub>M</sub>, V<sub>max</sub>, pH stability, thermal stability, solubility, substrate specificity or the requirement for a cofactor. When the crystal-line structure of the enzyme is not known, it is not possible to rationally hypothesize the exact amino acid substitution that will

**Table 1** Examples of enzyme stabilization studies using different strategies

Enzyme	Source	Application	Stabilization strategy	Mechanism of stabilization	Experimental evidence of stabilization	References
Lipase A	<i>Bacillus subtilis</i>	Interesterifications for production of flavors and structured lipids	Mutagenesis 12-point mutant	Formation of hydrogen bonds, increased rigidity, and stabilization of N-terminal helix	T <sub>m</sub> increased to 77 °C (22 °C greater than the wild type) and ΔG <sub>u</sub> increased to 15.1 kcal mol <sup>-1</sup> (3.7 kcal mol <sup>-1</sup> greater than the wild type)	<a href="#">Singh et al. (2015)</a>
α-amylase	<i>Geobacillus</i> sp.	Starch hydrolysis	Mutagenesis by deletion of two amino acids and replacement of another	Unclear	Half-life of the best mutant was 88 times smaller than the half-life of the wild type enzyme	<a href="#">Gao et al. (2017)</a>
Lipoxygenase	<i>Anabaena</i> sp. PCC 7120	Carotenoid bleaching and rheology improvement in bread making	Site-directed mutagenesis of one amino acid (N305D)	Increased hydrophobicity and hydrogen bonding at the protein surface. Stabilization of the α-helix and hydrophobic side chain	Two-fold increase in half-life relative to the wild type	<a href="#">Guo et al. (2014)</a>
Inulin fructotransferase	<i>Arthrobacter aureus</i>	Difuctose production	HHP	Formation of disulfide bonds and stabilization of hydrogen bonds	Inactivation rate decreased by 55.9% at 200 MPa relative to ambient pressure at 60 °C	<a href="#">Li et al. (2015)</a>
β-glucosidase	Almond	Aroma and flavor development	HHP	Strengthened hydration and stabilization of hydrogen bonds	Inactivation rate of enzyme decreased by 45% at 50 MPa relative to ambient pressure at 70 °C	<a href="#">Terefe et al. (2013)</a>
β-galactosidase	<i>Aspergillus oryzae</i> , <i>E. coli</i>	Dairy processing	HHP	Strengthened hydration	At 250 MPa, temperature leading to 50% activity loss within 30 min increased from 56 to 63 °C for enzyme from <i>A. oryzae</i> , and increased from 49 to 52 °C for enzyme from <i>E. coli</i>	<a href="#">Degraeve et al. (2002)</a>
Glucose dehydrogenase	Thermostable Bacterial strain SM4	Glucose biosensor	Glutaraldehyde crosslinking chemical modification	Prevention of subunit dissociation by Intra-molecular crosslinking of β and α-subunits	Retention of 90% of initial activity after 30 min at 65 °C and one optimum temperature (65 °C) instead of two (45 °C and 75 °C) relative to the native enzyme	<a href="#">Yamazaki et al. (1999)</a>
α-amylase	Not specified	Starch hydrolysis	Macromolecular cross-linked enzyme aggregates (M-CLEAs)	Stabilization of the quaternary structure by chemical cross-linking, retention of conformational flexibility	Two-fold increase in half-life relative to the free enzyme at 50 and 60 °C and 0.5-fold increase at 70 °C	<a href="#">Nadar et al. (2016)</a>
Pectate lyase	Psychrophilic <i>Bacillus subtilis</i> AKPSYP	Pectin degradation	Supplementation with calcium hydroxyapatite nanoparticles and entrapment in lipid functionalized single wall carbon nanotube (SWNT)	Protection of the Integrity of catalytic sites, improved catalytic efficiency by the large surface area of SWNTs	6.5 fold increase in activity with respect to free enzyme at 80 °C	<a href="#">Mukhopadhyay et al. (2015)</a>

result in the desired property change. In that case, random mutations (random mutagenesis) are produced. Each mutant is then tested for the desired property, the best is selected and cloned to mass-produce the enzyme with the desired property. When the crystalline structure is known (determined by X-ray diffraction) it is possible to hypothesize substitutions that result in the desired characteristic (Glick and Pasternak, 1994). Current computational power and software allow modelling such substitutions and predict some of the properties. Inaccuracy of such predictions is decreasing as models and computer power continue to improve. Then, site-directed mutations can be done experimentally by replacing specific nucleotides. The properties of the mutants are then determined and confirmed experimentally. The stability of wild-type and mutant enzymes is typically studied by micro-differential scanning microcalorimetry, which determines the melting temperature ( $T_m$ ) of the protein, which is typically associated to the disruption of the tertiary structure of the enzyme. A limitation of this measurement is that the enzymes can lose their activity upon heating at temperatures below  $T_m$ . Indeed, enzyme activity not only depends on the retention of the tertiary structure but also on the quaternary structure, the dissociation of a cofactor and other factors.

Comparison of enzymes from hyperthermophiles to their analogues from mesophiles has helped elucidating that multiple mechanisms and structural differences that contribute to stability. Enzymes from hyperthermophiles are 40%–85% similar in structure to their corresponding enzymes from mesophiles. Overall, enzymes from hyperthermophiles are more rigid and compact. Hydrophobic interactions in the core of the protein, salt bridges at the surface, alanine or glutamic acid stabilized  $\alpha$ -helices, number and size of loops, and/or hydrogen bonds contribute to the increased stability of enzymes from hyperthermophiles compared to their mesophiles counterparts (Vieille and Zeikus, 1996; Vieira and Degreve, 2009). These observations have contributed to strategically produce stable mutants. Enzymes from hyperthermophilic organisms have been also cloned into mesophilic organisms such as yeasts, *Escherichia coli*, or *Bacillus subtilis* (Schiraldi and De Rosa, 2002). Examples of such enzymes include  $\alpha$ -amylases, lipases, and other hydrolases used in the production of corn syrup from starch. However, because enzymes for hyperthermophiles can typically be cloned and produced in mesophiles, there is typically no need for further protein engineering.

Disulfide bonds typically help stabilizing proteins. Such bonds exist on some wild proteins but can also be formed by site-directed mutagenesis by substituting with cysteine pairs of amino acids that are spatially near each other. The selection of the sites for substitution is often guided by molecular simulations. Typically, such substitutions are done away from the active site of the enzyme to minimize effects on activity. Excessive addition of disulfide bonds can result in complete loss of enzyme activity that can be attributed to the distortion of the peptide backbone or to affecting the allostery of the enzyme, defeating the purpose of stabilization. Asparagine and glutamine can undergo deamidation when heated and destabilize the protein. Replacing these amino acids with others, in some cases increases protein stability (Glick and Pasternak, 1994). Salt bridges have stabilized proteins at high temperature but some reports indicate that they contribute little to stability at room temperature (Elcock, 1998).

Examples of enzymes with current or potential applications in food and feed processing or food analysis that have been stabilized by mutagenesis include lipases, (Singh et al., 2015; Mohammadi et al., 2016) amylases that work at acidic pH (Gao et al., 2017; Priyadharshini and Gunasekaran, 2007), pyranose oxidase (Masuda-Nishimura et al., 1999), lipoxygenase (Guo et al., 2014), and phytase (Shivange et al., 2016; Niu et al., 2017).

## Immobilization

Immobilization of enzymes consists of attaching an enzyme to a support material (carrier), creating enzyme agglomerates or entrapping enzymes into the support materials. There are two classes of immobilization methods physical and chemical. Physical methods involve weaker, non-covalent interactions such as hydrogen bonds, hydrophobic interactions, van der Waals forces, binding by affinity, ionic binding or mechanical containment. While chemical methods involve covalent bonds through ether, thio-ether, amide or carbamate bonds between the enzyme and support (Brena et al., 2013; Mohamad et al., 2015). Immobilization has been used to improve enzymes activity, stability, substrate specificity, reusability, continuous use, facilitate product separation and be environmentally friendly (Singh et al., 2013; Lee et al., 2017; Sheldon and Van Pelt, 2013). Some disadvantages are that enzyme conformation may change during immobilization or enzyme can be denatured, enzyme activity may be lower than free enzyme and mass transfer can be limited compared to free enzyme (Singh et al., 2013; Mateo et al., 2007). Many books and reviews on enzymes immobilization are available Guisan (2013) is an excellent reference book that describes immobilization protocols in detail that are simple and cost effective. Cao (2005) focuses more on the history, while also covering methods and principles of immobilization. Sheldon and Van Pelt (2013) review the basics of immobilization and its use in reactors. Reviews also have focused on immobilization of specific enzymes that are or have the potential of being used in industrial processes such as  $\alpha$ -amylases (Dey et al., 2016), lipases (Mateo et al., 2007; Shuai et al., 2017), cold adapted enzymes (Lee et al., 2017), thermophilic enzymes (Cowan and Fernandez-Lafuente, 2011). Combination of immobilization with chemical modification or protein engineering has also been covered (Singh et al., 2013; Fagain, 1995; Janecek, 1993). The most common immobilization techniques are adsorption, covalent tethering, crosslinking, and entrapment (Guisan, 2013; Mohamad et al., 2015) (Fig. 1). These four techniques are discussed below in more detail.

## Adsorption

Physical adsorption consists of the reversible immobilization of the enzyme on a solid support (carrier) and is rather random than targeted (Guisan, 2013; Sheldon, 2007; Lee et al., 2017; Mateo et al., 2007). Physical adsorption of lipases in hydrophobic supports

**Figure 1** Common Immobilization techniques. Note: Enzyme structure from the RCSB PDB ([www.rcsb.org](http://www.rcsb.org)) of PDB 5HSA Alcohol oxidase AOX1 from *Pichia Pastoris* (C. Koch, P. Neumann, O. Valerius, I. Feussner, R. Ficner) (2016) Crystal structure of alcohol oxidase from *Pichia pastoris*. PLoS One 11: e0149846-e0149846.

stabilizes their open structure and improves their activity (Guisan, 2013). Optimal reaction temperature of lipase from *Candida rugosa* increased from 35 °C to 50 °C when the enzyme was immobilized on a hydrophobic PVC support (Shaw et al., 1990). Physical adsorption of formaldehyde dehydrogenase (FDH) on mesoporous zirconia material (MPZ) improved thermal stability by preventing changes in the enzyme structure due to a strong interaction with the zirconia. While denaturation temperature of the immobilized enzyme was 78.9 °C compared to 51.8 °C of the native enzyme (Masuda et al., 2014).

### Covalent Tethering

Covalent tethering of enzymes to a solid support can be single or multipoint, or in the case of multimeric enzymes multi-subunit (Mateo et al., 2007; Pedroche et al., 2007; Lee et al., 2017). Multipoint covalent tethering consists of attaching the enzyme through specific residues on the enzyme surface to an activated support via short spacer arms (Guisan, 2013; Mateo et al., 2007) making the enzyme structure more stable by preventing conformational changes. Still the challenge is to achieve the desirable multiple-points configuration (Cowan and Fernandez-Lafuente, 2011; Singh et al., 2013). Multi-subunit covalent tethering has been combined with crosslinking of enzyme subunits to stabilize multimeric enzymes by preventing dissociation of the monomeric units (Mateo et al., 2007; Guisan, 2013). Activation groups commonly used are epoxy, glyoxyl groups or aldehyde (Lopez-Gallego et al., 2005). Glutaraldehyde is a cross-linker that is used to further stabilize enzymes covalently attached to a support via cross-linking with other enzymes or within their structure (Guisan, 2013). The carriers used in supporting bound immobilized enzymes (adsorption and covalent binding) can be synthetic organic polymers, biopolymers or inorganic solids (Sheldon, 2007). Multi-point attachment can increase the optimal temperature of enzymes. Shaw et al. (1990) increased *C. rugosa* optimal temperature from 35 °C to 55 °C using adsorption and multi-point attachment in chitosan using glutaraldehyde. The drawback of the multi-point attached enzyme was that the substrate accessibility was limited and the activity of the immobilized enzyme was lower than the adsorption approach. Lee et al. (2009) attributed the observed thermal stability of porcine pancreas lipase (PPL) immobilized on surface-modified nano-sized magnetite (S-NSM) at pH 7.7 to multipoint attachment or hydrophobic interaction or a combination of both. Activity of the immobilized PPL enzyme at 40 °C – 60 °C ranged from 43% to 133% higher than the free enzyme.

### Crosslinking

Crosslinking of enzyme aggregates or enzyme crystals requires bifunctional or polyfunctional reagents also called cross-linkers to keep enzymes together (Guisan, 2013; Sheldon, 2007) while a support (carrier) is not required (Nadar et al., 2016). Three common crosslinking techniques are cross-linked enzyme aggregates (CLEAS) (Nadar et al., 2016), cross-linked enzyme crystals (CLECs) and

combining 2 or 3 enzymes in a CLEAS (combi-CLEAS) (Sheldon and Van Pelt, 2013). CLEAS preparation involves two main steps: first precipitation of the enzyme in active form using precipitation agents such as water-miscible organic solvents, inorganic salts or non-ionic polymers; second cross-linking with bifunctional cross-linking reagents (Nadar et al., 2016). Glutaraldehyde is the most common cross-linker (Barbosa et al., 2014). Other cross-linkers are formaldehyde, aldehyde dextran, polyethylenimine (PEI) (Rueda et al., 2016). The crystalline matrix of CLECs seems to keep the structure of enzymes stable. CLEC of chloroperoxidase using glutaraldehyde as cross-linker kept 90% of the initial activity after 1 h incubation at pH 6, at 60 and 70 °C. While the soluble enzyme showed <10% of its initial activity. A limitation was that the immobilized enzyme had a lower activity than the soluble enzyme (Ayala et al., 2002). The stabilization mechanism of CLEAS has been attributed to the increase of rigidity of the enzyme caused by the covalent bond formed between enzyme and cross-linkers resulting in inhibition of conformational changes caused by heat. (Nadar et al., 2016). developed dextran and chitosan macromolecular cross-linked enzyme aggregates (M-CLEAs) and glutaraldehyde CLEAS (G-CLEAs) of  $\alpha$ -amylase. Inactivation rate constant of M-CLEAs and G-CLEAS were lower than the free enzyme at 50, 60 and 70 °C, at pH 6. While the activation energy for enzyme deactivation was the highest in M-CLEAs indicating a higher thermal stability than G-CLEAS. Additionally, the mass transfer of M-CLEAs was higher than G-CLEAS.

### Entrapment (Encapsulation)

Entrapment of enzymes is done via inclusion of enzymes within polymeric networks, membranes (Guisan, 2013), micro and nano-carriers (Yadav et al., 2011). To avoid confusion between entrapment and support binding Sheldon and Van Pelt (2013) defined entrapment as the enzyme being present during the synthesis of the polymeric matrix and support binding as the binding of the enzyme to a prefabricated support regardless if enzyme is inside or on the surface of the carrier. Entrapment of enzymes creates an optimal microenvironment for the enzyme and the structure of the enzyme remains stable because the enzyme is not chemically interacting with the material on which is entrapped. The drawback is that the diffusion of the substrate to the enzyme active site is limited (Mohamad et al., 2015; Gorecka and Jastrzebska, 2011) and entrapment is more commonly used to immobilize whole cells rather than enzymes.

### Chemical Modification (hydrophobic/hydrophilic modification)

Chemical modification of enzymes is an inexpensive and rapid way to improve biocatalyst performance and functionality, including thermostability, solubility and specificity. Modification includes attaching hydrophobic or hydrophilic groups, chemical cross-linking, or modifying the amino acid side-chains (Hassani, 2012). Improving enzyme thermostability is often achieved by modifying the hydrophobic/hydrophilic ratio on the enzyme surface (Longo and Combes, 1997, 1999). This approach works because it prevents the heat-induced denaturation caused by the interaction between hydrophobic clusters on the protein surface and the surrounding water. The contact of the non-polar region of enzymes with water is thermodynamically unfavorable and detrimental to the enzyme stability (Hassani, 2012). Chemical modifiers interact with the hydrophobic side chains of enzymes to create a shield protecting the hydrophobic clusters from interacting with water (Longo and Combes, 1997, 1999). Common used modifiers include polysaccharides, polyethylene glycol (PEG) (Longo and Combes, 1999; Liu et al., 2014; Daba et al., 2013), anhydride (Hassani, 2012; Xue et al., 2010), anthraquinone 2-carboxylic acid (AQ) (Mogharrab et al., 2007).

Chemical modification often changes the enzyme conformation by lowering the surface hydrophobicity and increasing hydrogen bond formation (Momeni et al., 2017; Liu et al., 2014). Introducing chemical modifiers, often hydrophilic modifiers, to the protein increases the general enzyme hydrophilicity (affinity to water). The surface hydrophobicity was often reported to decrease after attaching a hydrophilic modifier (Liu et al., 2014; Momeni et al., 2017). But Mogharrab et al. (2007) pointed out that the horseradish peroxidase modified by AQ changed the hydrophobic residues distributions rather than the total number on the enzyme surface. By reducing surface hydrophobicity, the attached hydrophilic groups prevent the hydrophobic regions from interaction with water, and thereby the enzyme thermostability increases. Generally, enzymes have higher thermal stability with introduction of additional hydrophilic groups (Hassani, 2012; Vinogradov et al., 2001). When more hydrophilic groups are introduced to the enzyme, there are less hydrophobic or non-polar groups interacting with water and then the enzyme is more resistant to heat. Introducing hydrophilic groups can also neutralize the positive charges (for example, on lysine residues) and then decrease the charge repulsion within polypeptides, which also contributes to increase the stability (Xue et al., 2010). However, adding too many hydrophilic groups to the enzyme surface can also increase the negative charges, and thereby increase the electrostatic repulsion when the negative charges become predominant. This repulsion prevents the protein refolding when unfolded at high temperatures. The higher the temperature, the less likely refolding will happen. Therefore, greater hydrophilization doesn't necessarily increase the enzyme thermostability (Hassani, 2012). Chemical modification can also increase the rigidity of the enzyme (Longo and Combes, 1999). After modifiers are attached to the enzyme, hydrogen bonds are formed between modifiers and solvent, or between the modifiers and amino acids (Hassani, 2012). A highly hydrogen-bonded structure increases rigidity which improves the conformation stability of the enzyme, decreasing the flexibility of the enzyme in solvent, which promotes thermostability (Liu et al., 2014).

## High Hydrostatic Pressure (HHP)

Though high hydrostatic pressure is typically used to inactivate enzymes, it also has the protective effect on enzymes against high temperature denaturation. This enables enzymes to work at higher temperatures, resulting in faster reaction rates (Li et al., 2015). But this protection effect has mainly been observed at high temperatures (above 50 °C) and relatively low pressures (below 400 MPa) (Terefe et al., 2013; Mozhaev et al., 1996). Pressure–temperature relationship has been comprehensively reviewed and explained (Eisenmenger and Reyes-De-Corcuera, 2009). An elliptical shaped plot (Fig. 2) has been used to show that pressure and temperature have antagonistic effect on the inactivation of enzymes. According to Fig. 2, enzymes in the native state (active) are inside the ellipse and denatured enzymes (inactive) are outside then at high temperature, moderately high pressure favors the native state of enzymes keeping them active (Terefe et al., 2013; Eisenmenger and Reyes-De-Corcuera, 2009; Degraeve et al., 2002).

HHP has a different enzyme inactivation mechanism from high temperature. The denaturation is more likely to be caused by penetration of water into the interior enzyme structure rather than completely unfolding. The electrostatic and hydrophobic interactions that support non-specific inter-protein aggregates are weakened by HHP (Degraeve et al., 2002). In many cases, the molar volume of pressure denatured enzyme is smaller than their native counterparts (Kirsch et al., 2013; Mozhaev et al., 1996). The mechanism of stabilizing enzymes by high pressure is not well understood. High pressure can cause protein conformation changes, hydration of charged groups, stabilization of hydrogen bonds, affect the reaction mechanism and the physical properties of solvent or substrate (Eisenmenger and Reyes-De-Corcuera, 2009; Kirsch et al., 2013). Pressure and temperature have opposite effects on the intramolecular interactions, and on the interaction between the protein functional groups and the solvent (Terefe et al., 2013; Eisenmenger and Reyes-De-Corcuera, 2009).

High temperature can cause the disruption of highly ordered structure of electrostricted water, resulting in the essential water loss at the beginning of the protein thermal inactivation, which will lead to structural rearrangement and denaturation. HHP, on the other hand, can strengthen the hydration of charged and non-polar groups since the electrostriction of water around the charged groups decreases the molar volume of water; and hence HHP can compress the protein hydration shell and counteract the process from high temperature (Terefe et al., 2013; Eisenmenger and Reyes-De-Corcuera, 2009; Degraeve et al., 2002; Mozhaev et al., 1996). High temperature weakens the intermolecular O–H interactions, resulting in softening the hydrogen bond network. HHP shortens the distance between the hydrogen bonds and thereby stabilizes them, which strengthens intermolecular O–H interactions (Li et al., 2015; Eisenmenger and Reyes-De-Corcuera, 2009). HHP can also strengthen the ion pairs which further stabilizes the tertiary and quaternary structures of enzymes (Li et al., 2015).

Disulfide bonds are important in the stability of the enzyme conformation. Introducing disulfide bonds into the enzyme is a common way to increase stability. Li et al. (2015) reported that HHP impeded the unfolding of the inulin fructotransferase (IFTase) conformation at high temperatures (70–80 °C). A 200 MPa treatment decreased the IFTase inactivation rate by 55.9% at 80 °C compared to the control enzyme at ambient pressure. Based on Far-UV circular dichroism spectra, fluorescence spectra and SDS-PAGE, the secondary and tertiary structure as well as the molecular weight didn't change. However, intramolecular disulfide bonds increased by 1.8-fold and 2.2-fold when IFTase was hold at 100 MPa and 200 MPa for 15 min at 80 °C. The formation of the intramolecular disulfide bonds was explained as the sulfhydryl-disulfide interchange reactions and the movement of the flexible thiol groups under high pressure; these bonds were related to the enzyme thermostability increase.

## Conclusions

As the structure of enzymes has become better known, the strategies to improve thermal stability have become more precise and effective. Simulation and knowledge of enzymes structure have further developed site-directed mutagenesis which combined

**Figure 2** Theoretical elliptical pressure and temperature diagram with native protein conformation inside and denatured conformation outside.

with tailor-made supports has made immobilization more specific. Hyperthermophile enzymes have been cloned to produce thermally stable mutants or being immobilized to increase reusability. Effectiveness of enzyme immobilization relies on maintaining the enzyme structure stable in the active configuration. Disulfide bonds formation, amino acids replacement, chemical cross-linking and modification of hydrophobic/hydrophilic ratio have been used to modify enzyme structures and make them more stable either through mutagenesis or chemical modification. HHP protective effect of enzymes from thermal denaturation happens at relative high temperatures and low pressures and although not fully understood yet, several mechanisms have been suggested. Combinations of mutagenesis, immobilization, chemical modification and HHP treatment are frequently used to further improve thermal stability of enzymes.

### Glossary

**Antioxidants** Substances that inhibit oxidation process

**Bioavailability** The proportion of a substance that enters the circulation when introduced into the body and can have an active effect on the physiological functions

**Biosynthesis** Production of complex molecules within living organisms or cells

**Carotenoids** Class of mainly yellow, orange, or red pigments in fruits and vegetables, which give color to plant parts and have health-promoting effects

**Phytochemicals** Naturally occurring plant substances having protective effects against diseases

### Introduction

Carotenoids are the organic pigments naturally present in plant-based foods. These are mainly comprised of 8 units of isoprene attached with a skeleton of 40 carbon atoms. There are over 600 known types of carotenoids out of which more than 100 types of carotenoids are found in plants. Additionally, these pigments are also present in some photosynthetic algae, fungi and bacteria. The existence of carotenoids has not been reported in animals including humans. The two broad categories of carotenoids are xanthophylls (astaxanthin, lutein and cryptoxanthin etc.) and carotenes ( $\alpha$ -,  $\beta$ -carotenes, lycopene and phytoene etc.). generally, xanthophylls are termed as oxygenated carotenoids whereas carotenes are referred as hydrocarbon carotenoids. In plants, carotenoids are responsible for imparting various colors to different parts of plants such as red, yellow and orange etc (Britton, 1993). In foods, carotenoids also provide attractive colors to the foods whereas in humans, carotenoids are claimed to have important functions (Stommel et al., 2005). For instance, most of the carotenoids are potent antioxidants while some are precursors of vitamin A ( $\beta$ -carotene).

Carotenoids are considered as important dietary bioactive components which are helpful in protecting against several degenerative conditions such as macular degeneration, cancer, diabetes, hypercholesterolemia, cardiovascular ailments, malfunctioning of immune system and cancer (Olson, 1999). Various mechanistic approaches have been reported to describe the health-promoting functionality of carotenoids: modulating the metabolism of carcinogens, ability to quench singlet oxygen, hindering proliferation of cells, scavenging of free radicals, improving the filtration of blue light, enhancing immune response and augmenting differentiation of cells through retinoids.

### Chemistry of Carotenoids

#### Structure and Classification

Carotenoids obtained from different sources have been isolated and characterized by various researchers. Generally, carotenoids are composed of 40 carbon atoms having conjugated double bonds in their structure. They are composed of 8 isoprenoid units which are linked in a way that their arrangement is reversed from the central point so that two methyl groups are arranged in 1,6-position whereas non-terminal methyl groups are positioned in 1,5-relationship. Carotenoid molecules have both cyclic and acyclic arrangements. Furthermore, a myriad of various structures has been seen through different modifications in the structural arrangement of carotenoid molecules which include cyclization, hydrogenation, dehydrogenation, migration of double bonds, extension or shortening of chains, isomerization or different combinations of these phenomena. Presence of conjugated double bonds in the structure of carotenoids is a distinctive property which is responsible for absorbance of light resulting in the development of different colors in various types of foods. Carotenoids are generally present in a stable *trans*-form however minor quantity is found in *cis*-form that are also converted to *trans*-forms during processing. Conventionally, trivial names are given to the carotenoids based on the biological sources from which these substances are derived. Contrarily, scientific names are given in a systematic way which describes their structures in an unambiguous manner. Common and technical names of some naturally-occurring carotenoids are given in Table 1.

**Table 1** Common and technical names of food carotenoids and their major sources

Trivial names	Technical names	Sources
Astaxanthin	3,3'-dihydroxy- $\beta$ , $\beta$ -carotene-4,4'-dione	Algae, shrimp, crabs
$\alpha$ -Carotene	$\beta$ , $\epsilon$ -carotene	Sweet potatoes, dark green vegetables, broccoli, green beans
$\beta$ -Carotene	$\beta$ , $\beta$ -carotene	Carrots, spinach, tomatoes, water squash, broccoli, sweet potatoes
$\alpha$ -Cryptoxanthin	$\beta$ , $\epsilon$ -carotene-3'-ol	Papaya, potatoes, orange rind
$\beta$ -Cryptoxanthin	$\beta$ , $\beta$ -carotene-3-ol	Oranges, persimmons
Lutein	$\beta$ , $\epsilon$ -carotene-3,3'-diol	Kale, spinach, broccoli, peas, lettuce
Lycopene	$\psi$ , $\psi$ -carotene	Tomatoes, watermelon, pink grapefruit, pink guava, papaya, sea-buckthorn, wolfberry
Phytoene	7,8,11,12,7',8',11',12'-octahydro- $\psi$ , $\psi$ -carotene	In majority of fruits and vegetables as precursor of carotenoids
Phytofluene	7,8,11,12,7',8'-hexahydro- $\psi$ , $\psi$ -carotene	In majority of fruits and vegetables as precursor of carotenoids
Zeaxanthin	$\beta$ , $\beta$ -carotene-3,3'-diol	Kale, spinach, broccoli, peas, lettuce

Modified from Rodriguez-Amaya (2001).

### Chemical Properties

The prime feature that provides the carotenoids their particular molecular shape, light-absorbing properties and chemical reactivity is the presence of alternate single and double bonds in their polyene chains. Mostly, carotenoids are lipophilic in nature having no or a very minute solubility in water and good solubility in different organic solvents. This property restricts them to the hydrophobic regions of the cell (inner core of cell membranes). However, sometimes carotenoids come in contact with the aqueous environment due to their interactions with proteins. *Trans*-form of carotenoids has linear structures and are found as rigid molecules due to the presence of strong conjugated double-bond system. However, *cis*-isomers greatly differ from the *trans*-configurations in their shape which significantly alters their reactivity. Additionally, the capability of *cis*-carotenoids to readily aggregate or crystalize also increases their solubility, absorbance and transportation.

Generally, carotenoids are unsaturated chemical compounds and are readily subjected to oxidation and isomerization. Interaction of active surface of the molecules with light, heat or acids results in isomerization of *trans*-configured carotenoids into *cis*-forms which results in loss of provitamin A activity and color. Oxidative degradation of carotenoids is the prime causative agent for loss of carotenoid activity and is usually stimulated by the presence of light, oxygen, metal ions and enzymes. The initial step in the oxidative denaturation of carotenoids is the generation of apo-carotenoids and epoxides. These molecules have shortened skeletons of carbon atoms and this fragmentation also leads to the formation of other smaller substances having low molecular weights like fatty acid oxidation process. The final consequence of this multi-step process is the complete loss of color and biological activity of carotenoids. Therefore, retention and stability of natural or added carotenoids in different food products is very important to preserve their biological activities.

### Biosynthesis of Carotenoids

Carotenoids are bio-synthesized in the chromoplasts through isoprenoid pathway. The biosynthesis of carotenoids is initialized with the condensation process in which pyruvate and glyceraldehyde 3-phosphate are converted to 2-C methyl-D-erythritol 4-phosphate. This compound is further metabolized to isopentenyl diphosphate via a series of different reactions after passing through the stages of reduction, phosphorylation and dehydration (Lichtenthaler, 1999). During the biosynthesis of carotenoids, C5 units are successively added to the C5 primer which results in the elongation of chain and formation of successive C10, C15 and C20 compounds. After that prenyl transferase enzyme builds up isoprenoid chain which is transformed to Ggps (geranylgeranyl diphosphate). Later, the two molecules of Ggps are linked (tail-to-tail combination) together to form phytoene. Phytoene is a colorless substance and undergoes a succession of chemical reactions leading to the development of new double bonds which extend the chromophore by two conjugating double bonds. The addition of double bonds on both sides of phytoene results in the formation of phytofluene. The end-product of the reaction is lycopene and carotenoids are claimed as the derivatives of lycopene.

The composition of carotenoids synthesized by plants is enriched by the presence of various biosynthetic precursors and derivatives of the main substances. Although, carotenoids are considered as plant pigments, these substances can also be encountered in animal-based food products. Animals are not capable of producing carotenoids so their carotenoids are usually derived from plant-based food/feed which they consume. These dietary carotenoids are accumulated in the animal tissues as unchanged pigments or transformed into animal carotenoids after slight modifications. Carotenoids can also be used as biomarkers to determine the quality of fruit-based food products or to detect the adulteration (Kurz et al., 2008).

### Sources of Carotenoids

As mentioned previously, carotenoids are majorly obtained from the plant sources. The other possible sources of carotenoids are bacteria, yeasts and algae. This section will mainly focus on the plants as prime sources of carotenoids.

### Fruits and Vegetables as Major Sources of Carotenoids

About 70%–90% of the totally consumed carotenoids is obtained from the fruit and vegetable origins. Plant-based foods are generally classified in three broad categories based on the presence of various types of carotenoids in them (Khachik et al., 1991).

1. Green vegetables generally contain different types of carotenes and xanthophylls. Examples include broccoli, green beans and spinach.
2. Red and yellow fruits and vegetables mainly possess carotenes. This group has more diversity of carotenoids as compared to the previous one. Plums, tomatoes, melons and carrots are included in this group.
3. Orange and yellow-colored fruits primarily have xanthophyll esters. This group generally consists of oranges (citrus group), pumpkins and peaches.

**Leafy vegetables** are considered as excellent source of carotenoids. They majorly contain lutein and  $\beta$ -carotene (80%) and traces of  $\alpha$ -carotene. In leafy vegetables,  $\beta$ -carotene is considered as the major source of vitamin A (Takyi, 2001). Studies have revealed that amongst various leafy vegetables, Moringa has  $\beta$ -carotene contents of 1400  $\mu\text{g}/100\text{ g}$  while lettuce has (19700  $\mu\text{g}/100\text{ g}$ )  $\beta$ -carotene contents (Bhaskarachary et al., 1995). Additionally, *Brassica oleracea* also contains significant quantities of lutein and  $\beta$ -carotene (Kopsell et al., 2004). Usually, lutein contents in *B. oleracea* are ranged from 4840–13430  $\mu\text{g}/100\text{ g}$  whereas  $\beta$ -carotene contents are present in the range from 3820–10000  $\mu\text{g}/100\text{ g}$ . Similarly, **roots** of carrots and sweet potatoes are also reported as imported sources of various dietary carotenoids. In addition to  $\beta$ -carotene,  $\alpha$ -carotene contents of carrots are also high. Generally, carrots possess 6500 to 8840  $\mu\text{g}/100\text{ g}$  of  $\beta$ -carotene (Muller, 1997; Murkovic et al., 2000).  $\beta$ -carotene contents of sweet potato ranged from 20  $\mu\text{g}/100\text{ g}$  (white-fleshed sweet potato) to 21800  $\mu\text{g}/100\text{ g}$  (yellow-fleshed sweet potato) in different cultivars sweet potato (Rodriguez-Amaya, 1997). Among **fruits**, pumpkin is one of the excellent sources of vitamin A and carotenoids.  $\beta$ -carotene concentration in different cultivars of pumpkin is varied from 60–7400  $\mu\text{g}/100\text{ g}$  while  $\alpha$ -carotene contents are ranged from 0–7500  $\mu\text{g}/100\text{ g}$  (Murkovic et al., 2000). Other important sources of carotenoids include mango, banana, watermelon, papaya and guava etc (Wall, 2006; Charoensiri et al., 2009). **Table 2** presents the quantities of various carotenoids in different fruits and vegetables.

### Health Benefits of Carotenoids

Carotenoids are present in plant tissues, algae and different microorganisms and majorly responsible for imparting color to different fruits and vegetables. Additionally, they also give color to the feathers and flesh of some birds and fish. Moreover, carotenoids also play an important role to improve the health of plants and animals. The major role of these phytochemicals is as antioxidants which is helpful in protecting tissue degradation due to oxygen and light (Britton et al., 1995). Because of increased awareness regarding the health-promoting functionalities of carotenoids, studies have been focused to develop functional food products having carotenoids as active ingredients. Dietary Carotenoids are claimed to play a vital role in upholding physical functions

**Table 2** Concentrations of different carotenoids in fruits and vegetables

Fruits/Vegetables	Carotenoid contents on fresh weight basis ( $\mu\text{g}/100\text{ g}$ )				
	Lutein	$\beta$ -Cryptoxanthin	Lycopene	$\alpha$ -Carotene	$\beta$ -Carotene
Apple	100–840	–	–	30	–
Apricot	0–141	28–231	0.5	0–37	140–6939
Avocados	–	36	–	28	53
Banana	0–37	–	–	0–157	0–92
Blackberry	270	–	–	9	100
Blueberry	230	–	–	–	49
Broccoli	830–4300	0	–	1	414–2760
Carrot	110–2097	–	–	530–35833	1161–64350
Grapefruit (red)	–	12	–	5	603
Guava	270	–	769–1816	–	102–2669
Lettuce	73–4537	–	–	–	48–3120
Mango	100	0–1640	–	–	300–4200
Orange	64–350	14–1395	–	0–400	0–500
Papaya	20–820	60–1483	2080–4750	0–60	71–1210
Peach	9–120	12–510	–	0–9	30–1480
Spinach	2047–20300	–	–	–	840–24070
Tomato	40–1300	–	21–62273	–	36–2232
Watermelon	0–40	62–457	2300–7200	0–1	44–324

Modified from Yahia and Ornelas-Paz (2010).

and preventing several diseases.  $\beta$ -carotene, lutein, lycopene and zeaxanthin are considered as the prominent carotenoids having numerous health benefits.

$\beta$ -carotene is helpful in maintaining the eye health, proper functionality of immune system, development of embryo and epithelial function (National Academy of Sciences et al., 2001). It is also important in reducing the risks of lung cancer and cardiovascular diseases. Similarly, consumption of lycopene is associated with the reduced risks of heart diseases (Wilcox et al., 2003) and various types of cancers viz. prostate (Miller et al., 1996), colon, skin, pancreas, esophagus, stomach (Clinton, 1998) and breast (Shi, 2000). Likewise, lutein and zeaxanthin prevent muscular degradation by delaying the aging process. Besides, lutein also reduces the incidences of cardiovascular disorders and cancer (Alves-Rodrigues and Shao, 2004).

## Factors Affecting Stability and Concentrations of Carotenoids in Foods

Various factors determine the quantity and stability of carotenoids in different food commodities. The most important contributors in this regard include variety of fruits or vegetables, type of product, stage of maturity or ripening, post-harvest handling, type of processing and storage conditions (Yahia et al., 2007). This section will provide an overview about the above-mentioned factors that influence concentrations of carotenoids and their stability.

### Fruit Maturity and Ripening Stage

Ripening or maturity stage of fruits and vegetables is regarded as the prime factor that affects carotenoid contents. Carotenoid contents are reported to increase during the ripening process due to metabolic action of ethylene (Carrillo-Lopez and Yahia, 2009). For example, lutein, carotene, xanthophyll and lycopene contents are increased at the stage of maturity in different fruits like mango, apricot, pepper and tomato. However, in some fruits carotenoid concentrations are decreased after ripening. For instance, studies have revealed that ripen dates have lower carotenoid contents as compared to the *Khalal* stage (Boudries et al., 2007).

During the ripening process, degradation of chlorophylls and chloroplasts occurs and chromoplasts are produced which lead to the increase in carotenoid contents. Additionally, several genes are switched-on during the ripening of fruits that enhance the production and accumulation of carotenoids in ripened fruits. Furthermore, several enzymes have also been detected that are responsible to increase the synthesis of carotenoids during the ripening process. An example is ripening-specific phytoene synthase which is activated in tomatoes at the stage of maturity and responsible for production of carotenoids (Fray and Grierson, 1993).

### Genotype

Genotype of fruits and vegetables is another important factor that influences the carotenoid contents in the final produce. A study confirms variations in carotenoid contents of various mango cultivars (Ornelas-Paz et al., 2007). Previous works have also demonstrated differences in the carotenoid concentrations in different varieties of other fruits such as tomato, apricot, cassava and sweet potato etc. Another investigation was based on determining the carotenoid contents in 52 different cultivars of lettuce (crisphead, butterhead, red leaf, Latin, romaine, stem lettuce, primitive and wild species) and proposed variations in carotenoid contents based on their genotypes (Beiquan, 2005). The study concluded that wild species had higher  $\beta$ -carotene contents as compared to cultivated varieties. Amongst cultivated varieties, the order of the carotenoid contents was; romaine > red leaf > butterhead > crisphead.

### Geographical Origin

Geographical origin of fruits and vegetables is also another important contributor that affects carotenoid contents in these commodities based on climatic conditions. For example, carotenoid contents of apricot fruit are reported to be higher in Mediterranean region as compared to the other geographical zones (Dragovic-Uzelac et al., 2007). Similarly, differences were observed in the carotenoid contents of same mango variety cultivated in two different regions of Brazil (Mercadante and Rodriguez-Amaya, 1998). These variations might be attributed to the differences in intensity, pattern and exposure time to sun light because these parameters also influence the stability of carotenoids.

### Structure of Fruits and Vegetables

Generally, carotenoid contents differ in their concentration in various parts of the same fruit or vegetable. Usually, peels of fruits or vegetables contain higher amounts of carotenoid contents as compared to pulp (Carrillo-Lopez and Yahia, 2009). This pattern is observed in different fruits such as tomato, kumquat, muskmelon, papaya, persimmon and mandarin hybrid. However, exceptions exist in nature. For example, red pomelo and pin-fleshed guava have shown higher carotenoid contents (particularly  $\beta$ -carotene) in pulp portion as compared to peels.

### Effect of Storage on Stability of Carotenoids

Storage conditions of fruits and vegetables also have considerable influence on the stability of carotenoids. It is generally observed that losses of carotenoids during the storage of mature fruits and vegetables are less in comparison with the ripened fruits and vegetables. Inappropriate storage conditions lead to the rapid loss of carotenoids during the storage period. Carotenoid losses are increased in the stored commodity due to the exposure of sunlight or oxygen during the storage or because of favorable conditions for wilting improper temperature. The interaction between temperature and maturity also influences the carotenoid stability during the storage period (Prono-Widayat et al., 2003). It is reported that mature and pre-mature pepino fruits showed significant increase in  $\beta$ -carotene contents at 18 °C as compared to 5 °C. It is also observed that storage of fruits at temperature range of 7 to 20 °C for 16 to 43 days causes a decrease in total carotenoid contents. Additionally,  $\alpha$ - and  $\beta$ -carotene contents are lost in carrots at storage temperature above 4 °C (Melendez-Martinez et al., 2004). On the other hand, lycopene contents in some fruits and vegetables are increased at about 25 °C (Lurie et al., 1996). Moreover, in low-temperature sensitive fruits (tomato) carotenoid contents are decreased if the temperature falls below chilling point (Yahia et al., 2007). It is also revealed that production of carotenoids is limited at storage temperature of 30 °C or above due to inhibition of enzymatic activity and ethylene production (Lurie et al., 1996).

### Effect of Processing on Stability of Carotenoids

Processing of fruits and vegetables also influences the stability and concentrations of carotenoids. The alteration in the carotenoid contents and stability may be influenced in a positive or negative way depending upon the processing type and conditions. Homogenization and chopping processes are reported to decrease carotenoid contents due to tissue disruption. For example, after maceration of green leaves, about 30% of  $\beta$ -carotene is lost in the first few minutes. Several carotenoids are also thought to be stable during the thermal processing. It is observed that during heat treatment, *cis*-lycopene is increased while *trans*-forms are decreased in guava juice. Additionally,  $\beta$ -carotene contents in mango are also retained during thermal processing.

### Strategies to Improve Stability of Carotenoids

Carotenoids have been extensively used in the food industry for imparting color to various food products or to enhance their storage stability (Britton and Khachik, 2009). Additionally, they have also been utilized as antioxidants to prevent oxidative degradation of emulsions such as in fat spreads, dairy products, salad dressings and mayonnaise etc (Lee and Choe, 2013). However, food processing or improper storage, transportation and handling of foods may cause decrease in the bioavailability and stability of carotenoids (Soukoulis and Bohn, 2018). These major factors include excessive storage period, exposure to light or oxygen and severe thermal treatments (Wang and Bohn, 2012). Hence, it is important to maintain the bioavailability and retention of carotenoid contents in various processed foods. Accordingly, this section will provide a brief description of various strategies to augment the stability of carotenoids during processing and storage of carotenoid-containing food products.

#### Encapsulation Techniques

Encapsulation is a technique which is used to provide a protection casing to the active compounds to enhance their stability. Encapsulation is aimed to provide protection to the active compounds against harsh environmental conditions (Augustin and Sanguansri, 2008). Selection of suitable carrier material for encapsulation is of prime importance. Important characteristics for encapsulating materials are inertness, safety (GRAS), versatility in organoleptic properties, cost-effectiveness, emulsifying & water-binding properties and controlled & targeted delivery (Connet et al., 2010). In case of carotenoids, some additional properties of wall-materials should also be kept under consideration which include solubility of the material in different solvents, crystallinity, changes in the droplet size during incorporation and structural modifications as these features directly affect the bioavailability, functionality and stability of carotenoids (Ribeiro et al., 2010). The most commonly employed encapsulating materials for carotenoids are soybean polysaccharides, mesquite gum, gellan gum, gum arabic and gelatin (Hojjati et al., 2011).

Various strategies have been adopted for encapsulating carotenoids to reap full benefits from these pigments in terms of their bioactive functionalities. The most extensively used techniques in this regard include freeze-drying, spray drying, formation of liposomes, use of inclusion complexes, coacervation and extrusion technology. Approaches to elevate the stability of carotenoids against several unfavorable environmental factors during processing and storage and to prevent the undesired chemical reactions with different food substances include micro- and nano-encapsulation techniques include use of nano-structured lipid carriers, solid-lipid nanoparticles, self-assembled protein nanomaterials (Soukoulis and Bohn, 2018).

#### Thermal and Non-thermal Treatments to Maintain Carotenoid Stability during Storage

Use of hot-air drying, freezing, pasteurization and freeze-drying etc. have been reported to maintain the stability of encapsulated carotenoids. In addition, these techniques have also shown their potential to reduce the losses of carotenoids during the storage of fruits and vegetables. For instance, spinach preserved through freezing or dehydration techniques did not show significant losses in lutein, zeaxanthin and violaxanthin contents during the storage (Rodriguez-Amaya, 1999). It is also reported that dehydration of mango fruits facilitates conversion of *trans*-forms of  $\beta$ -carotene to *cis*-forms (Pott et al., 2003). Similarly,  $\beta$ -carotene contents of

*Lycium barbarum* are also reported to increase up to 2–22 times during dehydration process (Wen-ping et al., 2008). Likewise, pasteurization of juices also results in improvement in the red color and carotenoid contents (Odriozola-Serrano et al., 2009).

Studies have also revealed less cooking time at low temperature also facilitates retention of carotenoids in fruits and vegetables. Additionally, scalding of carrots for 15 min. at different temperatures (50, 70, 90 °C) is also useful in maintain the lycopene contents (Meléndez-Martínez et al., 2004). Moreover, canning process is helpful in improving the stability of carotenoids during storage period. Studies have revealed that canning significantly increases the carotenoid contents in various fruits and vegetables such as 39% increase in sweet potatoes, 33% in carrots, 20% in tomato juice, 19% in collards, 13% in spinach and 10% in peaches (Yahia and Ornelas-Paz, 2010).

In addition to thermal processing techniques, some non-thermal processing approaches have also shown their potential in improving the stability of carotenoids. In this regard, pulsed electric field processing (Cortés et al., 2006), high pressure processing technique, osmotic dehydration (Tonon et al., 2007) and irradiation (Hajare et al., 2007) are reported to induce non-significant losses and improved stability of carotenoids in intact fruits and vegetables and their purees and juices. This discussion concludes that use of low-temperature processing methods, less processing time, prevention from exposure to oxygen and employing non-thermal processing methods can significantly prevent carotenoid losses and improve the stability of carotenoids during processing and subsequent storage.

## Conclusions

The present chapter concludes that carotenoids are quite beneficial for improving the health status of consumers. Food containing carotenoids are needed to preserve or process in a way so that their carotenoid contents are not lost during the processing and subsequent storage. In this regard several approaches including encapsulation technologies, freeze-drying, low-temperature storage, canning, pasteurization, scalding, dehydration, pulsed electric field technology, high hydrostatic pressure processing, osmotic dehydration and irradiation are reported to have positive effects in retaining the stability of carotenoids in various food commodities. Hence, it is recommended that use of these processing techniques and other related methods (Cryogenic freezing, ultra-freezing techniques, ultrasonication etc.) should be encouraged to maintain or enhance carotenoid contents in stored food products for maximum bioavailability of these beneficial phytochemicals.

## Glossary

**Allergens** substance that causes an allergic reaction by stimulating an abnormal response by the immune system.

**Bioactive peptides** protein hydrolysates which, upon entry and absorption into the body, have the ability to induce certain desirable and physiologically measurable activities such as immunomodulatory, cytomodulatory, antihypertensive, and antimicrobial activities.

**Bioinformatics** an integration of methods, software and statistical tools for studying and analysing complex biological data.

**Chemoinformatics** the collection, analysis and storage of biochemical data.

**Chemometrics** the use of mathematical and statistical tools to analyze biochemical data and develop models for better understanding a biological or chemical system.

**In silico** scientific experiments or research conducted or produced by means of modelling or simulation on a computer.

**Quantitative structure-activity relationship (QSAR)** the application of bioinformatics to identify relationships between chemical structure (or structural-related properties) and biological activities (or target property) of compounds.

**Tastant** A taste-provoking chemical compound.

## Definition, Health Functions, and Applications of Bioactive Peptides

By definition, the bioactive peptides discussed in this paper are short amino acid chains derived from proteins by the proteolytic actions of exogenous or endogenous enzymes, or microorganisms used for fermentation (Agyei and Danquah, 2012; Udenigwe and Aluko, 2012). These peptides are also known as cryptic peptides, to indicate that they are inactive or hidden within the parent protein structure; therefore, enzymatic release is necessary for the peptides to exhibit their biological activities (Udenigwe, 2014). As briefly discussed in this section, food-derived peptides have several biological roles. These activities mostly stem from the fact that the peptides are structurally similar to endogenous peptide ligands, which bind their physiological receptors to trigger signalling processes in cells. Therefore, some food peptides can mimic these endogenous peptides in regulating cellular functions, especially in preventing and managing aberrant health processes and conditions. The diverse structural features of the peptides also broaden these possibilities. For instance, the range of peptide molecular size, net charge and hydrophobicity, increases the chances of their binding to many biological targets.

Most food-derived bioactive peptide reported to date downregulate blood pressure increases during hypertension. This biological function involves structure-dependent binding and can be achieved through various mechanisms including inhibition of angiotensin converting enzyme (ACE) and renin activities, upregulation of ACE2 expression, production of vasorelaxation factors, and angiotensin II receptor and calcium channel blocking effects (Majumder and Wu, 2014; Udenigwe and Mohan, 2014). Moreover, some amino acid residues act as electron donors, prooxidant metal chelators, radical trapping agents, and activators of cellular redox enzymes, which make them to become antioxidative and useful in combating cellular oxidative stress (Samaranayaka and Li-Chan, 2011). Other notable biological activities reported for food peptides include antimicrobial activity (due to peptide amphipathicity) (Haque and Chand, 2008), and hypolipidemic activity (due to their roles in binding bile acids, disrupting intestinal lipid micelles, regulating lipogenic genes/proteins in hepatocytes and adipocytes) (Howard and Udenigwe, 2013). Furthermore, some food peptides possess anticancer properties (Rajendran et al., 2017) and anti-diabetic activity (due to inhibition of dipeptidyl peptidase [DPP-IV] and incretins) (Lacroix and Li-Chan, 2014; Nongonierma and Fitzgerald, 2016). These bioactivities form the basis of application of peptides in the food and health sectors as nutraceuticals and functional ingredients for health product and cosmetics formulations.

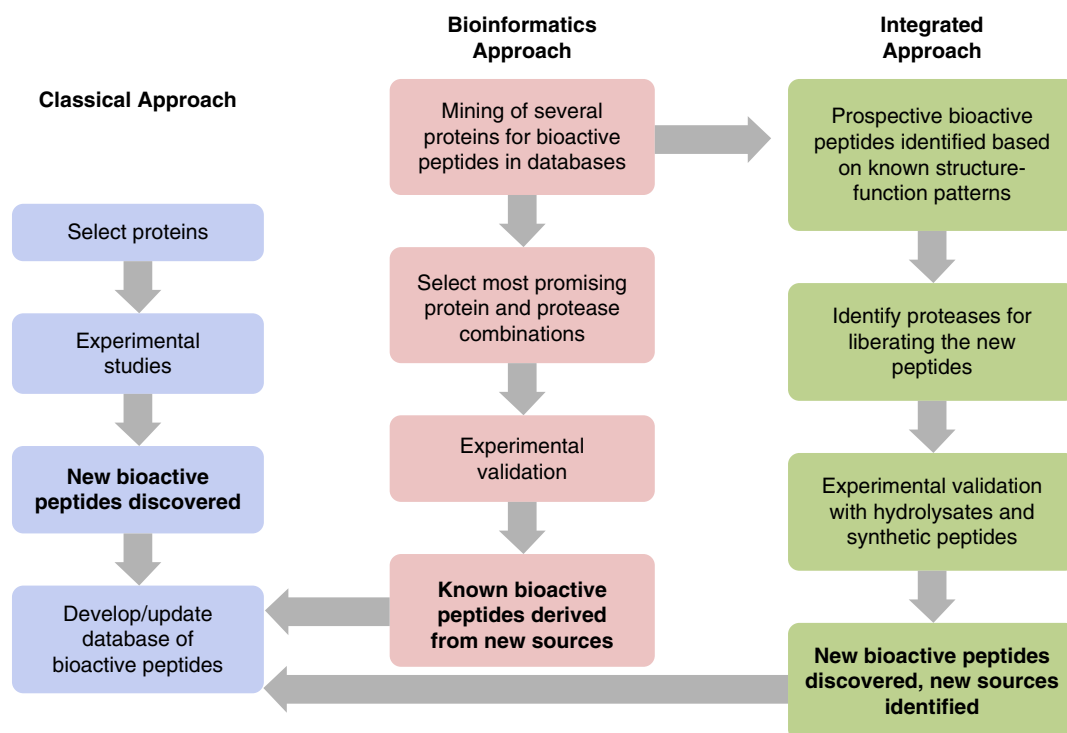

## Prospects of Bioinformatics in the Production of Bioactive Peptides

The bioactivity of a given peptide ligand is heavily dependent on its chemical structure. Therefore, the success of peptide discovery research lies on having a solid knowledge of peptide chemistry and processing techniques for releasing and fractionating the peptides of interest. The traditional approach used to discover bioactive peptides from food proteins could be laborious when evaluating many food proteins and proteases. Typically, a few starting materials are selected for bioactive peptide discovery, which may lead to limited positive leads for further exploration. Moreover, the process cannot easily capture the diverse structural features of peptides or recover high yields of the peptides when there is limited knowledge of the chemistry of the starting materials. For

instance, dipeptides with N-terminal bulky amino acid and C-terminal aliphatic amino acid would likely inhibit ACE and DPP-IV activities whereas a combination of net cationic charge and hydrophobicity of peptides is typical for antimicrobial peptides. Likewise, antioxidant peptides often need to have the sulfhydryl group of cysteine or free radical trapping moiety of phenylalanine in their structures. Traditional method of protein/protease selection and bioassay-guided fractionation for food peptide discovery does not particularly rely on these important structure-function relationships. Consequently, the use of bioinformatics facilitates the strategic screening of combinations of protein sources, hundreds of protein sequences and tens of proteases with defined specificities, in order to find the best matches that can yield the desired bioactive peptides. An integrated approach to the discovery of bioactive peptides combines the predictive powers of bioinformatics and experimental validation with using synthetic or pure peptides and hydrolysates. A comparison of the various discovery strategies are captured in Fig. 1.

Bioinformatics has been successfully used in analysing bioactive peptides in food proteins (Holton et al., 2013b; Iwaniak et al., 2015; Udenigwe, 2014). The *in silico* process can allow for a closer look at the important structural information needed for the desired activity and application, and the design of tailored processing methods for the release and fractionation of peptides with such properties from their parent proteins (Agyei et al., 2016). Furthermore, bioinformatics tools can help in identifying negative attributes during bioactive peptide production. For instance, it is possible to detect the presence of known or potential allergenic epitopes in food proteins using *in silico* tools (Hayes et al., 2015). This information can help in developing appropriate measures to avoid their presence, limit their amounts, or remove them entirely from the peptide preparations prior to experimental studies or functional food product formulation.

Besides bioactivity, peptides have a wide range of taste including bitterness (Temussi, 2012), which would likely influence quality and consumer acceptability of the products containing them (Udenigwe, 2014). Peptide bitterness is often evaluated after their production, using trained human tasters or computerized approaches e.g. electronic tongue. As discussed below, *in silico* tools also provide information on the bitterness potential of peptides based on the presence of bitter-tasting hydrophobic amino acid residues e.g. phenylalanine and proline (Iwaniak et al., 2016a). This prediction helps in identifying and eliminating peptide bitterness early in the discovery phase prior to product development. Furthermore, many peptides need to be transported across cells and be bioavailable in order to exhibit their bioactivities. Bioinformatics tools are being developed to predict the cell penetrating properties of peptides (Holton et al., 2013a), which can provide important information on their potential bioavailability. Therefore, the *in silico* approach has the potential to enhance various aspects of food peptide research, especially when complemented with wet lab analyses and *in vivo* studies.

## Bioinformatics Tools in the Discovery of Bioactive Peptides

Bioinformatics use computer software, mathematical algorithms, and statistical tools to archive, retrieve, and analyze biological data (Aamer Mehmood, 2014). Due to their ability to analyze huge amount of biological data quickly and cost-effectively, bioinformatics tools are vastly used in studies of bioactive peptides to characterise the structure and properties of these peptides, thereby assisting in the prediction of their potential impacts on human health and in food quality estimation (Iwaniak et al., 2015; Udenigwe, 2014). In this context, several databases exist for purposes such as generating peptides from protein sequences in silico, characterising the biological (including allergenicity and toxicity) and sensorial properties of the peptides generated. The web addresses of some of these databases and in silico tools are shown in Tables 1–4, and are freely available for access and use.

### Databases for In Silico Digestion and Bioactivity Prediction

The first step is to select food source and/or proteins and retrieve their amino acid sequence from databases such as UniProt, Pubmed, and BIOPEP. BLAST (Basic Local Alignment Search Tool) and ExPasy ProtParam tools are often used to compare and to calculate significant areas of commonality between protein sequences in order to avoid repetition of data. The selected proteins are then subjected to in silico proteolysis or “enzyme action” by using popular in silico proteolysis tools such as BIOPEP and ExPASy Peptide Cutter. Suitable enzyme are selected based on the goal of the, i.e. whether the aim is to generate novel peptides from a known food protein or to generate peptides from newly discovered proteolytic enzymes. These databases also allow the selection of multiple enzymes to act sequentially; and this makes it possible to predict the release of peptides following a physiologic process such as simulated gastric digestion. Known and unknown peptides generated in silico are identified by using databases such as BIOPEP, CAMP and PeptideDB. These databases also help identify which of the derived peptides are bioactive, by comparing with published bioactive peptide sequences. To determine the peptide rank and prospect of bioactivity based on established structure–function patterns, peptides from each protease/subunit combination can be entered into Peptide Ranker in the Bioware webserver (Lafarga et al., 2014, 2015a; Udenigwe, 2014; Udenigwe et al., 2013). The best protein-protease combinations are then used in follow-up studies to experimentally confirm under laboratory conditions, the production and bioactivities of the peptides generated in silico. This approach to the discovery of bioactive peptides has been used to predict the release of various bioactive sequences from a range of different food sources (Nongonierma and Fitzgerald, 2014), including dipeptidyl peptidase IV (DPP-IV) inhibitory peptides from camel milk (Nongonierma et al., 2018), soy and lupin proteins (Lammi et al., 2016), and silver carp (Zhang et al., 2016); prolyl endopeptidase inhibitors from meat proteins (Lafarga et al., 2015a); antihypertensive peptides from Rubisco cereal proteins (Udenigwe et al., 2013); and multifunctional (DPP-IV, renin and ACE inhibitory) peptides from bovine serum albumin (Lafarga et al., 2014) and bovine fibrinogen (Lafarga et al., 2015b). Tables 1 and 2 shows a list of protein/peptide sequence databases, and databases for in silico digestion/bioactivity prediction respectively.

### Databases for Chemometric Characterisation of In Silico Peptides

While chemometrics involves the use of mathematical and statistical tools to analyze biochemical data and develop models for better understanding a bio/chemical system (Bertacchini et al., 2013); the collection, analysis and storage of biochemical data is known as chemoinformatics (Wishart, 2007). In chemometrics, analysis of molecules are done to predict biological activity of interested molecules, and the molecular activity, and the properties of biomolecules are defined as endogenous and exogenous variables respectively. To explain the effects of endogenous and exogenous variables on bioactivity, several mathematical models based on regression analysis are used. Artificial neural networks (ANNs), principal component analysis (PCA) and partial least squares (PLS) regression are examples of the most widely used chemometric models. Chemometrics is made possible by the fact that proteins, peptides and amino acids under certain conditions have a defined 3D conformation which exhibit a high degree of structure–activity relationships. The principle for predicting biological properties of designing processes for separation of the peptides may be informed by mechanistic modelling of the quantitative structure–activity relationships (QSAR), based on molecular properties such as size, charge, and polarity or hydrophobicity (Agyei et al., 2016; Li-Chan, 2015). Some databases that hold chemical information, properties and structures of molecules are PubChem, eMolecules, DrugBank, ChemSpider, and AAindex (Iwaniak et al., 2015).

The role of chemometrics in the discovery and characterisation of bioactive peptide has been demonstrated in a number of studies. The amino acid concentration of selected proteins can be determined using ProtParam, an in silico analysis program which computes the physicochemical properties of a peptide or protein from its amino acid sequence (Lafarga et al., 2015a). Chemometric analysis of the amino acid has also been done using PLS regression method to investigate antioxidant activities of food protein hydrolysates (Udenigwe and Aluko, 2011). QSAR studies have been used to identify the structural properties of peptides that is responsible for the biological properties of peptides. For example, the factors that determine the antioxidant activities of tuna protein hydrolysate fractions have been identified to be short peptide sequence (between tripeptides and hexapeptides), low molecular weight, the presence of hydrophobic and aromatic amino acid residues, and a peculiar order of amino acid sequences (Chi et al., 2015). A list of databases for chemometric characterisation of peptides is shown in Table 3.

Chemical Entities of Biological Interest (ChEBI) <a href="https://www.ebi.ac.uk/chebi/">https://www.ebi.ac.uk/chebi/</a>	Electronic dictionary of molecular entities focused on small chemical compounds

### Databases for Predicting Tastant Peptides

The basic taste sensations associated with food components are sweet, sour, salty, bitter and umami. Among these, sweet, bitter, and umami have been linked to the peptide components of some foods (Iwaniak et al., 2016a). Taste-provoking peptides are called peptide tastants, and a number of research studies have shown that most bioactive peptides reported in the literature exhibit one or more of the aforementioned tastes (Cheung and Li-Chan, 2010; Cheung et al., 2015; Li-Chan, 2015). But bitterness is often distinctively avoided and thought to be a protective mechanism against consuming toxics (Breslin, 2013). Many clinical drugs cause bitter tastes which presents a major compliance problem for pediatric drugs (Bahia et al., 2017; Dagan-Wiener et al., 2017). Prediction of bitterness is important in food industry because, for the most part, consumers avoid bitter foods no matter how healthy or rich in bioactive components (Drewnowski and Gomez-Carneros, 2000). Prediction of bitterness is also important as it assists in the development of bitterness masking products and procedures (Dagan-Wiener et al., 2017). Bitterness is recognized in human by 25 G-protein-coupled receptors of hTAS2R gene family. These receptors are expressed in the oral cavity, the gastrointestinal tract, the upper airways, and the heart and in other tissues (Bahia et al., 2017; Dagan-Wiener et al., 2017; Li-Chan, 2015; Wiener et al., 2012). Efficient tools for predicting, measuring and masking bitterness of ingredient is often sought after by pharmaceutical and food industries. The chemical diversity of bitter compounds, and occurrence of minor differences between bitter and non-bitter compounds are the main challenge in computational bitterness prediction. Ligand-based methods, structure-based methods, and machine learning techniques are few models used in bitterness prediction. Consequently, most of the predictive models focus on specific families of bitter compounds such as cynaropicrin and grosheimin derivatives, and benzenesulfamates (Dagan-Wiener et al., 2017). However, previous studies have proposed a correlation between hydrophobicity and bitterness. For example, bitterness of the soy peptides is predominantly associated with molecular mass (Wiener et al., 2012). Chemical structure-based computational prediction approach were used in BitterDB, a database of bitter compounds. It includes structurally diverse bitter compounds such as ions, peptides, alkaloids, polyphenols, glucosinolates (Dagan-Wiener et al., 2017). The BIOPEP database also has a built-in function that gives information about the sensory properties of peptides (Iwaniak et al., 2016b). This function is accessible by clicking the "Sensory Peptides and amino acids" link on the database homepage. Other databases for predicting taste-evoking properties of peptides is given in Table 4.

**Table 4** Some databases or in silico tools for predicting tastant properties of peptides and amino acids

<i>Tastant prediction</i>	
BIOPEP <a href="http://www.uwm.edu.pl/biochemia/index.php/en/biopep">http://www.uwm.edu.pl/biochemia/index.php/en/biopep</a>	Database of protein and bioactive peptide sequences, allergenic peptides with their epitopes, and sensory peptides and amino acids
BitterDB <a href="http://bitterdb.agri.huji.ac.il/dbbitter.php">http://bitterdb.agri.huji.ac.il/dbbitter.php</a>	A database of bitter compounds
BitterPredit <a href="http://bitterdb.agri.huji.ac.il/dbbitter.php#BitterPredit">http://bitterdb.agri.huji.ac.il/dbbitter.php#BitterPredit</a>	A platform for the structure-based prediction of bitterness of compounds
BitterX <a href="http://mdl.shsmu.edu.cn/BitterX/">http://mdl.shsmu.edu.cn/BitterX/</a>	A web server on bitter compound, their identification, and prediction (especially in the case of small molecule compounds)

### Databases for Allergenicity and Toxicity Prediction

Food allergies are a major health concern in the development of food products, and recent studies show that cases of food allergies in developed countries are on the rise (Prescott et al., 2013; Tang and Mullins, 2017). The detection and elimination of food-derived allergens is therefore of prior concern to the food technologists. Since almost all allergenic compounds in food are protein in nature (Verhoeckx et al., 2015), it is important to study the allergenic potential of bioactive peptides, or use peptides and protein hydrolysates as a molecular marker for the detection of food allergens. Further, being able to predict the potential toxicity of peptides saves time, money and effort in the development of peptide-based functional foods and pharmaceuticals. The importance of this is highlighted by the fact that the WHO and FAO have proposed guidelines for the studying and predicting the allergenic potential of food proteins (FAO/WHO, 2001).

Predicting whether a food peptides could be toxic or allergenic is made possible because the sequences and structures of several allergenic or toxic proteins is already known. The bioinformatics approach for predicting toxic or allergenic peptides relies on identifying structural similarities and sequence identity of the peptide with those of known allergenic protein/peptide epitopes or toxic regions in protein sequences (Dziuba et al., 2013; Gupta et al., 2013; Schein et al., 2007). These in silico tools allow the prediction of allergenic peptides by one or more of the following approaches: mapping IgE epitopes; searching for allergenic motifs using motif-based sequence analysis tools such as MAST (motif alignment and search tool) and Multiple EM for Motif Elicitation (MEME); support vector machine modelling of the composition of amino acids and (di)peptides; and Basic Local Alignment Search Tool (BLAST) searches of allergen-representative peptides (ARPs). The accuracy of prediction is enhanced by using a hybrid approach which combines one or more of the above approaches.

In silico prediction of allergenic peptides has been studied in a number of food products, including a tryptic digests of the marine bivalve *Ruditapes philippinarum* using AlgPred. Out of 966 peptides generated, 510 and 31 peptides were identified to be allergens or potential allergens respectively (Yu et al., 2017). Further, the toxicity of the meat-derived prolyl endopeptidase inhibitors has been studied with ToxinPred (Lafarga et al., 2015a). Table 5 gives a list of other databases or in silico tools for predicting toxicity and allergenicity in peptides.

### Challenges With the Use of Bioinformatics in Bioactive Peptides Discovery

Despite the prospects discussed above, there are some limitations to the use of bioinformatics in analysing food proteins towards bioactive peptide discovery. First, during in silico analysis, it is assumed that the structure of the protein substrate is linear (primary structure), and that the selected protease will cleave every possible peptide bond that it can to release a repertoire of peptides, some of which can be bioactive. This approach does not consider the 3-dimensional structure of proteins, stabilized by covalent and non-covalent bonds, which would create a sort of hindrance that limits protease accessibility to peptide bonds in the protein core. We found that this issue led to the generation of more peptides in silico than experimentally during potato protein hydrolysis (Rajendran et al., 2016). Moreover, the effect of food processing on the structural integrity of the protein prior to hydrolysis is unaccounted for during in silico digestion. For instance, protein aggregation can occur during heating and high-pressure treatments, and this can perturb protein-protease interactions and limit protein hydrolysis. Our peptidomics study also noted the occurrence of post-translational modifications (PTMs) in peptides generated by protein hydrolysis (Rajendran et al., 2016). The PTMs include methionine oxidation and glutamine/asparagine deamidation. Based on fundamental chemistry, the peptides are also susceptible to undergo other PTMs e.g. dehydration, acetylation, pyro-glutamate formation, trimethylation, etc. This factor is important because the PTMs can alter the structure, function/bioactivity, and bioavailability of the peptides. While it is possible to map the amino acid residues susceptible to PTMs in silico, currently available bioinformatics tools cannot predict their occurrence during protein hydrolysis. This makes it challenging to predict accurately the nature of the released peptides using bioinformatics. Finally, while comprehensive databases exist for some protein sources (e.g. bovine milk), proteins from non-traditional sources such as microalgae and

**Table 5** Some databases or in silico tools for predicting toxicity and allergenicity in peptides

<i>Name of database/in silico tool</i>	<i>Description available on homepage</i>
ToxinPred <a href="http://www.imtech.res.in/raghava/toxinpred/">http://www.imtech.res.in/raghava/toxinpred/</a>	In silico tool to predict and design toxic/non-toxic peptides
BIOPEP <a href="http://www.uwm.edu.pl/biochemia/index.php/en/biopep">http://www.uwm.edu.pl/biochemia/index.php/en/biopep</a>	Database of protein and bioactive peptide sequences, allergenic peptides with their epitopes, and sensory peptides and amino acids
AlgPred <a href="http://www.imtech.res.in/raghava/algpred/">http://www.imtech.res.in/raghava/algpred/</a>	Plat-form for predicting allergenic proteins and peptides and mapping immunoglobulin E epitopes
Allerdictor <a href="http://allerdictor.vbi.vt.edu/">http://allerdictor.vbi.vt.edu/</a>	A sequence-based allergen prediction tool
SORTALLER <a href="http://sortaller.gzhmu.edu.cn/">http://sortaller.gzhmu.edu.cn/</a>	An online allergen classifier
ProPepper™ <a href="https://propepper.net/">https://propepper.net/</a>	Database of cereal prolamin epitopes, peptides and proteins
IEDB <a href="http://www.iedb.org/">http://www.iedb.org/</a>	Database characterizing antibody and T cell epitopes studied in humans, non-human primates, and other animal species

edible insects are yet to be completely identified, and many of their sequences are currently not available in protein databases. This limits the exploration of such proteins, commonly regarded as sustainable, as precursors of bioactive peptides, which would potentially leading to missed opportunities.

## Concluding Remarks

The traditional means of bioactive peptide discovery for food applications is labour intensive and often involves working with a few protein-protease sample sets at a time, with limited knowledge of structure-function relationships. Bioinformatics offers a unique approach that can rapidly screen many proteins for bioactive motifs, with detailed information on their structural properties. Although with limitations, the ability to predict undesirable features, such as peptide bitterness and allergenic epitopes, and rank a wide range of food proteins using the in silico approach facilitates the selection of top candidates for bioactive peptide discovery. Furthermore, the bioinformatics method can result in the rapid discovery of new bioactive peptides that would otherwise require lengthy procedures to accomplish. Future studies need to address the challenges discussed in this paper in order to strengthen the use of bioinformatics in food-derived bioactive peptide research.

## Introduction

Lipids are one of the macronutrients in food and play an important role in the food system such as texture, flavour and taste. Lipids can be in the solid (fat) or liquid (oil) forms at ambient temperature, soluble in the organic solvents and insoluble in water. The major component of lipids is triglycerides that consist of glycerol and fatty acids. Previous studies have shown that omega-3 fatty acids are beneficial to human health such as reducing the risk of cardiovascular disease, cancers, inflammatory disorders, cognitive decline and Alzheimer's disease (Holub, 2009; Calder, 2006; Mandal et al., 2010; Cockbain, 2012; Morris et al., 2005). Fish oil and omega-3 fatty acids concentrates have been incorporated into the food products and marketed as functional foods. However, these foods are more susceptible to oxidation due to the high polyunsaturated fatty acids content in them.

Lipid oxidation can occur in the presence of oxygen, light, temperature, moisture and trace metals. Lipid oxidation will decrease the food quality, stability, safety and nutritive value of the food (Luther et al., 2007) as it produces unpleasant off-flavours and unhealthy compounds such as free radicals and reactive aldehydes (Jacobsen et al., 2008). It also gives a negative impact on sensory and customer acceptance to the food products fortified with fish oil (Sullivan et al., 2011; Dekker et al., 2012). Humans have a low sensory threshold for volatile off-flavours resulting from oxidation of omega-3 fatty acids, therefore oxidised food products are less acceptable to the consumers (Frankel, 2005). Furthermore, consumption of high amounts of oxidation products can cause oxidative stress in the human body, which may increase the risk of prevalence of cancer, coronary heart disease and other diseases (Frankel, 2005).

Oxidative stability is an important quality control parameter for the manufacturers and users of many different types of commercial materials including edible fats and oils (Hassel, 1976). Fish oil is susceptible to oxidation due its high polyunsaturated fatty acid (PUFA) content. Thus, oxidative and thermal stability of fish oil are important parameters in the processing and production of fish oil and fish oil-fortified food products (Tengku-Rozaina and Birch, 2016). Autoxidation is the most common oxidation that leads to oxidative deterioration of lipids in the presence of oxygen (Shahidi and Zhong, 2005). Oxidation of lipids at high temperature is known as thermal oxidation.

## Lipid Oxidation (Autoxidation)

Lipid oxidation (autoxidation) is a free radical chain reaction and occurs in three steps: initiation, propagation and termination (Fig. 1). According to Shahidi and Wanasundara (2002), initiation of lipid oxidation begins with abstraction of a hydrogen atom adjacent to a double bond in a fatty acid (RH), to form an alkyl free radical (R<sup>•</sup>). The free radical will then react with atmospheric oxygen to produce a peroxy radical (ROO<sup>•</sup>) and sequester a hydrogen atom from another unsaturated fatty acid (RH) to form a hydroperoxide (ROOH) and a new alkyl radical (R<sup>•</sup>). Further oxidation is initiated by the new alkyl radical that contributes to the chain reaction (propagation). The chain reaction will be terminated when two radical species are combined to produce non-radical products.

Hydroperoxides are the primary oxidation products produced at the beginning of oxidation. These products are stable at room temperature but decompose at elevated temperatures, or in the presence of metals, or when exposed to light (Frankel, 2005; Choe

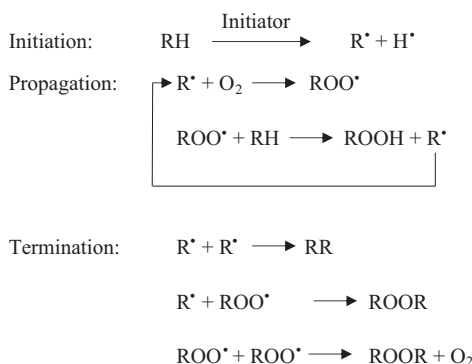

Figure 1 Mechanism of lipid oxidation.

and Min, 2006). The breakdown or decomposition of hydroperoxides leads to the formation of secondary oxidation products such as aldehydes, ketones, acids, esters, alcohols and short chain hydrocarbons (Choe and Min, 2006).

### Conventional (Physical and Chemical) Methods of Lipid Oxidation Measurement

Analysis of lipid oxidation can be carried out through chemical, physical, instrumental and sensory methods. Among the common chemical methods are peroxide value (PV), p-anisidine value (p-AnV), free fatty acid (FFA), total polar compounds (TPC) and total oxidation (TOTOX) value. PV and p-AnV are two common oxidation methods that have been used to measure the oxidative stability of oils. PV is a measurement for primary oxidation compounds (hydroperoxides) in the oil and can be carried out by an iodometry technique. This technique is based on the reduction of the hydroperoxide group (ROOH) with iodide ion ( $I^-$ ). The concentration of peroxide is proportional to the liberated iodine ( $I_2$ ) from potassium iodide (Shahidi and Wanasundara, 2002). Since hydroperoxides are produced in the beginning of oxidation and then decomposed to produce secondary oxidation products, the PV may not represent the actual oxidation stage of the oil.

p-AnV is a measurement for secondary oxidation products produced during oxidative degradation of oil. Aldehydes, will react with p-anisidine reagent under acid conditions and produce yellowish products (Shahidi and Wanasundara, 2002). p-AnV is useful in determination of the quality of crude oils and the efficiency of the processing procedure (O'Brien, 2004). The TOTOX value has been carried out extensively to estimate oxidative deterioration of food lipids (Rossell, 1983) as it combines the evidence about the past history (as reflected in the p-AnV) and the present state (as evidenced in the PV) of an oil (Shahidi and Wanasundara, 2002).

Physical methods of lipid rancidity are refractometry, specific density, weight gain, dielectric constant, viscosity and others (Shahidi and Zhong, 2005). Refractive index is a measurement of the change in unsaturation of fat or oil during hydrogenation (O'Brien, 2004) or onset of rancidity (Arya et al., 1969). The value for refractive index increases during autoxidation possibly due to conjugation and polymerisation of partially oxidised oils and fats (Arya et al., 1969).

Analysis of weight gain can be carried out by heating the oil in an oven. The oil is then taken out from the oven, cooled and weighed. This method can be used to measure the induction period of the oil sample and prediction of shelf life (Shahidi and Zhong, 2005). However, this method has several disadvantages since the heating is not continuous and the results may not be reproducible, require intensive labour and is time consuming (Shahidi and Zhong, 2005). Taking this limitation into consideration, Antolovich et al. (2002) suggested the instrumental techniques, namely Differential Scanning Calorimetry (DSC) and Thermogravimetric Analysis (TGA) as replacement for the conventional weight gain method.

### Instrumental Methods of Lipid Oxidation

The instrumental methods are less tedious and hazardous compared to the conventional physical and chemical methods. The commercial instruments used to measure oxidative stability of fats and oils are Rancimat and Oxidative Stability Instrument (OSI) (Tan et al., 2002). Other instrumental methods in assessing lipid oxidation in fats and oils are by Nuclear Magnetic Resonance (NMR), Fourier Transform Infrared (FTIR), Active Oxygen Method (AOM) and gas chromatography (GC). Nowadays, Differential Scanning Calorimetry (DSC) and Thermogravimetric Analysis (TGA) are two thermal analysis methods that have gained popularity due to their simplicity and rapid operation, requirement of a small sample size and no chemical or solvent use.

Oxidative stability of fats and oils measurement by DSC and TGA can be carried out by isothermal or non-isothermal operation. DSC and TGA have been used in previous studies on oxidative stability analysis of vegetable oils (Cross, 1970; Mikula and Khayat, 1985; Tan and Che Man, 2002; Arain et al., 2009; Ostrowska-Ligeza et al., 2010; Pardaul et al., 2011) and fish oils (Tengku-Rozaina and Birch, 2016; Sathivel et al., 2003; Sathivel, 2005; Huang and Sathivel, 2008; Araujo et al., 2011). Previous studies on oxidative stability of vegetable oils showed a good correlation between DSC and AOM (Cross, 1970), Rancimat (Arain et al., 2009; Ostrowska-Ligeza et al., 2010) and OSI (Pardaul et al., 2011) methods. DSC (Shahidi and Zhong, 2005; Arain et al., 2009; Ostrowska-Ligeza et al., 2010; Pardaul et al., 2011; Tan et al., 2001; Litwinienko, 2005) and TGA (Mikula and Khayat, 1985) are reported as rapid methods for analysis of lipid oxidation.

### Thermal Analysis of Lipid Oxidation

#### Oxidative Stability by DSC and TGA (Isothermal)

DSC is the most frequently (70%) used instrument for thermal analysis (Thomas and Schmidt, 2017). Oxidative stability and shelf life analysis by the DSC technique can be carried out in a short time (a day) instead of a few months by other methods (Cipriotti and Chiavaro, 2015). Furthermore, Hassel (1976) stated that measurement of oxidative stability of oil samples can be carried out in less than 4 hours by DSC compared to 14 days by the Active Oxygen Method (AOM).

The DSC technique measures the heat flows during a sample phase transition (Tan et al., 2002) or thermal changes during oxidation reactions (Shahidi and Zhong, 2005), as a function of time and temperature. Measurement of oxidative stability of fats and oils by the DSC technique is based on the thermal release of oxidation products associated with temperature and time (Tan and Che

**Figure 2** DSC curve of hoki oil during isothermal heating.

Man, 2002). Oxygen (purge gas) or air atmosphere are used with a calorimeter to measure the heat flow into (endothermic) or out of (exothermic) an oil sample undergoing oxygen changes. On the other hand, TGA measures the weight changes of a sample as a function of temperature and time during heating. Therefore, it can be used to measure the oxidation process through weight gain of the sample or oxygen uptake during decomposition (Hassel, 1976).

The onset time or induction period measured by TGA and DSC indicates the beginning of lipid oxidation and change in oil quality, respectively (Wesolowski and Erecinska, 1998). In the DSC oxidative analysis, the onset time for oxidation ( $t_o$ ) can be measured by intersection of extrapolated baseline and tangent line (leading edge) of the exotherm (Tan et al., 2002) as shown in Fig. 2. Time for maximum reaction (heat flow) was recorded as  $t_{max}$  (Tengku-Rozaina and Birch, 2016). Meanwhile, the onset time for oxidation analysis by TGA can be measured from the extrapolation of the baseline and upward portion of the curve (Mikula and Khayat, 1985) as shown in Fig. 3. The maximum rate of weight gain ( $R_{WG}$ ) of the TGA was determined from the slope of an upward portion of the curve (Mikula and Khayat, 1985). The onset time is related to the stability of the sample. In both DSC and TGA, a sample with a higher onset time is more stable compared to a sample with a lower onset time.

Oxidation of the oil occurs in three stages as illustrated by the TGA curve (Fig. 3). Phase 1 is the beginning of oxidation and the quality of the oil is measured by the induction period (IP) or onset time for oxidation ( $t_o$ ), where the oil is resistant to oxidation (Mikula and Khayat, 1985). Oil that has a higher IP is more resistant to oxidation. In phase 1, a weight change is minimal. Phase 2 is an autocatalytic oxidation phase where the sample gains weight due to formation of hydroperoxides as indicated by PV analysis. The final stage of oxidation occurs in phase 3 where weight loss is observed. In this phase, hydroperoxides start to decompose and volatile compounds such as aldehydes, ketones and alcohols are produced.

**Figure 3** TGA curve of hoki oil during isothermal heating.

Figure 4 Oxidative stability of hoki oil by DSC and TGA.

The trend for time ( $t_{max}$ ) for maximum thermal decomposition (DSC) and weight gained (TGA) of oil was similar to that of its onset time ( $t_o$ ), where the  $t_{max}$  for TGA was earlier than the  $t_{max}$  for DSC (Fig. 4).

#### Effects of Changing the Isothermal Temperature on Oxidative Stability of Oil

DSC and TGA can also be used to measure effects of a change in isothermal temperature on oxidative stability of the oil. Tengku-Rozaina and Birch (2016) studied the effects of oxidative stability of hoki oil by DSC (Fig. 5). They (Tengku-Rozaina and Birch, 2016) found that the onset time for oxidation ( $t_o$ ), time for maximum weight gained ( $t_{max}$ ) and time for maximum rate of thermal decomposition ( $t_{mdr}$ ) of hoki oil were inversely correlated with heating temperature. A similar finding was reported in the previous studies on vegetable oils by DSC (Tan et al., 2001, 2002; Pardaul et al., 2011). Cross (1970) reported a good correlation coefficient ( $r = 0.974$ ) between a conventional AOM and DSC, indicating that DSC is a rapid method to measure oils stability. Arain et al. (2009) also reported a good correlation ( $r > 0.99$ ) on the oxidative stability of plant oils measured by DSC and Rancimat.

Effects of temperature on the oxidative stability of hoki oil by TGA were carried out by Tengku-Rozaina and Birch (2016) as shown in Fig. 6. They (Tengku-Rozaina and Birch, 2016) found that the times recorded for  $t_o$ ,  $t_{max}$ ,  $t_{mdr}$ , and maximum weight gained ( $W_{max}$ ) of hoki oil were inversely correlated with heating temperature. Their findings are in agreement with Frankel (2005) who suggested that the oxidation rate of lipid is exponentially associated with temperature. The hydroperoxide formation and the decomposition of hoki oil reached an equilibrium level faster as the temperature increased (Tengku-Rozaina and Birch, 2016) and in accordance with a PV plot against time at different heating temperatures for linseed oil (Hess and O'Hare, 1950). On the

Figure 5 Oxidative stability of hoki oil at different temperatures measured by DSC.

**Figure 6** Oxidative stability of hoki oil at different temperatures measured by TGA.

other hand, the maximum rate of weight gained ( $R_{WG}$ ) increased with increasing temperature. The results of the effect of temperature on oxidative stability of hoki oil in [Tengku-Rozaina and Birch \(2016\)](#) are in accordance with [Mikula and Khayat \(1985\)](#) findings on soybean oil.

The maximum weight gained ( $W_{max}$ ) for hoki oil decreased with heating temperature since hydroperoxides do not accumulate but rapidly decompose at high temperatures. This finding is supported by an earlier  $t_{max}$  of hoki oil at a higher heating temperature compared to the lower temperature. The hydroperoxides started to decompose after they reached the  $t_{max}$  and the secondary oxidation products such as aldehydes, ketones and alcohol were produced ([Tengku-Rozaina and Birch, 2016](#)).

Both DSC and TGA data in [Tengku-Rozaina and Birch \(2016\)](#) study on the effects of temperature on oxidative stability of hoki oil follow the  $Q_{10}$  law on the relationship between temperature and rate of chemical reaction. The  $t_o$ ,  $t_{max}$  and  $t_{mdr}$  of hoki oil were reduced by approximately half with an increase of 10 °C. A similar finding on reduction of onset time for oxidation ( $t_o$ ) of vegetable oils measured by DSC was reported in previous studies ([Tan et al., 2002](#); [Arain et al., 2009](#); [Pardaul et al., 2011](#)).

### Prediction of Shelf Life of Oil by DSC and TGA

DSC and TGA can also be used as accelerated heating methods to replace conventional heating methods to predict the shelf life of the oils. Prediction of shelf life of the oils is possible by an Arrhenius extrapolation from elevated isothermal DSC and TGA analyses. The data of onset time for oxidation ( $t_o$ ) or induction period are used in plotting an Arrhenius plot to predict shelf life of the oil. [Tengku-Rozaina and Birch \(2016\)](#) predicted the shelf life of hoki oil at lower temperature using onset time for oxidation data obtained via DSC and TGA by construction of Arrhenius plots ([Fig. 7](#)) according to equations ([SETARAM, 2010](#)) as follows:

**Figure 7** The Arrhenius plot for oxidation and decomposition onset times of hoki oil by DSC and TGA.

$$\ln \text{ Onset} = A(1/T) + B$$

$$E_a = A \times R$$

where:  $T$  = temperature ( $^{\circ}\text{K}$ );  $A$  = slope of an Arrhenius plot;  $E_a$  = activation energy;  $R$  = gas constant ( $8.314 \text{ J/mol}^{\circ}\text{K}$ ).

Activation energy ( $E_a$ ) of the oil also can be measured by DSC and TGA through the Arrhenius equation. The  $E_a$  value is one of the important parameters in characterisation of oils since it indicates the delay of the initial oxidation process (Farhoosh et al., 2008). The  $E_a$  for oil that has a high polyunsaturated fatty acid content is lower than the oil with a higher saturated fatty acid content (Adhvaryu et al., 2000).

### Thermal Decomposition of Oil by TGA (Non-isothermal)

Studies on the effects of programmed heating (non-isothermal) on fats and oils can provide information on thermal behaviour and stability of the fats and oils during processing and the processing method employed. Thermal stability of the oils is related to their fatty acid analysis and antioxidants present (Santos et al., 2002). Previous researchers have studied the thermal behaviour of vegetable (Santos et al., 2002, 2004; Dweck and Sampaio, 2004; Szabo et al., 2012) and fish oils (Tengku-Rozaina and Birch, 2016; Araujo et al., 2011) during non-isothermal heating by TGA.

Fig. 8 illustrates the weight loss and the rate of weight loss during thermal decomposition process for hoki oil heated from  $25^{\circ}$  to  $700^{\circ}\text{C}$  by TGA in Tengku-Rozaina and Birch (2016) study. Data on the percentage of weight changes were obtained from the TA Universal Analysis and further analysed using a Microsoft Excel spread sheet. A slight increase (0.1%) in the initial sample weight was observed in hoki oil at temperature between  $100^{\circ}\text{C}$  and  $150^{\circ}\text{C}$  which showed the beginning of oxidation as the oil gained weight due to oxygen uptake, and formation of hydroperoxides (Tengku-Rozaina and Birch, 2016). An increasing weight loss of hoki oil due to temperature increase was observed after this temperature range. A similar finding was observed in previous works on unrefined tuna oil (Tengku-Rozaina and Birch, 2016), pink and red salmon oils (Sathivel, 2005), unrefined salmon oil (Huang and Sathivel, 2008) and unrefined pollock oil (Sathivel et al., 2008).

The oil with a high saturated fatty acid content is more resistant to heat and formation or build up of polymer (Tengku-Rozaina and Birch, 2016). Furthermore, the length and degree of unsaturation and intermolecular dispersion forces influenced heat decomposition of fatty acids (Sathivel et al., 2003). Fatty acids with a longer carbon chain are more stable toward thermal decomposition than a short chain fatty acid due to an increase of intermolecular dispersion forces (Nawar, 1996).

Thermal decomposition of hoki oil occurred in three stages or temperature ranges, possibly related to degradation of polyunsaturated fatty acids, monounsaturated fatty acids, saturated fatty acids, followed by volatilization of polymerisation and pyrolysis products (Tengku-Rozaina and Birch, 2016). The onset time for thermal decomposition was extrapolated from the thermal decomposition curve (Dweck and Sampaio, 2004). A higher value of the initial decomposition temperature implies better quality of oil (Wesolowski and Erecinska, 1998).

Thermal decomposition of oils is related to their fatty acid contents and positional distribution. For example, thermal decomposition of tuna oil occurred at lower temperature compared to hoki oil as observed in Tengku-Rozaina and Birch (2016). This is due to tuna oil having a higher PUFA content which makes it more susceptible to oxidation compared to hoki oil (Tengku-Rozaina and Birch, 2014). However, tuna oil was more stable at higher temperature due to its higher saturated fatty acid content, and

Figure 8 Thermal decomposition of hoki oil.

positional distribution of docosahexaenoic acid (DHA). Tuna has more DHA in the *sn*-2 compared to *sn*-1,3 positional distribution (Tengku-Rozaina and Birch, 2014) which makes it more stable to oxidation. This is in accordance with Wijesundera et al. (2008) who stated that PUFA are more stable to oxidation when located a *sn*-2 position compared to *sn*-1,3 position.

## Conclusion

DSC and TGA can be used as rapid methods to assess oxidative stability of oils and to predict shelf life of the oil using Arrhenius extrapolation from elevated isothermal analyses. Both DSC and TGA elevated isothermal analyses data showed the effects of temperature on oxidative stability follow the  $Q_{10}$  law on the relationship between temperature and rate of chemical reaction. DSC data on the oxidative stability of oils correlated well with other instrumental methods such as Active Oxygen Method, Rancimat, and Oxidative Stability Instrument (OSI). The DSC and TGA methods are faster, require less sample size and no chemicals or solvents compared to other conventional and modern oxidative stability methods and conventional shelf life estimation.

# Pyrazines in Thermally Treated Foods

Javier García-Lomillo and Maria L González-SanJosé, University of Burgos, Burgos, Spain

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Pyrazines is a family of volatile compounds with a common chemical structure that includes a monocyclic aromatic ring with two nitrogen atoms in para position. Since different groups (alkyl, methoxy or sulfur-containing chains) may be incorporated at 2-, 3-, 5- and 6- positions, a wide range of pyrazines may be present in foodstuff. The main source of food pyrazines is their formation during thermal treatments of raw foods. However, some pyrazines appear in nature as products of secondary plant metabolism and as metabolites of different microorganism (Gronquist and Schroeder, 2010). Generally, these compounds are methoxypyrazines which are very stable and, although they are masked by the formation of other volatile during food processing, they may cause serious problems in the quality of the final products. The role in food of methoxypyrazines is not discussed in the present work.

Pyrazines usually present a low vapor pressure and low values of odor thresholds (concentration at which they are detected). They largely impact flavor profile and give foods a very specific organoleptic characteristics mainly associated to roasted and nutty aromatic notes, although some of them also can give unpleasant green and burnt notes (Wang et al., 1968, 2017).

The first found papers about pyrazines in foods were published in the 1960s. They mainly focused on the effect of pyrazines on the flavor of different food matrices as cocoa, coffee and peanuts among others (Mason et al., 1966; Rizzi, 1967; Bondarovich et al., 1967; Wang et al., 1968). From these years, papers dealing with food pyrazines have been continuously published, although with variable ranges among years. In a basic search using "food pyrazines" as topic into the Web of Science data base, 1371 works published from 1965 to 2017 are found. Probably, the correlation of pyrazines with sensory properties of foods has been the most extensively studied topic. In this way, basic search using "pyrazines" and "food flavor" indicated 635 papers; using "pyrazines" and "food aroma" 521 papers, and 401 papers were found using "pyrazines" and "food quality". According to these results, many papers showed information about analytical methods (sample treatment, extraction and isolation techniques, etc.) and about parameters that influence the synthesis or formation of pyrazines in foods.

The first review about pyrazines in food was published by Maga and Sizer (1973) and Maga and Katz (1982) published an updated version citing 173 references 9 years later. These reviews discussed the occurrence of pyrazines in food, their organoleptic properties, as well as the current theories and proofs for their formation in foods. In similar date, Flament (1981) published other compiling work about "naturally-occurring pyrazines" which were isolated from raw, cooked or roasted foods. This author pointed out the potential and unique organoleptic properties of pyrazines, their analytical properties, reactive capacities and different formation phases.

A relatively large information about pyrazines of different foods as barley, malt, beer, bread, cocoa, coffee, roasted seed and nuts, dairy products, fish, poultry and other meat products, mainly beef meat, was able at 1980s. However, most of the studies about food pyrazines were carried in the ulterior decades, specially from the beginning of the 21st century. During the last 17 years, the 66% of the global 1371 previously indicated papers have been published, and according to the Web of Science data base, 2014 was the most prolific year (74 papers). In the last decades, papers studying healthy properties of pyrazines have increased notably. In the past century, pyrazines were related to some negative healthy effects mainly associated to their mutagenic potential (Spingarn and Garvie, 1979). However, nowadays, it is accepted that the negative effects could be caused by other products formed during food heating and cooking, such as acrylamide, rather than by pyrazines (Ehling and Shibamoto, 2005; Low et al., 2006). Currently, they are considered safe and can be used as GRAS flavor ingredients (Adams et al., 2002) since pyrazine metabolism produce innocuous products (Mattia et al., 2006). Furthermore, some positives effects have been described for such as antimicrobial (Seitz et al., 2002; Premkumar and Govindarajan, 2005) chemopreventive (Kim and Kim, 1999) and vascular protective properties (Jiang et al., 2015). The potential benefits of pyrazine is corroborated by the large number of patents submitted in the last decade to their application in food industry as reviewed by Ferreira and Kaiser (2012).

## General Notes About Pyrazine Formation in Thermally Treated Foods

Generally, pyrazine formation takes place in high-temperature processing (usually above 100 °C). The chemical mechanism behind pyrazine formation is closely related to the so-called Maillard reactions. The main route of pyrazine formation is the condensation of  $\alpha$ -dicarbonyl with aminoacids rendering diverse types of pyrazines. Three main stages can be described in pyrazine formation: Strecker degradation, condensation of aminoketones and incorporation of alkyl chains.

Strecker degradation can be generally defined as the decarboxylation and deamination of an aminoacid group produced by a Strecker reagent (usually a carbonyl group). The reaction between the carbonyl and aminoacid groups is followed by dehydration producing the so-called Schiff base that is very unstable and is rapidly decarboxylated and hydrolyzed forming the so-called Strecker aldehyde and an aminoketone (Fig. 1). The most commonly source of Strecker reagents is the reducing sugars, although other alternative pathways have been described in the literature such as ascorbic acid or quinones (Adams and Kimpe, 2009). Other compounds derived from lipid oxidation such as 2,4-decadienal may also enter the reaction as Strecker reagents which explain the correlation between lipid oxidation and pyrazine formation (Hidalgo and Zamora, 2016). Regarding the source of amino group

**Figure 1** Strecker degradation between an  $\alpha$ -dicarbonyl and an amino acid group.

required for Strecker degradation, it might be amino groups from amino acids, peptides or proteins. Ammonia is also able to participate in the Strecker degradation leading to the formation of aminoketones (Rizzi, 1999).

Aminoketones formed as consequence of the Strecker degradation may undergo further condensation with other aminoketones produced by similar reactions resulting in diverse dihydropyrazine structures (Fig. 2A), which are also very unstable and may rapidly be oxidized to form different pyrazines. Dihydropyrazine can also react to another carbonyl or aldehyde group present in the medium leading to the formation of alkylpyrazines (Fig. 2B).

These reactions play a key role in the wide diversity of pyrazines that may be formed during thermal processing since many different compounds can be formed depending on the compounds that are incorporated into the pyrazine structure. According to that, the next paragraphs show a summary of the most frequent pyrazine structures formed in thermally treated foods.

The simplest structure is the unsubstituted pyrazine (without any group attached in the aromatic ring). It is usually present in a wide range of products, but its relevance is limited since it is usually masked by other pyrazines (Maga, 1992).

The most frequent formed pyrazines are alkylpyrazines (Maga and Katz, 1982; Maga and Sizer, 1973), which include those with a chain in the 2-, 3-, 5- or 6- substituent of only carbon and hydrogen atoms. There has been found more than 70 types of alkylpyrazines with different substituents, including methyl, ethyl and propyl chains (Table 1).

Generally, alkylpyrazines present nutty and roasty aromas which are highly appreciated in cooked products. However, some of them present earthy or potato-like odors, which may present negative connotations. Pyrazines with long alkyl-substituted chains present green or burdock-like odors (Mihara and Masuda, 1988). Methylpyrazines are those pyrazines produced at the largest concentrations, being the most frequent in food systems 2-methylpyrazine followed by 2,6-dimethylpyrazine and 2,5-dimethylpyrazine. The relatively high odor threshold of these pyrazines (higher than 1 ppm) limits their relevance in food systems. In contrast, those pyrazines with an ethyl group that are formed in a lower proportion, present a higher relevance due to their lower threshold values (Table 1).

**Figure 2** Condensation of aminoketones to form a dihydropyrazine followed by the formation of a pyrazine (A), or a new alkylated pyrazine (B).

**Table 1** Daily intakes and odor thresholds of the most relevant pyrazine in foods

Pyrazines substituents	Daily intake ( $\mu\text{g}/\text{person and day}$ )	Odor threshold (ppb)	Aroma
Unsubstituted	0.2	500,000	Pungent, corn-like, hazelnut
2-Methyl	7	60,000	Popcorn, burnt, nutty, roasted
2,3-Dimethyl	4	2500	Green, nutty, caramel, pungent
2,5-Dimethyl	8	800	Roasted, butter, fried, nutty, musty, earthy
2,6-Dimethyl	2	200	Roasted, coffee, nutty, peanuts, chocolate flavor, potato aroma.
Trimethyl	46	400	Earthy, nutty
Tetramethyl	19	10	Pungent, flowery
2-Ethyl	6	6000	Musty, nutty, buttery, roasted
2-Ethyl-3-methyl	9	0.4	Burnt, cereal, nutty, roasted, earthy
2-Ethyl-5-methyl	1	100	Nutty, roasted.
2-Ethyl-6-methyl	0.4	40	Roast, sweet.
2-Ethyl-3,5-dimethyl	9	1	Nutty, burnt
2-Ethyl-3,6-dimethyl	9	0.4	Nutty, burnt
(2 or 5 or 6)-Methoxy-3-methyl	14	3	Odor reminiscent of roasted peanuts, hazelnuts, almond
2-Ethyl-(3 or 5 or 6)-methoxy	1	0.4	Roasted nut character; hazelnut, earthy
2-isoButyl-3-methoxy	1	0.002	Hot paprika, earthy
Acetyl-	122	62	Roasted corn
(3 or 5 or 6)-(Methylthio)-2-methyl	13	1–4	Toasted, roasted, nutty, caramel corn-chip

Modified from Mihara and Masuda (1988), Xu et al. (2017), Adams et al. (2002), and Maga and Sizer, 1973.

Regarding the relation between chemical structure and odor threshold, this seems to be correlated to the polarity of the molecule and the polarity of their substituents. Increasing lipophilicity leads to lower odor threshold (Mihara and Masuda, 1988). In fact, Guadagni et al. (1972) found that pyrazine threshold may be between 2 and 60 times higher in oil matrix than in aqueous.

Alkoxy-pyrazines include those compounds with an oxygenated functional group in the aliphatic side chain. The most studied alkoxy-pyrazines are those with undesired pea and potato-like odors causing negative impacts on wine, coffee and cocoa. These pyrazines are usually correlated to microbial metabolism rather than with thermal formation. Others alkoxy-pyrazines present similar olfactory notes than alkylpyrazines (nutty, roasted and burnt notes) (Table 1). For instance, acetyl-pyrazines are associated with popcorn notes odors. They are formed usually at lower levels than alkylpyrazines, but they may have odor threshold as low as 0.01 ppb as in the case of 2-methoxy-3-methyl-5-(2-methylbutyl)-pyrazine (Shibamoto, 1986).

Thiopyrazines include the pyrazines with a sulfur substituent in the aliphatic side chain of the pyrazine ring (Fig. 3). According to published data, the compounds formed at the largest concentration are 3 or 5 or 6-(methyl-thiol)-2-methylpyrazine with odor thresholds ranging between 1 and  $7 \times 10^{-17}$  ppb (Brown, 2003; Mihara and Masuda, 1988).

## Main Factors Influencing Pyrazine Formation in Thermally Treated Foods

### Temperature and Heating Time

Pyrazine formation under 100 °C is negligible and start being constant at temperatures between 120 and 130 °C. Generally, papers indicated that the formation of pyrazines in thermally treated food increased with the temperature, time and heating ranges (Neill et al., 2012; Potočník and Košir, 2017; Maga and Sizer, 1973).

Huang et al. (1989) observed, in an arginine-glucose model, a linear relationship between pyrazine formation and temperature, with higher formation at higher temperature. Regarding heating time, pyrazine stop forming when pyrazine concentration reaches an equilibrium. Several studies have reported that the activation energy is similar to all the pyrazines (between 13.09 and

**Figure 3** Formation of thiopyrazines through the condensation of two aminoketones and a sulfur-containing chain.

18.84 kcal/mol), which suggests that the pathway formation is similar to all of them (Huang et al., 1989). However, the pathway of pyrazine formation may be different at different temperatures, mainly because at high temperatures sugars are transformed into many small fragments of  $\alpha$ -dicarbonyl groups which can go into the Strecker reaction, fact that is not possible at temperatures lower than 110 °C (Koehler and Odell, 1970; Jusino et al., 1997).

The type of pyrazine formed is also affected by the range of heating temperature. For instance, dimethylpyrazine formation is promoted over methylpyrazines in the range of 110–130 °C (Koehler and Odell, 1970). The increase of heating times also promotes pyrazine formation, however this fact could have lower relevance due to higher formation of other volatiles which could mask pyrazines (Macleod and Coppock, 1976). The correlation between temperature–time and pyrazine formation was also studied by Liu et al. (2015a). They concluded that high temperatures (over 100 °C) applied to model system with chicken peptides and xylose, increase the formation of meaty aroma that was correlated with the pyrazines formed, whereas lower temperature and longer heating times tended to generate a broth-like taste.

### Type of Aminoacids and Sugars

The studies carried out in model systems allowed to obtain interesting information about the effect of sugars and aminoacids on the formation of pyrazines. It is known that pentoses produce higher levels of pyrazines than hexoses (Burton and Mcweeny, 1963) and promote the formation of methylpyrazine over dimethylpyrazines (Koehler and Odell, 1970). Martin and Ames (2001) showed that asparagine produced the highest formation of pyrazines in a fried potato model with glucose, followed by glutamine and phenylalanine. Ten times less formation of pyrazines was observed using leucine, isoleucine and methionine. Chun and Ho (1997) observed similar results in the total amount of pyrazines, but asparagine produced larger amount of ethylpyrazine and methylpyrazine than glutamine, which increased the formation furylpyrazines.

Leahy and Reineccius (1989) observed the highest rate of pyrazine formation in systems with lysine-ribose followed by lysine-glucose, whereas the lowest rate was found for asparagine-fructose. Differences between pyrazine proportion was also found. The unsubstituted pyrazine was the major compound formed in the reaction between lysine-glucose, whereas 2-methyl-pyrazine was the predominant pyrazine with the combination of lysine-fructose, lysine-ribose and asparagine-glucose. The combination of asparagine-glucose produced very similar proportions of 2-methyl pyrazine, 2,5-dimethyl and 2,6-dimethyl pyrazine. It seems that the presence of fructose, instead of glucose, promotes the formation of 2,5(6)-dimethylpyrazine, 2-ethyl-6-methylpyrazine and 3-ethyl-2,5- dimethylpyrazine, and decreases the formation of pyrazine, ethylpyrazine, vinylpyrazine, and 2-vinyl-6-methylpyrazine (Leahy and Reineccius, 1989; Martin and Ames, 2001).

The ratio sugar:aminoacid also impacts on the final yield of pyrazines formed, since an excess of sugar in a ratio 3:1 strongly inhibited the final pyrazine yield in comparison to a ratio 1:1. In contrast, the excess of aminoacid levels did not produce relevant effects (Koehler and Odell, 1970).

In contrast with the effect of aminoacids, the role of peptides in the formation of pyrazines may have been underestimated and it has been less studied. Scalone et al. (2015) indicated that the presence of oligopeptides from hydrolyzed whey protein contributed notably to pyrazine formation; while free aminoacids, formed by the total hydrolysis of proteins, had a much lower contribution. Similar results were observed with chicken peptides that caused an increase in pyrazine content, imparting a nutty and roasted aroma (Liu et al., 2015a,c). The combination of chicken peptides-xylose-leucine was more effective, regarding pyrazine formation, than models with peptides-xylose or xylose-leucine (Liu et al., 2015a). The low-molecular-weight peptide (<500 Da) was considered as the main contributor to pyrazine formation (Liu et al., 2015c).

### pH and Water Activity

Some works showed a promoting effect of higher pH on the formation of pyrazines, most likely due to the increased reactivity of the amino group as well as the rearrangement and fragmentation of sugars (Meynier and Mottram, 1995; Müller and Rappert, 2010). In agreement with this comment, Liu et al. (2015c) noted that pH lower than 5.0 inhibited the generation of pyrazines in a model system with chicken peptides. Regarding water activity, lower values are usually linked to increases in the pyrazine formation (Scalone et al., 2015).

### Presence of Reducing Compounds (Other Than Sugars)

Recently, there has been a growing literature concerning the effect of natural antioxidant (such as polyphenols) on the formation of pyrazines and other Maillard-reaction products, obtaining contradictory results. For instance, Porter et al. (2006) noted that ellagic acid strongly promoted pyrazine whereas gallic acid inhibited almost completely the reaction. A total inhibitory effect of pyrazine formation was also described to rosmarinic acid and epigallocatechin-3-gallate in model system, bakery rolls and applesauce (Favreau-Farhadi et al., 2015). However, Wilker et al. (2015) observed that pure polyphenols, specially gallic acid, were able to promote the Maillard reaction. In contrast, Misnawi Jinap et al. (2004) showed that samples with higher phenolic content produced lower levels of pyrazines during roasting process and modified pyrazine profile, affecting specially the formation of 2,3-dimethylpyrazine. The inhibitory effect was ascribed to the radical scavenging activity of phenols, while the promoting effect was correlated with the capacity of phenols to promote the formation of  $\alpha$ -dicarbonyls derived from carbohydrates (Wilker

et al., 2015; García-Lomillo et al., 2016). Furthermore polyphenols, in their quinone state, can also be modified as a Strecker reagent, promoting the formation of aminoketones in the Strecker degradation (Rizzi, 2006).

### Storage Time

Pyrazines are relatively stable volatile compounds and the concentration remains very stable over storage in contrast to other volatile compounds such as 2-methyl-3-furanthiol or pyrrolines (Kaneko et al., 2013). In terms of pyrazine relevance, it may be reduced due to the formation of new volatiles derived from lipid oxidation which may mask them. Furthermore, some slight pyrazine degradation may be caused by free radicals and hydroperoxides derived from lipid oxidation (Williams et al., 2006).

## Pyrazines in Foods

Probably, cocoa, coffee, nuts and roasted seeds, cereals and meat products are the most common foods in which the formation and levels of pyrazines have been studied. For that reason, the next paragraphs try to summarize the available information about pyrazines in these foods, including also some brief recently notes about other food matrices. In advance, the authors want to indicate that by logistic reasons it has been impossible to include all the published references and they want to apologize for those references not cited in this work. Furthermore, authors recommend consulting the reviews previously cited in this article.

### Coffee

Green coffee beans present a flavor profile very different from the final beverage. The variety and extension of coffee flavor is developed mainly during roasting process. Due to the relevance in the economy of coffee industries and the high relevance of pyrazines in the final quality of its aroma, coffee was probably one of the first food matrix in which pyrazines were evaluated (Bondarovich et al., 1967; Goldman et al., 1967). More than 200 different pyrazines has been identified in coffee (Maga, 1992), however it is widely recognized that the key odorant are alkylpyrazines with ethyl groups as 2-ethyl-3,5-dimethylpyrazine and 2,3-diethyl-5-methylpyrazine (Belitz and Grosch, 1999).

Several factors may impact the concentration of the different pyrazines in the final beverage. For instance, Robusta varieties produced larger amounts of pyrazines than Arabica varieties (Hashim and Chaveron, 1995), and roasting parameters and brewing steps also produce very important differences. Strongly roasted coffees are usually linked to higher pyrazine concentration (de Toledo et al., 2016). Hashim and Chaveron (1995) observed an intense increase in pyrazine formation for roasting at 205 °C and 10 min, whereas higher temperatures or longer roasting times produced lower amounts of pyrazines. The ratios 2-methyl-/2,5-dimethyl- or 2-methyl-/2,6-dimethyl- pyrazines were proposed as indicators of roasting conditions, and authors noted significant correlation between consumers' preference and coffees with ratio value of 2.5. In contrast, Yang et al. (2016) did not find significant differences when the roasting temperature decrease from standard (210 °C) to 135 °C. Interestingly, lower temperatures and longer roasting times (160 °C, 30 min) seem to reduce acrylamide formation and catechin degradation with an adequate pyrazine formation (Mizukami et al., 2008). Recently, the important role of pyrazines as markers of roasting degree of coffee and then as quality markers of roasting process has been once again pointed out. Different pyrazines were selected by discriminant analysis as roasting markers (de Toledo et al., 2016, 2017), being the pyrazine family the most abundant among the volatile selected markers.

As it was described in the introduction, some microorganism can produce methoxypyrazines, this fact is of paramount importance in the case of coffee since infected beans usually showed significant levels of these pyrazines, revealing important defects of aroma (Cruz-López et al., 2016). However, methoxypyrazines are not the unique pyrazines considered as low-quality markers. Toci and Farah (2014) suggested as potential defective seed's markers the presence of 2-butyl-3,5-dimethylpyrazine, 2,3,5,6-tetramethylpyrazine and 2-butyl-3-methylpyrazine.

### Cocoa

Green cocoa beans, as green coffee beans, have a very simple aroma profile compared with the flavor of final cocoa products. The characteristic aroma profile of cocoa is developed during different steps of cocoa bean processing, being fermentation, drying and roasting the most significant steps. Roasting intensely affect the development of the cocoa flavor, being one of the most important operation in the cocoa-based industries.

The pyrazine content in cocoa beans and cocoa products have been intensively studied, and the first studies appeared in similar data than for coffee (van Praag et al., 1968; Rizzi, 1967). Some similarities regarding coffee and cocoa pyrazines have been pointed out along the time. For instance, 2-ethyl-3,6-dimethylpyrazine and 2-ethyl-3,5-dimethylpyrazine are also recognized as the key pyrazines of cocoa roasted beans, and some methoxypyrazines present in green bean or developed during fermentation may also negatively impact the final quality of the cocoa products (Belitz and Grosch, 1999; Aprotosoai et al., 2016).

Among other studies, Serra Bonvehí and Ventura Coll (2002) pointed out that pyrazine concentration rapidly increased after 3 minutes of roasting and then reaches a stable concentration. Roasting at 135 °C increased total pyrazine formation and specially 2,3,5-trimethylpyrazine; and bean alkalization before roasting, which produced oxidative deamination of aminoacids, induced a drastic reduction in the final pyrazine formation. Roasting at different temperatures (150–250 °C) and times (10–50 min), using

superheat steam, produced significant differences in pyrazines formation. Although pyrazines were formed in all the treatment assayed, the highest total quantity was observed in treatment of 200 °C and 10 min (Zzaman et al., 2017).

A relatively recent work by Rodriguez-Campos et al. (2012) studied the effect of drying conditions on pyrazines formation and no significant differences were observed between traditional drying processes (sun-dried) and beans dried at 70 and 80 °C.

Six pyrazines were selected among the 32 major aroma-active compounds of chocolate, and analyses indicated that dark chocolate usually content more quantity of pyrazines than milk chocolate, and this fact was well correlated with the sensory properties of each product (Liu et al., 2015b).

### Roasted Nuts and Seeds

Traditionally, consumers appreciate the typical roasted nut flavor which are closely linked to pyrazine. This explains that the presence of pyrazines in roasted nuts has been largely studied and the first studies also appears in the 1960s (Mason et al., 1966). More than 70 pyrazines have been found in roasted nuts which provide them with their excellent organoleptic properties and notably contribute to their flavor profile (Maga, 1992).

Regarding the pyrazine type, formed quantity and their relation to the typical roasted flavor, bibliography shows some apparently contradictory data. Buckholz et al. (1980) described that 2-methyl and 2,6-dimethyl pyrazines were the compounds formed at the largest concentration during the roasting of peanuts, but they indicated that 2-ethyl-6-methyl pyrazine and 2-ethyl-3,6-dimethyl pyrazine had the biggest effect on the consumer preference. In contrast, Wang et al. (2017) have pointed out that 2,5-dimethyl pyrazine and 3-ethyl-2,5-dimethyl pyrazine were formed at the largest concentration, whereas 2-ethyl-6-methyl pyrazine had the largest impact on roasted liking flavor. Kaneko et al. (2013) found that 2-ethyl-5-methylpyrazine and 2,5-dimethyl-3-ethylpyrazine were the main compounds with roasted notes in-shell peanuts. These differences and other could be attributed to different factors, such as the composition of each nuts and the roasting parameters (time, temperature, type of oven, etc.). In this sense, 2,3-Diethyl-5-methylpyrazine and 3,5-dimethyl-2-ethylpyrazine, together with some pyrroline derivatives, were also pointed out as appropriate marker odorants to differentiate the various nut aromas (Kiefl and Schieberle, 2013). These authors indicated that pyrazine level must not be excessive to avoid an over-roasted smell, and the desired aroma can be obtained for the different nut cultivars, applying specific roasting times, temperatures, and roasting techniques adapted to each cultivar characteristics. Increasing of roasting time usually promotes the total pyrazine formation, although some exception has been reported for specific pyrazines, mainly due to the volatilization of some compounds during roasting (Buckholz et al., 1980).

Pyrazines were detected in significant quantities after roasting almonds but not in fried almonds (Valdés et al., 2015). Xiao et al. (2014) reported similar results after roasting of almonds although they indicated that 2,5-dimethylpyrazine was also detected in raw almonds.

One of the main issue concerning roasted nuts is the development of “flavor fade” which is a defect related to the development of lipid oxidation products (mainly aldehydes) that mask positive notes from pyrazines. In fact, the formation of lipid-oxidation-derived products presented the largest and negative impact on consumer liking rather than pyrazine content (Wang et al., 2017). This would explain the decrease in liking score despite the relatively high stability of pyrazines during storage. Authors indicated that pyrazines remained in the product during storage with only slight losses, being 3,5-dimethyl-2-vinylpyrazine the compound with the largest loss among pyrazines (only 36%, after 6 months). Slight decreased of pyrazines during storage of roasted peanuts was also indicated by Jiao et al. (2016).

Relatively recent studies showed the effect of roasting on flavor and pyrazines content of different products derived from roasted rich-oil seeds and kernels. The roasting of palm kernels improved the aroma of palm kernel oil; and roasting treatment and enzymatic kernel pretreatment before roasting induced significant differences. Tenfold higher quantities of pyrazines were detected in palm oil derived from the enzymatic pre-treated medium roasted kernels (Zhang et al., 2016). This may be interesting to increase the flavoring properties of oil, with nutty notes, that may be applied in bakery and confectionary industries but also to widen the scope of its applications (Zhang et al., 2016). Similar results were observed in pepper seed oil after roasting the pepper seeds applying temperatures above 140 °C, and maximum content of 2, 3, 5, 6-methyl pyrazine was reached increasing the roasting time until 20 min (Lu et al., 2017). The roasting treatment of pumpkin seeds over 110 °C until 200 °C increased the content of pyrazines in the respective oil. However, this increase might be considered as negative since consumers prefer oils with green and fresh notes which disappear to higher temperatures (Potočník and Košir, 2017). Formation of pyrazines, mainly alkyl derivatives, were also reported during roasting of kirilowii seeds by Wu et al. (2014).

The content of pyrazines was increased after prolonged roasting time of sesame seeds (Zhao et al., 2016). Furthermore, the effect of “new” conservation methodologies on pyrazine formation has also been studied. For instance, the relative content of pyrazines in sesame paste treated with high-pressure thermal sterilization process (combined 400 MPa and 45 °C) has been shown to be 2.73 times higher than those in fresh paste, fact that was associated to the increment of aromatic intensity and quality of the sesame paste (Ren et al., 2016).

### Cereals and Cereal Products

The contribution of pyrazines to the highly appreciated roasted flavor of cereals products has been also the main reason to study their formation in this type of food matrix. In this case, many of the first published papers focused on the pyrazines formed during roasted barley and malts due to their important role in the flavor of beers (Wang et al., 1968). Harding et al. (1978) described 21

pyrazines isolated from roasted barley, six of them described in roasted barley by the first time. Methylpyrazine was the most abundant, followed by 2,3-, 2,5- and 2,6- dimethylpyrazines and by trimethylpyrazine. Authors indicated that pyrazines contributed to the flavor of beer brewed with roasted barley.

Furthermore, pyrazines strongly contribute to the flavor of crust bread aroma. 2-Acetyl pyrazine and 2-methyl-3-ethyl pyrazine were described as some of the compounds responsible for bread crust aroma (Fadel and Hegazy, 1993). Chang et al. (1995) described 2-ethyl-3-methyl pyrazine and methylpyrazine as the two most abundant pyrazines (among 13 detected) in the crust of different wheat breads contributing notably to their pleasant flavor.

Heat-treatment of flours has gained popularity in the recent years due to the technological benefits exerted by this technology such as: increasing microbial safety, improve rheological properties and development of positive odors (Neill et al., 2012). Xu et al. (2017) noted that the positive odor effect depends on the heating severity. Low-temperature treatments (100–110 °C) have a positive effect by elimination of “rancidity” component, but without inducing the formation of additional positive roasted notes. Treatments at 120 °C or higher temperatures induced the formations of pyrazines, furans and others, giving roasting flavor. Authors indicated that, considering organoleptic properties, heating at 140 °C was the most optimum treatment. Furthermore, Bettge et al. (2000) indicated that waxy flour was prone to the formation of active odor components. The higher free reducing sugar content of this flour and the higher level of damage of starch could be explain this fact. The positive effect on bread aroma have been also described to oatmeal. Heat treatments applied before baking produced significant increase of pyrazine formation, resulting a strong flavor associated with baking (Gu et al., 2015). A recent review showed the effect of sourdough on volatile compounds of bread, including data about 11 pyrazines (Pétel et al., 2017).

The lack of flavor of gluten-free bread has been correlated to the low quantities of pyrazines detected in this sort of bread. This negative effect may be mitigated by the addition of aminoacids and sugars before baking. The tandem proline-glucose allowed to obtain gluten-free bread more desirable, to celiac patients, than control one (Pacyński et al., 2015).

The possible negative effect of some Maillard-reactions products such as acrylamide, whose formation is coupled to pyrazine formation in bread crust, cookies and other cereals products is one of the main concern of baking, pastry and confectionery industries. In this sense, different studies showed the natural antioxidants as phenolic compounds may be able to block of acrylamide formation (Hedegaard et al., 2008; Jin et al., 2013), although this positive effect may also affect roasting flavor due to the accompanying reduction of pyrazines formation, which can reach until 81% of reduction in bread (Mildner-Szkudlarz et al., 2017). Similar results were found in potatoes chips using vacuum frying, with up to 300 times reduction of pyrazine formation (Belkova et al., 2018). Furthermore, together with the block of pyrazines other negative effect as the formation of unpleasant flavor components have been described when feruloylated oligosaccharides were used in different dough model systems (Zhao et al., 2017).

## Meat Products

The main role of pyrazines in meat products is also related to their flavor notes, mainly due to their contribution to roasted and cooked aromatic notes. There are several families of odorants that have been associated with the quality of cooked meat, being among them pyrazines, which are solely formed during heat treatments of meat products. Pyrazines have been widely detected and accepted as key odor components in roasted chicken, beef, pig, turkey and lamb products (Shahidi, 1994). However, meat flavor is a rather complex issue, in which many factors may impact the quality of the final product, beginning with the state and composition of the raw material (Shahidi et al., 1986) and followed by those related to the cooking procedure. Roasting is the cooking technique that induces the largest formation of pyrazines, and much less pyrazines (and in less quantities) were detected in boiled and microwaved cooked meat (Macleod and Coppock, 1976). Furthermore, significative differences in the pyrazine profile were observed in meat cooked by different techniques: 2-ethyl-6-methylpyrazine and 2,3,5-trimethylpyrazine were predominant in boiled meat, whereas methylpyrazines and 2,3-dimethyl-5-ethylpyrazine and 2,5-dimethyl-3-ethylpyrazine were more relevant in microwaved meat products. Authors ascribed this fact to a rapid surface dehydration induced by microwave treatment, so the low water content would may promote pyrazine-formation reactions. Yang et al. (2017) reported that pyrazines presented much higher relevance (approximately 80% of total volatile concentration) in electric oven-cooked pork loin, whereas the relevance in air fryer or oven was much lower. The difference in the type of cooking was ascribed to the different temperature profile for each method. The pyrazine level was higher in pork neck cutlets marinated with and aqueous solution with 1% of glucose compared to those marinated without glucose, being pyrazines some of the discriminant volatile compounds proposed to justify the differences among samples (Biller et al., 2016).

## Miscellaneous

Roasting stem tea has a characteristic flavor derived from the roasting process of the tea stems. This flavor has been associated to higher pyrazine levels of roasted stem than roasted leaf. This fact may have an important impact on the development of new tea products (Sasaki et al., 2017). Previous paper indicated the presence of different pyrazines (methyl-, ethyl- and 2-ethyl-5-methyl- derivatives) in Kangra orthodox black teas, and ethylpyrazine was pointed out as one of the odor active components of this type of tea (Joshi and Gulati, 2015).

Recently, three pyrazines have been indicated as important discriminant markers and responsible of the different aroma of cane brown sugars (Asikin et al., 2017). Previously, Asikin et al. (2016) described the relation of 5-methyl-2pyrazinylmethanol and 2,5-

dimethylpyrazine with the nutty-roasted note of the cane brown sugar. Authors also indicated that pyrazines were mainly formed when drying solidification process were carried out in open pan against horizontal or vertical thin-film dryers.

Recent papers indicated the role of some pyrazines as 2,5- and 2,6- dimethylpyrazines on the flavor of different fish products. These pyrazines seem to be useful to characterize grass carp soup (Li et al., 2017). Similar results were described to seaweed (López-Pérez et al., 2017), although in this case 2,6 dimethylpyrazines and tetramethylpyrazine were the selected markers. Working with fish powder hydrolysate, Peinado et al. (2016) indicated that EPA, DHA and fish oil promoted formation of pyrazine and methylpyrazine but reduced the formation of 2,5-dimethylpyrazine. Pyrazines were also present in ready-to eat-fried loach but not in fresh loach (Lv and Zhao, 2016).

## Conclusion and Future Trends

It seems that there will be an increase in the pyrazine studies and applications in the following years since their flavor is highly appreciated by consumers, they are natural compounds and do not present any hazard to population health. Although they have been historically studied, food scientists will face new challenges in the field:

- Improve the detection techniques of those pyrazines produced at low concentration but with extremely low thresholds
- Increase the understanding of pyrazine profile in complex matrix (synergism with different volatiles), not only according to their concentration but also according to their relevance.
- Optimization of the conditions (temperature, time, pH) in thermal-heating process to obtain the desired pyrazine profile according to the consumer's liking preference.
- Reduction the presence of carcinogenic compounds whose formation is also coupled to Maillard-type reaction (acrylamide, heterocyclic amines) without modifying pyrazine flavor profile.

# Formation of Selected Heterocyclic Flavor Chemicals in Beverages

Takayuki Shibamoto, University of California, Davis, CA, United States

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Heterocyclic compounds are aromatic chemicals with heteroatom, such as oxygen, nitrogen and sulfur, in their rings. One striking quality of heterocyclic compounds is that they possess unique and strong characteristic odors. Since the mid-1950th, in particular after the development of gas chromatography, relatively low molecular heterocyclic compounds have been identified in beverages (wine, coffee, and cola) and have come to receive considerable attention by flavor chemists as compounds formed by the Maillard reaction. Formation of these heterocyclic flavor chemicals has been studied intensively using Maillard reaction model systems consisting a sugar and an amino acid (Hodge, 1953; Shibamoto, 1983; Ledl et al., 1989; Martinez et al., 2001). Fig. 1 shows a typical gas chromatogram of a dichloromethane extract of a Maillard reaction solution prepared with a *D*-glucose/cysteine Maillard model system. As the chromatogram shows, there are over 1000 peaks, suggesting that a simple Maillard reaction model system produces tremendous numbers of volatile chemicals. These volatile chemicals are mainly heterocyclic chemicals. Fig. 2 shows the approximate number of volatile heterocyclic compounds reported up to the present (prepared based on Shibamoto, 1983; Whitfield, 1992). It should be noted that these numbers are increasing because many studies on the formation of these chemicals are currently underway around the world. Volatile heterocyclic compounds play an important role in heat-treated foods and beverages with preferable flavors because these chemicals are mainly formed through Maillard reaction (Yamaguchi et al., 1979; Shibamoto, 1980, 1989; Fors, 1983; Mottram, 1998).

In 1912, French chemist L. C. Maillard hypothesized the reaction that accounts for the browning pigments and polymers produced from the reaction of the amino group of an amino acid and the carbonyl group of a sugar as shown Fig. 3. The Maillard reaction is also called the Non-enzymatic browning reaction, and it occurs readily upon heat treatment in any matrix containing amines and carbonyls. Therefore, Maillard reaction products include many different types of chemicals including brown pigments, flavor chemicals, pro- and anti-oxidants, pro-and anti-mutagens and carcinogens. It is obvious that many heterocyclic compounds form in foods and beverages by heat-treatment. There have been numerous reports on the formation of these products in heated (cooked) foods because these volatile heterocyclic compounds possess a characteristic roasted or toasted flavor.

However, some Maillard reaction products are not preferable because they damage the freshness of products, such as fruit and vegetable juices, beer and wine. On the other hand, they play an important role in heat-treated beverages, such as tea and coffee. Fig. 4 shows typical flavor characteristics of basic heterocyclic compounds along with their structures. There are many flavor chemicals related to these simple five- and six-ring compounds.

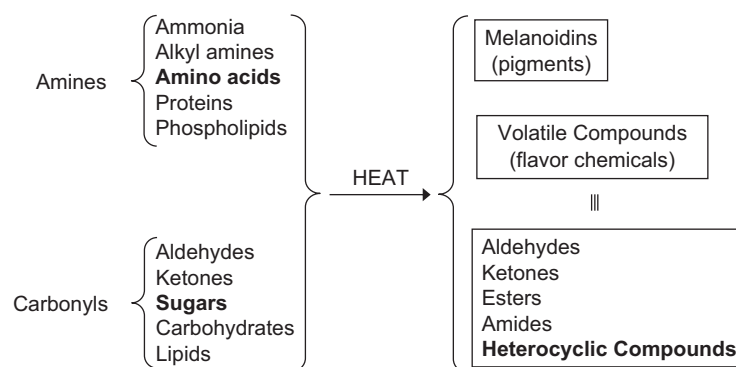

The presence of heterocyclic compounds in fruit and vegetables juices is due to the incidental heat-treatment during preparations, such as in sterilization. On the other hand, coffee and tea go through intentional heat-treatment in preparation, suggesting that they contain many of these chemicals. Therefore, beverages are divided into two kinds of product: one is prepared without heat-treatment like fruit and vegetable juices as well as alcoholic beverages, such as wine and beer; the other is prepared with heat-treatment and includes tea and coffee.

**Figure 1** Typical gas chromatogram of a volatile extract from a *D*-glucose/cysteine Maillard model system. A 60 m × 0.25 mm × 0.25 μm DBWAX bonded phase fused silica capillary column was used. The oven temperature was held at 35 °C for 5 min and then programmed to 250 °C at 2 °C/min. The linear carrier gas flowrate was 33 cm/s at split ratio of 1:40.

**Figure 2** Approximate number of volatile heterocyclic compounds reported up to the present.

**Figure 3** General scheme of Maillard reactions and their products.

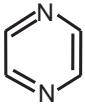

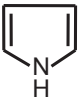

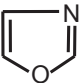

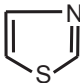

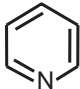

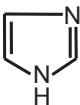

## Furans

Furans are the most abundant heterocyclic compounds found in foods and beverages. There are many review articles summarizing formation pathways of furans in Maillard reaction systems. Their major proposed pathways involve carbonyl compounds formed from lipids or sugars and amine compounds as precursors (Yaylayan, 2006; Paine et al., 2008; Owezarek-Fendor et al., 2011; Shibamoto, 2014). It should be noted that furans do not contain nitrogen atoms but their formation is catalyzed by amine compounds. However, as mentioned above, most heterocyclic compounds form from heat-treatment *via* Maillard reaction. They are recognized as artifacts rather than preferable components in fresh juices. In fact, fresh juice manufacturers are trying to avoid formation of these compounds as much as possible during juice preparation.

## In Fruit and Vegetable Juices

Only a few reports on the presence of furan and related compounds in fruit and vegetable juices are available. Kim et al. (2016) reported  $0.59\text{--}27.39\text{ ng mL}^{-1}$  of furan in 18 commercial orange juices. Their values were significantly higher than the juice obtained from a fresh orange directly by squeezing, suggesting that some heat-treatments, such as sterilization, cause furan formation. On the other hand, Wongfhun et al. (2010) reported that more 2-pentylfuran was found in fresh pennywort juice ( $87.9 \pm 23.7\text{ ng L}^{-1}$ ) than in sterilized pennywort juice ( $34.2 \pm 19.9\text{ ng L}^{-1}$ ). Another study found that furan in carrot and prune juices ranged from zero to  $33\text{ ng g}^{-1}$  and from  $0.7$  to  $14.2\text{ ng g}^{-1}$ , respectively (Wegener and Lopez-Sanchez, 2010).

Furfural and 5-hydroxymethylfurfural form naturally from pentose and hexose, respectively, and are found in various foods and beverages. However, only a few reports showed their presence in fresh fruit and vegetable juices. Abu-Bakar et al. (2016) found furfural ranging from  $0$  to  $16.2 \pm 0.14\text{ ng L}^{-1}$  (mango), 2-furoic acid ranging from  $0$  to  $8.72 \pm 0.38\text{ ng L}^{-1}$  (mango) and 5-hydroxymethyl furfural ranging from  $19.5 \pm 0.49\text{ ng L}^{-1}$  in 17 fresh fruit (mango, date, roselle, orange, pomegranate, mangsteen, soursop) juices. Two orange juice samples contained furfural at levels of  $8.5\text{ }\mu\text{g g}^{-1}$  and  $6.3\text{ }\mu\text{g g}^{-1}$  (Terixidó et al., 2006). Furfural was also found in 5 orange juice samples at levels ranging from less than LOD to  $106 \pm 1.7\text{ mg kg}^{-1}$  (Terixidó et al., 2011). Furfural and 5-hydroxymethylfurfural were found in an apple juice at the level of  $0.3$  and  $0.2$ , respectively (Gaspar and Lucena, 2009). Terixidó

Name		Structure	Typical substituents	Sensory description
Common	UPAC			
Furan	Oxole		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , CH <sub>2</sub> OH, CHO, Acetyl	Sweet caramel-like, slightly cinnamon-like
Pyrazine	Pyrazine		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , OCH <sub>3</sub>	Roasted, toasted, cooked flavor
Pyrrole	1H-Pyrrole		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , CHO, Acetyl	Sweet, ethereal, burnt-nauseating odor
Thiophene	Thiophene		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , CHO, SH, Acetyl	Onion-like, slightly-sulfurous odor
Oxazole	1,3-Oxazole		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , CHO	Sweet, roasted
Thiazole	1,3-Thiazole		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , CH <sub>2</sub> OH, CHO, SH, Acetyl	Cooked-meat, sulfurous-odor, characteristic foul-like odor
Pyridine	Pyridine		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub> , CHO	Pungent, smokey fishy-odor
Imidazole	1,3-Imidazole		CH <sub>3</sub> , C <sub>2</sub> H <sub>5</sub>	Pungent off-flavor

**Figure 4** Typical flavor characteristics of basic heterocyclic compounds along with their structures.

et al. (2011) reported furfural in five apple juice samples at the levels ranging from less than LOD to  $3.51 \pm 1.0 \mu\text{g kg}^{-1}$ . 5-Hydroxymethylfurfural was also found in apple juices ( $0.36 \pm 0.021$ – $3.05 \pm 0.23 \mu\text{g g}^{-1}$ ) and pear juices ( $0.09 \pm 0.001$ – $1.04 \pm 0.28 \mu\text{g g}^{-1}$ ) (Marsol-Vall et al., 2016). Wongfhun et al. (2010) reported the formation of tetrahydrofuran in a pennywort juice ( $71.5 \pm 58.1 \text{ ng L}^{-1}$ ) prepared by high pressure processing. Same authors also found 2-pentylfuran in pennywort juices:  $87.9 \pm 23.7 \text{ ng L}^{-1}$  in fresh juice, trace amounts in high pressure processed and  $13.7 \pm 12.3 \text{ ng L}^{-1}$  in pasteurized samples. Furfural was found in 12 commercial tomato juices in amounts ranging from  $0.27 \pm 0.02 \text{ mg kg}^{-1}$  to  $4.20 \pm 0.18 \text{ mg kg}^{-1}$  (Vallverdu-Queral et al., 2013). Formation of furfural by heat-treatment was strongly suggested by its presence in cooked tomato (5.91 ppb), whereas furfural was not detected in fresh tomato essence (Zhu et al., 2017).

## In Beer

Only a few furans are reported in alcoholic beverage beer. Their levels in beer are relatively low. Their formation in alcoholic beverages is proposed to form from sugars *via* fermentation processes. In fact, furfural was found in an alcoholic beverage produced by whey fermentation at the level of  $101.1 \mu\text{g L}^{-1}$  (Dragone et al., 2009).

Vesely et al. (2003) found furfural in beer when they were analyzing aldehydes in beer. The furfural levels ranged from 28.8 ppb stored at  $0^\circ\text{C}$  to 458.3 ppb stored at  $30^\circ\text{C}$  for 12 weeks, suggesting that furfural forms during storage at high temperatures. Wort from beer also contained furfural at the levels of 4–400  $\text{ng L}^{-1}$  (de Schutter et al., 2008a). When wort was boiled, furfural, furfuryl alcohol and acetylfuran increased with time, suggesting that furfural and related compounds are formed by the Maillard reaction (de Schutter et al., 2008b). Vanderhaegen et al. (2004) detected furfuryl alcohol ( $1.741 \text{ mg L}^{-1}$ ), furfuryl ethyl ether ( $0.006 \text{ mg L}^{-1}$ ), furfural ( $0.045$ ), 3-methylfural ( $0.007 \text{ mg L}^{-1}$ ), 3-acetylfuran ( $0.020 \text{ mg L}^{-1}$ ) and 5-methyl-2-furfural ( $0.008 \text{ mg L}^{-1}$ ) in fresh beer. Among these, furfuryl ethyl ether was associated with a solvent-like stale flavor. They also found that addition of deoxyribose increased furfuryl alcohol significantly when beer was stored at  $60^\circ\text{C}$  for 7 days, suggested that the solvent-like off flavor was due to the formation of furfuryl alcohol. 3-Hydroxymethyl furfural formed in malt during roasting and then it was reduced during fermentation upon transferring to 5-hydroxymethyl furfuryl alcohol (Akilhoglu et al., 2011). When a fresh Pilsner type beer was forced to age under deaerated condition, the levels of furfural and 5-hydroxymethylfurfural increased from  $0.26 \pm 0.001 \mu\text{M}$  to  $4.2 \pm 0.2 \mu\text{M}$  and  $19.3 \pm 0.3 \mu\text{M}$ , respectively. On the other hand, the levels of furfural and 5-hydroxymethylfurfural increased from  $0.26 \pm 0.001 \mu\text{M}$  to  $5.5 \pm 0.2 \mu\text{M}$  and  $21 \pm 2 \mu\text{M}$ , respectively, under aerated conditions (Rakete et al., 2014). Rico-Yuste et al. (2016) determined furfural levels using a colorimetric method in beer during storage. They found a linear correlation between the storage time and the furfural concentration. The furfural concentrations were  $205 \pm 13 \mu\text{g L}^{-1}$  at 49 days storage,  $330 \pm 14 \mu\text{g L}^{-1}$  at 187 days storage,  $366 \pm 26 \mu\text{g L}^{-1}$  at 284 days storage and  $687 \pm 46 \mu\text{g L}^{-1}$  at 627 days storage. Moreiz et al. (2013) analyzed 10 beer samples using an automated headspace solid-phase microextraction (HS-SPME) combined with gas chromatography and ion trap mass spectrometry detection (GC-IT/MS). They found furfural ( $1.68 \mu\text{g L}^{-1}$  –  $32.7 \mu\text{g L}^{-1}$ ), 5-methylfurfural ( $5.82 \mu\text{g L}^{-1}$  –  $6.55 \mu\text{g L}^{-1}$ ) and 5-hydroxymethylfurfural (not detected –  $2019 \mu\text{g L}^{-1}$ ).

## In Wine

Ubeda et al. (2016) reported furfural ( $0.14$ – $1.03 \mu\text{g L}^{-1}$ ), 5-methyl-2-furfural ( $3.45 \mu\text{g L}^{-1}$ ), 5-hydroxymethyl furfural ( $1.83$ – $3.45 \mu\text{g L}^{-1}$ ) and furfuryl alcohol ( $0.16$ – $0.66 \mu\text{g L}^{-1}$ ) in Chilean sparkling wines. Various furfural and related compounds were also found in Zalema white wines: furfural ( $60.4 \pm 33.1 \mu\text{g L}^{-1}$ ), 5-methylfurfural ( $8.9 \pm 2.0 \mu\text{g L}^{-1}$ ), 5-hydroxymethylfurfural ( $90.7 \pm 49.6 \mu\text{g L}^{-1}$ ), ethylfuroate ( $20.8 \pm 12.9 \mu\text{g L}^{-1}$ ) and furfuryl alcohol ( $10.90 \pm 3.3 \mu\text{g L}^{-1}$ ) (Gómez-Míguez et al., 2007). Ma et al. (2017) reported furaneol ( $175.2 \pm 3.3 \mu\text{g L}^{-1}$ ) as a furan compound which had significant effects on ice wine character. Formation of some toxic chemicals in wine, including furan and furfural, has been reported to be associated with the ripeness and maceration of the grapes (Lago et al., 2017). Burin et al. (2013) analyzed heterocyclic compounds in 29 French wine samples of different origins, types and vintages. They found that 5-methylfurfural ranged from  $1.5 \mu\text{g L}^{-1}$  (Bordeaux red wine) to  $250 \mu\text{g L}^{-1}$  (Bordeaux white wine), 3-acetyl-2,5-dimethylfuran ranged from 0 (Bordeaux red wine and Bourgogne red wine) to  $0.9 \mu\text{g L}^{-1}$  (Bordeaux red wine, Bourgogne red wine and Bordeaux white wine), 2,3-dihydrobenzofuran ranged from 0 (Bordeaux red wine and Alsace white wine) to  $0.67 \mu\text{g L}^{-1}$  (Bourgogne red wine) and acetylfuran ranged from  $1 \mu\text{g L}^{-1}$  (Alsace white wine) to  $50.2 \mu\text{g L}^{-1}$  (Bordeaux red wine).

## Pyrazines

Pyrazines are most abundant heterocyclic flavor compounds formed by the Maillard reaction. There have been numerous reports on their presence in heat-treated foods and beverages (Maga and Sizer, 1973; Muller and Rappert, 2010). Therefore, many heterocyclic flavor compounds found in beverages which are not treated by heat have been considered as off-flavor chemicals. On the other hand, only a few pyrazines (mainly methoxypyrazines) found in non-heat processed beverages are reported. Methoxypyrazines are known to be present in natural plants, insects, fungi and bacteria (Lei et al., 2017). Therefore, they may be produced naturally or by fermentation processes in non-heated beverages, such as wine.

The most commonly used method for methoxypyrazine analysis is gas chromatography/mass spectrometry (GC/MS), of which LOD and LOQ in wines are generally  $> 0.03 \text{ ng L}^{-1}$  and  $1 \text{ ng L}^{-1}$  (Alberts et al., 2009; Hjelmeland et al., 2016). Also, solid phase extraction method is the most commonly used method for sample preparation in methoxypyrazine analysis in wine, and generally, nearly 100% recovery efficiencies were achieved (Ortega et al., 2001).

## In Wine

Fig. 5 shows the amounts of methoxypyrazines found in wines along with their structures. These pyrazines are not formed by heat but by biosynthesis (Helwi et al., 2015). They are present in various wines at levels ranging from  $1 \text{ ng L}^{-1}$  (2,5-

**Figure 5** Amounts of methoxypyrazines found in wines along with their structures.

dimethylmethoxypyrazine) to 27.8 ng L<sup>-1</sup> [2-methoxy-3-(2-methylpropyl) pyrazine]. Addition of 2,5-dimethylmethoxypyrazine (0, 50 and 120 ng L<sup>-1</sup>) to wines lower intensity ratings for cherry and red berry descriptors and higher ratings for earthy/musty and green/vegetal descriptors (Botezatu and Pickering, 2012). There are many reports on relationships between the presence of methoxypyrazines in wine and grapes with ladybeetles. 2-Isopropyl-3-methoxypyrazine increased beetle density in wine, whereas it decreased when grapes were heated prior to fermentation (Kögel et al., 2015). Botezatu et al. (2013) reported that ladybeetles caused formation of tainted wine associated with 2-isopropyl-3-methoxy pyrazine and consequently promoted a negative impact on wine quality. A strong correlation between the levels of 3-isobutyl-2-methoxypyrazine in wine-grapes and wines was observed (Ryona et al., 2009). Levels of 3-alkyl-2-methoxypyrazines remained the same during alcoholic and malolactic fermentation but they increased during the first day of maceration (Sala et al., 2002).

When 2-isobutyl-3-methoxypyrazine with a green pepper-like odor was found in Cabernet Sauvignon grapes in 1975, it was sensational because its odor threshold level was extremely low of 0.002–0.005 ng L<sup>-1</sup> (Sidhu et al., 2015). Consequently, these methoxypyrazines have received much attention as chemicals that play an important role in wine flavors (Lei et al., 2017).

### Heterocyclic Favor Chemicals Formed in Roasted Coffees

Components of green coffee beans are ideal to produce Maillard reaction products, mainly heterocyclic flavor chemicals, by heat-treatment (roasting). Fig. 6 shows the chemical compositions of green and roasted coffee beans. Some chemicals, such as hemicelluloses, cellulose, lipids, lignin, and caffeine, did not show any significant changes after roasting. On the other hand, sucrose,

**Figure 6** Average composition (percentage) of chemicals in coffee beans before and after roasting.

proteins and chlorogenic acids decreased considerably. It is obvious that the Maillard reaction occurred between sucrose and proteins and the resultant heterocyclic compounds were formed as described above (refer to Fig. 3).

### Maillard Reaction Products

Fig. 7 shows typical gas chromatograms of coffee volatiles extracted from a brewed coffee taken by three different detectors. Chromatogram A was taken by a flame ionization detector (FID). Chromatogram B was taken by a flame photometric detector (FPD). Chromatogram C was taken by a nitrogen-phosphorous detector. FID is a comprehensive detector and sensitive to most organic compounds. FPD is a selective and highly sensitive detector for sulfur-containing compounds including thiophenes and thiazoles. NPD is a selective and highly sensitive detector for nitrogen containing chemicals including pyrroles, thiazoles, oxazoles, pyridines, pyrazines, and imidazoles.

Tremendous numbers of heterocyclic flavor compounds have been found in brewed coffee (Fig. 8) and their role in characteristic brewed coffee flavors has been reported in many references (Goldman et al., 1967; Vitzthum and Werkhoff, 1976; Tressl and Silwar, 1981; Shibamoto et al., 1981; Shibamoto, 1991; Flament and Bessiere-Thomas, 2002). The numbers of such compounds found must keep increasing as more studies are conducted. To date, the most abundant compounds are furans followed by pyrazines, pyrroles and sulfur-containing compounds. This trend is exactly the same as that of the number of heterocyclic compounds found in the Maillard reaction as shown in Fig. 2. It is obvious from these reports that pyrazines and thiazoles are strongly associated with roasted or toasted flavors of heat-treated foods and beverages.

### Degradation Products From Chlorogenic Acids

As mentioned above, chlorogenic acids reduce significantly during roasting (refer to Fig. 6). Chlorogenic acids are naturally occurring flavonoids and more than 70 isomers have been found in various natural plants including coffee beans, fruits, and vegetables (Upadhyay and Mohan Rao, 2013). They are divided into three groups: caffeoylquinic acids (CQA), dicaffeoylquinic acids (diCQA) and feruloylquinic acids (FQA). They are esters of quinic acid and caffeic acid and each moiety possesses unique nature as shown in Fig. 9. The nine chlorogenic acids found in green coffee beans are shown in Fig. 10 (Fujioka and Shibamoto, 2007). Total amounts of chlorogenic acids in four commercial green beans ranged from  $86.42 \pm 2.04 \text{ mg g}^{-1}$  to  $61.15 \pm 1.40 \text{ mg g}^{-1}$ . When these green beans were roasted under light roast condition ( $230^\circ\text{C} \pm 12 \text{ min}$ ) and French roast condition ( $250^\circ\text{C} \pm 21 \text{ min}$ ), reduction rates ranged from 45.2% to 54.0% and >99%, respectively (Moon et al., 2009). These results indicate that obvious degradation of chlorogenic acids occurred in roasting. Among the 9 chlorogenic acids found in green coffee beans, the levels of 5-CQA were the greatest, ranging from  $50.7 \pm 1.61 \text{ mg g}^{-1}$  to  $40.15 \pm 0.71 \text{ mg g}^{-1}$ , which is nearly 70% of total chlorogenic acids in coffee beans. When 1 g of 5-CQA was heated at  $250^\circ\text{C}$  for 30 min, 2,5-dimethylfuran ( $59.8 \mu\text{g g}^{-1}$ ), pyridine ( $5.3 \mu\text{g g}^{-1}$ ) and 5-methylfurfural ( $1.8 \mu\text{g g}^{-1}$ ) were found. One study reported that thermal degradation of 5-CQA produced many heterocyclic compounds with strong antioxidative activity, such as phenols (Kamiyama et al., 2015). These reports indicate that many biologically active heterocyclic compounds are formed in brewed coffee.

**Figure 7** Typical gas chromatograms of coffee volatiles extracted from a brewed coffee taken by three different detectors. A  $30\text{ m} \times 0.25\text{ mm} \times 0.25\text{ }\mu\text{m}$  DBWAX fused silica capillary column was used. The oven temperature was held at  $50\text{ }^{\circ}\text{C}$  for 10 min and then programmed to  $200\text{ }^{\circ}\text{C}$  at  $3\text{ }^{\circ}\text{C}/\text{min}$ . The linear carrier gas flowrate was  $30\text{ cm/s}$  at split ratio of 1:40.

**Figure 8** Numbers of heterocyclic flavor compounds found in a brewed coffee.

#### 4(5)-Methylimidazole [4(5)-MI]

Even though formation of imidazoles was found in a Maillard reaction system consisting of a sugar and an amino acid more than 50 years ago (Tsuchida and Komoto, 1967), imidazoles have not received much attention among flavor chemists because of their lack of characteristic flavors. Fig. 11 shows proposed formation pathways of imidazoles formed in Maillard reaction model systems. In this proposal, dicarbonyls and aldehydes are formed from either sugars or lipids and ammonia is formed from amino acids

**Figure 9** Structure of chlorogenic acid and nature of each moiety.

**Figure 10** Chlorogenic acids found in green coffee beans.

produced by Strecker degradation (Strecker 1863; Shibamoto and Bernhard, 1978; Yaylayan, 2006; Shibamoto, 2014). Moreover, imidazoles were considered chemicals contributing off-flavors to cooked foods (Arctander, 1969). The time when imidazoles, in particular 4(5)-MI, had begun to receive much attention is rather recent. The National Toxicology Program (NTP) identified 4(5)-MI as a cancer-causing chemical in 2007. Subsequently, many analytical results on 4(5)-MI in foods and beverages, including coffee and colas, as well as in Maillard reaction systems have been reported (Hengel and Shibamoto, 2013).

Mainly, 4(5)-MI forms in caramel products, which are prepared with a sugar and ammonia. There are four types of caramel color. Types I and II are prepared from carbohydrates without ammonia, whereas Types III and IV are prepared from carbohydrates with ammonia. It is obvious that these products are produced by Maillard reaction systems. In particular, Type IV has been used commonly for soft drinks, such as colas, and beer. Levels of 4(5)-MI in beverages were summarized in one review article (Hengel

**Figure 11** Proposed Formation Pathways of Imidazoles.

and Shibamoto, 2013). The levels of 4(5)-MI in caramel color Types III and IV ranged from 0.025 ppm to 463 ppm and from 0 to 1276 ppm. Brand colas analyzed for 4(5)-MI in 2009 and 2013 contained from 188 ng mL<sup>-1</sup> to 613 ng mL<sup>-1</sup> and from 7 ng mL<sup>-1</sup> to 28 ng mL<sup>-1</sup>, suggesting that cola manufacturers have tried to reduce the levels of 4(5)-MI. On the other hand, the levels of 4(5)-MI in non-colored soft drinks ranged from 6.7 ng mL<sup>-1</sup> to 44 ng mL<sup>-1</sup> in 2009 and from 1.7 ng mL<sup>-1</sup> to 5.5 ng mL<sup>-1</sup> in 2013. Selected brand beers contained 4(5)-MI from 0 to 424 mg mL<sup>-1</sup> in dark beer (Cunha et al., 2011). Also, selected roasted-brand coffees had 4(5)-MI in the levels ranging from 0.307 ppm to 2.05 ppm (Casal et al., 2002; Klejdus et al., 2006).

After NTP reported that 4(5)-MI was a possible carcinogen in 2007, many studies on the toxicity, including carcinogenicity (Chan et al., 2008), of 4(5)-MI have been conducted using various experimental animals (Hengel and Shibamoto, 2013). According to these reports, California State Proposition 65 set its acceptable daily intake (ADI) as 16 µg day<sup>-1</sup>. However, it is extremely difficult to set ADI for chemicals naturally present or formed during processing in foods and beverages, such as 4(5)-MI and acrylamide. For example, by a simple calculation, one cup (150 mL) of coffee contains 4(5)-MI at levels ranging from 9.62 µg mL<sup>-1</sup> to 273.15 µg mL<sup>-1</sup> (Lee and Lee, 2016), most of which exceed the ADI set by Proposition 65.

## Conclusions

Heterocyclic compounds formed from the Maillard reaction possess characteristic cooked or roasted flavors. Among over 1200 heterocyclic compounds found in Maillard reaction systems, furans and pyrazines play an important role in the palatability of beverages. Many heterocyclic compounds, either synthetic or Maillard reaction products, have been used to prepare preferable beverages. Beverages which require freshness do not generally benefit from the formation of heterocyclic compounds but some naturally occurring heterocyclic compounds, such as furfurals and methoxypyrazines, contribute important flavors to beverages, such as fruit and vegetable juices. On the other hand, the most popular beverage, coffee, requires various heterocyclic compounds, the formation of which is strongly associated with the Maillard reaction. Recently, the biological activities of heterocyclic compounds, such as antioxidants, have begun to receive much attention in addition to their flavors. Therefore, there is still much research to be performed on the heterocyclic compounds found in foods and beverages.

### Nomenclature

XOR xanthine oxidoreductase

XDH xanthine dehydrogenase

FAD flavin adenine dinucleotide

H<sub>2</sub>O<sub>2</sub> hydrogen peroxide

RSNO S-Nitrosothiols

MFGM milk fat globule membrane

NAD<sup>+</sup> nicotinamide adenine dinucleotide

HPLC high-performance liquid chromatography

### Background

Xanthine oxidase, a complex iron-sulphur molybdenum flavoprotein enzyme and a form of xanthine oxidoreductase (XOR), is one of the most important enzymes found within the milk of mammals and is broadly disseminated amongst different species, from bacteria to humans (Ardan et al., 2004; Bray, 1975; Chang et al., 1992). Xanthine oxidase can also be obtained from xanthine dehydrogenase (XDH), through a reversible (oxidation of –SH groups to S–S bonds) or irreversible (trypsin or pancreatin proteolysis) reaction. It was more than a century ago when Schardinger (1903) identified this enzyme in the form of XOR for the first time in cow's milk. The newly discovered enzyme was later named 'xanthine oxidase' by Burian (1905).

### The Structure and Function of Xanthine Oxidase

The molecule is a large protein, a dimer with a density of 290 kDa, while every 145 kDa monomer is composed of 20, 45, 85 kDa domains. As shown in Fig. 1, there are two flavin molecules (bound as flavin adenine dinucleotide; FAD) in each dimer, attached to two molybdenum atoms as well as eight iron atoms. These iron atoms, which are the important part of [2Fe–2S] ferredoxin iron-sulfur clusters, play an important role in the electron transfer reactions as part of the ferredoxin iron–sulfur clusters (Harrison, 2002). The molybdenum atoms, which are considered as the active sites of xanthine oxidase, are bounded as molybdopterin

**Figure 1** The chemical structure of xanthine oxidase. Bounded FAD (red), FeS-cluster (orange), molybdopterin cofactor with molybdenum (yellow), and salicylate (blue). Obtained from Wikipedia at [https://en.wikipedia.org/wiki/Xanthine\\_oxidase](https://en.wikipedia.org/wiki/Xanthine_oxidase).

cofactors. In addition to the molybdopterin unit with the molybdenum atom in the active site of xanthine oxidase, there are sulfur atoms and a terminal OH group (Hille, 2006).

Xanthine oxidase plays a significant role in the catabolism of purines, pyrimidines, petrin, and a lot of aldehyde substrates in mammals including humans (Enroth et al., 2000; Harrison, 2002). Xanthine oxidase is the enzyme responsible for the oxidation of xanthine to urate, before which xanthine is formed from the oxidation of hypoxanthine. XOR and xanthine oxidase catalyze the oxidation of hypoxanthine to xanthine and then xanthine is catalyzed to uric acid by the same enzymes (Eq. 1).

The mechanism by which xanthine oxidase catalyzes the oxidation of hypoxanthine and xanthine along with the chemical structure of these purins and the end product (urate) is also represented in Fig. 2. To convert xanthine to uric acid (the second reaction in Eq. 1), an oxygen atom has to be transferred from molybdenum to xanthine, and so there are several intermediates involved in such a reaction. When water is present, the reformation of the active molybdenum center happens and the oxygen atom (introduced to the substrate by xanthine oxidase) originates from water not from dioxygen ( $\text{O}_2$ ).

Xanthine oxidase can also catalyze the decomposition of S-Nitrosothiols (RSNO), which are considered as reactive nitrogen species. Xanthine oxidase converts RSNO to nitric oxide, by which the formation of peroxynitrite under aerobic conditions happens (Trujillo et al., 1998). In addition, it has been reported (Bonini et al., 2004) that in the presence of catalase and bicarbonate, this

**Figure 2** The main catalization mechanism of purins by xanthine oxidase.

enzyme can contribute to the production of the strong one-electron oxidant carbonate radical anion (from oxidation with acetaldehyde). In regards with the effects of the processing conditions such as heat treatment, it has been reported that xanthine oxidase aggregates at heating temperatures about 60 °C, when heated for 10 min or more (Ye et al., 2002). In particular, pasteurization of raw milk can inactivate xanthine oxidase, and consequently affect the flavor quality of the product(s) (Walstra et al., 2005).

### Quantification of Xanthine Oxidase in Milk and Dairy Foods

Apart from the existence of xanthine oxidase in other tissues and organs, there has been an interest in the form of the enzyme found in cow's milk (within the fat globule membranes) for a long time (Battelli et al., 1973). It was found that this enzyme represents approximately 8% of the intrinsic proteins existing in the milk fat globule membrane (MFGM) (Briley and Eisenthal, 1975), while now it is believed that this enzyme accounts for about 20% of the total proteins in MFGM (Singh, 2006). The location of xanthine oxidase within the MFGM trilayer has not been fully understood yet, and since the enzyme is recovered after washing raw cream with  $MgCl_2$ , it is suggested that this enzyme is a peripheral protein (Mather and Keenan, 1975). The suggested location of xanthine oxidase within MFGM is shown in Fig. 3 (Gallier et al., 2014). This type of enzyme (oxidase type found in cow's milk) can be converted into a  $NAD^+$ -dependent dehydrogenase; however, this conversion happens to a small extent as XDH is inhibited by  $NADH$ , due to its competition with  $NAD^+$  (Enroth et al., 2000; Harrison, 2002).

When studying the enzymology of milk and dairy products, the quantification of xanthine oxidase present in different types of milk and dairy products is very important. There are some old published standard methods, which are based on measuring the factors such as oxygen uptake and coupling of xanthine oxidation to the reduction of a dye or cytochrome C (Gudnason and Shipe, 1962; Greenbank and Pallansch, 1962; Zikakis and Treece, 1971). However, such methods only estimate the apparent activity of the enzyme (xanthine oxidase) and are not an accurate quantification. Among all, the most appropriate method used for measuring the activity of xanthine oxidase in milk and dairy products is the old reference method of Cerbulis and Farrell Jr (1977). Until very recently, this method was still considered as a standard technique for measuring xanthine oxidase activity in dairy products (Wiking et al., 2003; Kathiriarachchi et al., 2014; Aboul-Enein et al., 2003; Sharma et al., 2014). Briefly, the sample is mixed into a phosphate buffer (pH 7.4) and water is added before adding a standard solution of xanthine as a xanthine oxidase substrate. The mixture is then incubated at 25 °C for 5–6 min followed by addition of an acid (trichloroacetic acid, 20%, w/v) in order to stop the reaction. The sample is then centrifuged and the solid phase is separated from the liquid phase. To determine the apparent concentration of xanthine oxidase, the absorbance of the accumulated uric acid in the liquid phase is measured at 290 nm and the activity is expressed as milliunits per mL of sample ( $mU\ mL^{-1}$ ) (Cerbulis and Farrell Jr, 1977), equal to  $nmole/min/mL$ .

**Figure 3** The location of xanthine oxidase within the milk fat globule membrane (MFGM). Modified from Gallier et al. (2014).

**Table 1** Xanthine oxidase activity of different milk and dairy foods as measured by the developed HPLC method

Sample	Decrease of initial xanthine/ $\text{mmol min}^{-1}$	Fat content (%)
Raw milk	$4.72 \pm 0.13$	5.2 <sup>1</sup>
Commercial full-fat milk	$2.77 \pm 0.09$	3.3
Commercial low-fat milk	$1.78 \pm 0.15$	0.5
Unwashed raw cream	$27.9 \pm 1.8$	ND
Washed raw cream	$34.1 \pm 1.1$	ND
Commercial cream	$23.9 \pm 1.2$	36.9
Jarlsberg cheese	$25.0 \pm 1.1$	27.1
Parmesan cheese	$20.6 \pm 1.1$	29.9
Mozzarella cheese	$12.0 \pm 1.0$	22.3
Blue vein cheese	$8.3 \pm 0.6$	29.8
Edam cheese	$13.7 \pm 1.1$	27.8

ND: not determined.

Modified from Rashidinejad et al. (2016).

Although this method can be a fast and convenient technique for measuring xanthine oxidase, recently, it was challenged and replaced by an accurate HPLC method (Rashidinejad et al., 2016) for the following reasons. First and foremost, as the method by Cerbulis and Farrell Jr (1977) relies on the absorbance of uric acid formed at 290 nm, we can say that this technique is only an apparent estimation of the activity of xanthine oxidase in the corresponding samples. The second reason is related to the assumption made regarding measuring the absorbance of urate at 290 nm, which does not consider other compounds in the sample which may be present in the liquid phase and contribute to the absorbance at 290 nm (e.g. water-soluble peptides, amino acids, and phenolic compounds). The next reason is that obtaining a clear supernatant containing urate, as reported by other researchers, using a conventional centrifugation process (e.g. 2000×g for 10 min) at temperatures ranging from 5–25°, is not possible since the supernatant contains a fat layer sitting on top of the sample, above an almost a clear phase in the middle of the centrifugation tube (i.e. the middle phase) (Rashidinejad et al., 2016). Possibly, the previous researchers have measured the absorbance of the middle phase, not the supernatant. The supernatant may be contaminated with fat globules, which will interfere with the spectrophotometric analysis. Further, if there has been any filtration or similar processes involved in order to separate the clear phase (i.e. the middle phase) from the supernatant (containing fat), this is not reported by the researchers who used the method. Last but not least, as xanthine itself is used as a substrate for this enzymatic assay established by Cerbulis and Farrell Jr (1977), some of the xanthine may remain as the unreacted substrate, which interestingly, shows a relatively strong absorbance at 290 nm (Rashidinejad et al., 2016). HPLC analysis showed that the maximum peak for urate could be obtained at 298 nm, not 290 nm (Rashidinejad et al., 2016). Therefore, measuring the absorbance of even a very clear phase after centrifugation could be giving a total absorbance from both the remaining substrate (xanthine) and the generated product (urate), thus confounding the analysis.

The improved HPLC method was able to quantify the amount of both substrate (xanthine) and the product (urate) in a variety of milk, cream, and cheese samples (Table 1). Validation, linearity, and reliability of this newly developed method were assessed by testing different concentrations of xanthine and uric acid in standard solutions and plotting the corresponding standard curves. The response of xanthine oxidase to xanthine was also investigated and the linearity tested. This is an isocratic HPLC method with short retention times for xanthine and urate (6.76 min and 4.92 min, respectively), meaning that the method is both fast and convenient for quantification of the activity of xanthine oxidase in milk and dairy products.

## The Effect of Xanthine Oxidase on Flavor Development in Dairy Products

Most of the aldehydes present in cow's milk, such as acetaldehyde, hexanal, propanal, *trans*-2-nonenal, *trans*-2-heptenal, and *trans*-2-hexenal are considered as substrates for xanthine oxidase. Accordingly, xanthine oxidase is known as a substantial factor contributing to oxidative reactions in milk (Morpeh, 1983; Bounds and Winston, 1991; Steffensen et al., 2002). The association between the activity of xanthine oxidase and oxidative deterioration of milk and dairy foods and the effect of such enzymatic activity on the development of the off-flavors in milk and dairy products has been investigated long ago (Aurand et al., 1967; Aurand and Woods, 1959). It was observed that a high level of xanthine oxidase was associated with the occurrence of a spontaneously-oxidized flavor in milk and the inhibitors of this enzyme could prevent the off-flavor development (Aurand et al., 1967; Aurand and Woods, 1959). As xanthine oxidase induces oxidation of the aforementioned aldehydes and produces different acids in milk and dairy foods (Harrison, 2006; Anderson and Brooker, 1975), it can lead to some considerable changes in the amounts and/or ratios of volatile acids and aldehydes in these products (Kathiriarachchi et al., 2014). This correspondingly, may affect the flavor development in dairy products, such as cheese (Rashidinejad et al., 2016). Xanthine oxidase has also been reported to interact with compounds such as minerals (e.g. copper), zinc superoxide dismutase, polyphenols, arsenate, and nanoparticles (Hille et al., 1983; Zhou et al., 2005; Al-Hakeim et al., 2014; Chang et al., 1992; Nagao et al., 1999; Lin et al., 2002).

## Health Concerns About Dairy Foods Containing Xanthine Oxidase

One of the substantial aspects for which xanthine oxidase in bovine milk has been under consideration is the speculation regarding its contribution to the growth of illnesses such as coronary artery and gout-related diseases, as well as its contribution in oxidative damage to living tissues (e.g. liver and kidney) in the human body (Bierman and Shank, 1975; Oster, 1971; Harrison, 2006; Lin et al., 2002). This may happen via the oxidation of hypoxanthine and xanthine to urate, and correspondingly, the formation of super oxide radicals which can promote the oxidation level in the body leading to xanthine oxidase being considered as a significant biological source of superoxide radicals (Fridovich, 1970; Cos et al., 1998) (Eq. 2). Super oxide radicals (e.g. peroxynitrite), formed by xanthine oxidase, can react with DNA, cells, and proteins and cause damage/toxicity to the cells. In addition, reactive oxygen species can be coupled with reactive nitrogen signalling and contribute to a central part of myocardial and vascular function, indicating the link of excess amount of xanthine oxidase with cardiovascular health (Zimmet and Hare, 2006). Regarding gout, which may be caused by xanthine oxidase, as this enzyme is a metabolic pathway in the formation of urate, allopurinol (as the inhibitor of xanthine oxidase) is used for the treatment of the disease (i.e. gout) (Heunks et al., 1999).

On the other hand, a rare genetic disorder called ‘xanthinuria’ can also happen, where a high concentration of xanthine in blood forms due to the lack of xanthine oxidase, which accordingly may result in some serious health problems such as renal failure. Obviously, to date, there is no definite cure for this problem; doctors advise the sufferers to take a diet low in purine and intake a high amount of fluids daily (Reiter et al., 1990).

In 1971, it was strongly believed that the consumption of homogenized milk could result in excessive mortality from coronary artery disease due to the release of xanthine oxidase through homogenization process (Oster, 1971); however, this claim was not supported by the later research (Bierman and Shank, 1975). McCarthy and Long (1976) reported that xanthine oxidase activity in blood serum of pigs receiving 7.6 L of full-fat milk daily during a 100-day period of study, was not significantly ( $p > 0.05$ ) different than the pigs that did not receive any milk in their diet. Also in the case of humans, there was not seen any casual or statistically-significant association between the activity of xanthine oxidase in blood and the average daily milk consumption, age, or sex (McCarthy and Long, 1976). Interestingly, there seems to be not-enough new scientific evidence on the association between milk/dairy consumption and the activity of xanthine oxidase in human blood, or any comprehensive study to confirm a link between milk/dairy food intake and gout and/or hyperuricemia caused by xanthine oxidase in milk and its products.

Whether the new findings in the future find a relationship between the aforementioned health problems and xanthine oxidase, and correspondingly, the consumption of dairy products or not, it is crucial to have enough knowledge about the concentration of xanthine oxidase in different types of milk and dairy products. According to the newly developed HPLC method for quantification of xanthine oxidase in different dairy products (Rashidinejad et al., 2016) introduced previously (section **Quantification of Xanthine Oxidase in Milk and Dairy Foods**), it was reported that raw milk possessed a higher xanthine oxidase activity than the commercial milk. And, the commercial full-fat milk contained a higher xanthine oxidase activity than the commercial low-fat milk (Table 1). The amount of xanthine oxidase in unwashed raw cream was lower than washed raw cream; whereas, both cream samples (unwashed and washed) presented greater values for xanthine oxidase activity than for the commercial cream. Testing several different varieties of cheeses (e.g. Parmesan, Jarlsberg, Colby, Mozzarella, Blue, and Edam), it was found that Jarlsberg and Blue had the highest and lowest activities of xanthine oxidase, respectively (Table 1). The differences in the activity of xanthine oxidase found between full-fat and low-fat milk and between full-fat and low-fat cheeses, can be related to the fact that xanthine oxidase is located in the MFGM (Fox and Kelly, 2006; Harrison, 2006).

As mentioned before (section **The Structure and Function of Xanthine Oxidase**), it is believed that processing conditions of milk such as homogenization can result in the reduction of the activity of the enzyme in this product (Cerbulis and Farrell Jr, 1977). This can be the reason for a higher degree of xanthine oxidase activity in raw milk compared with commercial pasteurized milk, regardless of the different fat contents in the two samples. It has been reported that washing cream products may selectively decrease (or even remove) MFGM components, which can accordingly decrease the enzymatic activity (Kathiriarachchi et al., 2014; Zittle et al., 1956). Rashidinejad et al. (2016) stated that xanthine oxidase activity in cheese samples depended upon the cheese preparation method; however, they did not confirm if a mature cheese with a longer ripening period could contain a higher or lower activity of xanthine oxidase. It appears that the cheeses manufactured from raw milk (e.g. Jarlsberg) can show the highest xanthine oxidase activity (Cerbulis and Farrell Jr, 1977; Rashidinejad et al., 2016).

It is notable that the effect of milk processing on the activity of xanthine oxidase has been of interest for a long time. For instance, about half a century ago, Greenbank and Pallansch (1962) studied the effect of different processing methods (e.g. pasteurization, homogenization, condensation, and drying) on the activity of xanthine oxidase in milk and dairy products. These researchers (Greenbank and Pallansch, 1962) found that the heat-treatment of full-fat milk to 195 °F for 15 seconds could inactivate the xanthine oxidase activity meaningfully. However, when they condensed the same milk to 50% total solids followed by homogenization at 4500 psi, xanthine oxidase was reactivated. It was also found that when the same milk was exposed to sonic vibrations (frequency of 10,000 vibrations/s for 7.5 h), about 94% of the enzyme was inactivated.

## Conclusion

In contrast to the possible health concerns attributed to the xanthine oxidase activity in milk and dairy products, this enzyme is influential in flavour development of many of these products, both due to the negative effects from inactivation during the processing and flavorful oxidative changes during storage (e.g. during cheese ripening). The old methods for analyzing xanthine oxidase in dairy products do not provide the appropriate quantification of the enzyme, but a new HPLC method has been developed for the accurate quantification of both xanthine (substrate) and urate (product). Such quantification would be very beneficial for understanding the contribution of xanthine oxidase to flavor development in dairy products, as well as for understanding the effect of the enzyme on the occurrence of the proclaimed corresponding diseases. It appears that the processing conditions such as homogenisation and heat treatment have a substantial effect on the amount of xanthine oxidase and its activity in milk and dairy products.

### Introduction

Bioactive peptides are derived from food proteins and exert a positive effect in humans due to its health-promoting properties. Bioactive peptides can exert several beneficial effects like preventing diseases or modulating the physiological systems once they are absorbed in the human body. There is a broad range of functions, depending on the sequence of the bioactive peptides, so that they can be involved in the gastrointestinal system such as the anti-obesity and satiety peptides, the cardiovascular system such as antihypertensive, antithrombotic, antioxidant and hypocholesterolemic peptides, the immune system such as antimicrobial, cytomodulatory and immune-modulatory peptides, and the nervous system such as opioid peptides.

Bioactive peptides usually contain between 3 and 20 amino acid residues and remain inactive while the sequences are kept within the parent protein. They are active once released by enzymatic hydrolysis by peptidases during food processing and/or during gastrointestinal digestion. In order to exert a positive health effect, bioactive peptides must cross the gastrointestinal (GI) barrier and survive enzyme degradation.

Numerous bioactive peptides have been reported in recent years as naturally present or generated from food proteins of different origins like milk, eggs, soya, fish, and meat. In this sense, the most extensively studied bioactivity during the last decade has been the antihypertensive activity through the measurement of angiotensin I-converting enzyme (ACE) inhibitory activity. The reason for this interest is mainly because high blood pressure is one of the major, independent risk factors for cardiovascular diseases, and the main reason of death in developed countries. Peptides with this type of activity are generically termed as bioactive peptides even though other activities such as antioxidant, antimicrobial, opioid, antithrombotic, antidiabetic, etc ... also fit into the general bioactive peptide term.

### Bioactive Peptides From Food Proteins

There are sequences of bioactive peptides that remain inactive while forming part of the parent proteins but, once released, they exert its bioactivity. Bioactive peptides can be released during food processing either by spontaneous endogenous enzymatic hydrolysis of food proteins, or by controlled hydrolysis with commercial peptidases. Bioactive peptides can also be released during the gastrointestinal digestion of the ingested foods. However, the released bioactive peptides must remain intact through gastrointestinal digestion and must be absorbed intact when crossing the intestinal barrier and reach the blood stream to exert their physiological action. All these pathways of generation are schematized in [Fig. 1](#) and briefly summarized below.

#### Bioactive Peptides Naturally Generated From Food Proteins

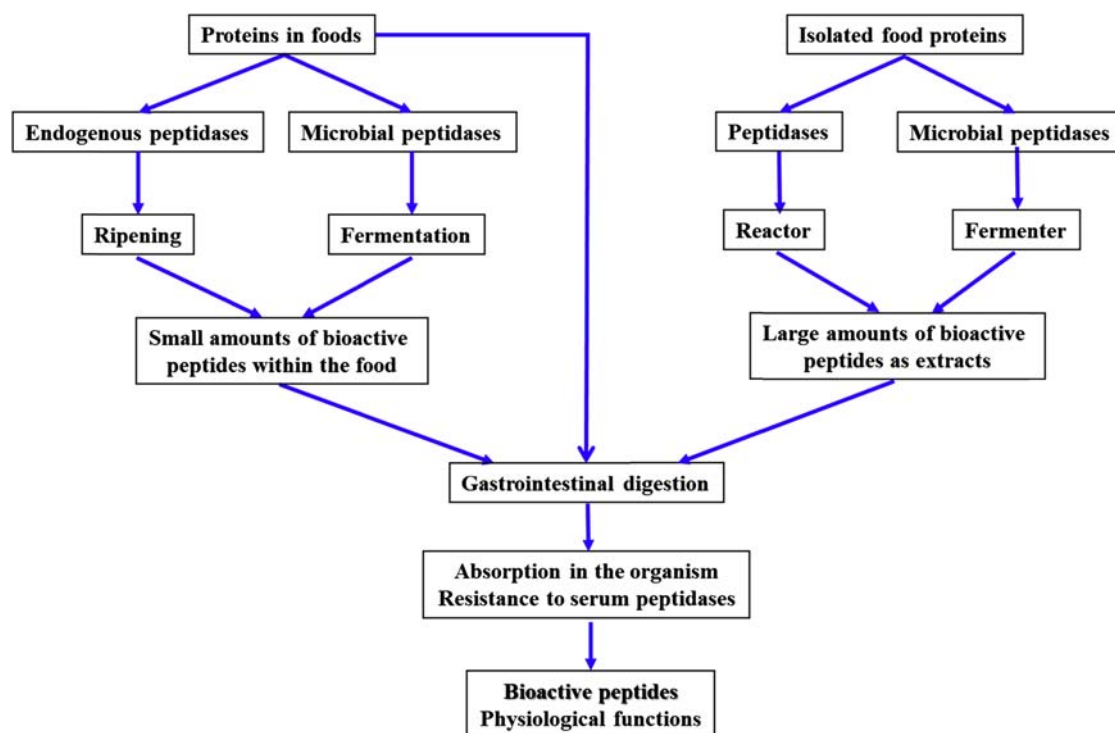

There are several pathways for the release of bioactive peptides from food proteins during processing. All of them involve the presence of endogenous endo- and exo-peptidases and adequate processing conditions for such enzymes to be active. Under these circumstances, bioactive peptides are released from meat and fish proteins which are hydrolyzed during ageing or ripening at mild temperatures. In other cases, bioactive peptides can be released by a combined action of endogenous and microbial peptidases, like in fermentation or curing processes of meat, fish and dairy products (i.e., dry fermented sausages, dry-cured ham, cured cheese, yogurt, etc.). Some lactic acid bacteria contribute with active endo- and exo-peptidases.

#### Bioactive Peptides Generated Through Hydrolysis of Food Proteins With Commercial Proteolytic Enzymes

The most usual way to produce bioactive peptides consists of the controlled hydrolysis of specific food proteins by commercial peptidases from animal, plant or microbial sources, or combinations of these. Main peptidases used for protein hydrolyzates are papain, thermolysin, Alcalase, Neutrase, Flavourzyme, or Actinase E, and its characteristics are compiled in [Table 1](#). In some cases, fermentations with Generally Recognised As Safe (GRAS) bacteria such as *Lactobacilli* also contribute to large generation of bioactive peptides. In most cases, proteins from food by-products constitute the substrate for obtaining enriched bioactive peptides fractions, so that an added-value is obtained while reducing the environmental impact. The resulting bioactive peptides must be extracted, partially purified, characterized or identified, and the *in vitro* and *in vivo* bioactivity determined. A scheme for the full process is shown in [Fig. 2](#).

#### Bioactive Peptides Generated Through Gastrointestinal Digestion of Ingested Food Proteins

Bioactive peptides that are encrypted into the protein structure may be released during gastrointestinal digestion by peptidases such as pepsin, trypsin and chymotrypsin. The routes of generation are usually confirmed in laboratory by using specific proteins and

**Figure 1** Scheme of the generation of bioactive peptides from protein hydrolysis in foods and/or the hydrolysis of isolated food proteins. Reproduced with permission from Toldrá, F., Reig, M., Aristoy, M.C. & Mora, L. Generation of bioactive peptides during food processing. Food Chemistry, 2018, in press. <https://doi.org/10.1016/j.foodchem.2017.06.119>.

simulated ingestion and gastrointestinal digestion with trypsin and/or chymotrypsin reproducing the conditions of all steps in real digestion. The bioactivity of the generated peptides is usually assayed *in vitro* but it is really necessary to perform additional *in vivo* assays with animals to verify such physiological effect.

### Functional Activity of Bioactive Peptides

Bioactive peptides exert its physiological effect when they are consumed. Once ingested, peptides are susceptible to be hydrolyzed by enzymes involved in the gastrointestinal digestion. Smaller peptides are released either by brush border membrane peptidases, intracellular peptidases or peptidases from the intestinal microbial flora. A requirement for peptides to be bioactive is that they must remain intact during their transport in the intestine, and be able to cross the intestinal membrane and be transported intact into bloodstream for reaching their target sites, and exert their physiological benefit. Different types of activity have been reported in the literature (see Fig. 3), and the most relevant are summarized below.

#### ACE Inhibitory Activity Peptides

These peptides are inhibitors of the angiotensin-1 converting enzyme (ACE or ACE-1) and can thus prevent hypertension. ACE has a relevant role in the regulation of blood pressure in the renin-angiotensin system because this enzyme converts the inactive decapeptide angiotensin I into the potent vasoconstricting octapeptide angiotensin II and this results in an increase in blood pressure (see Fig. 4). Such enzyme is also able to inactivate bradykinin. So, ACE inhibitory peptides can reduce the blood pressure a few hours after oral administration through the inhibition of ACE that is a dipeptidyl carboxypeptidase usually membrane-bound in vascular endothelial cells.

The intensity of ACE inhibition by specific peptides is measured through respective  $IC_{50}$  values but they do not always correlate with their real antihypertensive physiological effect in the body. Sometimes, promising peptides with low  $IC_{50}$  values are inactive by oral administration because they may be hydrolyzed during gastrointestinal digestion into smaller peptides with poorer inhibitory activity on ACE enzyme.

There are hundreds of ACE inhibitory peptides reported in the literature from many types of hydrolyzed foods like milk, fish, meat, eggs, soybean, corn, wheat, seaweed, etc. Some of them have been assayed for *in vivo* antihypertensive activity (see Table 2). Such assays use spontaneously hypertensive rats (SHR) who are orally administered the peptides and its antihypertensive effects are followed after several hours of ingestion. Fig. 5 shows an example of such *in vivo* assay with 3 different peptides. The antihypertensive effect of such peptides was clearly established with spontaneous hypertensive rats, that showed a decrease of systolic blood pressure within the range 25–35 mm Hg after 6 h of oral administration (Fig. 5).

**Table 1** Examples of commercial peptidase preparations for proteins hydrolysis

Enzyme preparation	Origin	Manufacturer	Activity
Flavourzyme 1000M	<i>Aspergillus oryzae</i>	Novozymes	3 endopeptidases, 2 aminopeptidases, 2 dipeptidylpeptidases, 1 $\alpha$ -amylase
Valkerase	<i>Bacillus licheniformis</i>	Bri Enzymes	Keratinase, Serin Endopeptidase
Prolidase	<i>L-lactis cremoris</i> Other many sources		Dipeptidase
Biopraser SP-20FG	<i>Bacillus sp</i>		Subtilisin, Endo metalloprotease, Aminopeptidase
Neutrase	<i>Bacillus subtilis</i> <i>B. amyloliquefaciens</i>	Novozymes	Metalloprotease
Alcalase 2.4 L	<i>Bacillus licheniformis</i>	Novozymes	Subtilisin, Alkaline serin endopeptidase, Extracellular neutral metallo protease, Aminopeptidase
Esperase	<i>Bacillus lentus</i>	Novozymes	Subtilisin, Alkaline serin endopeptidase

Ficin (ficin)	<i>Figs latex</i>	Sigma-Aldrich	Cysteine-type peptidase

## Opioid Peptides

Opioid peptides have a good affinity for an opioid receptor and are thus able to exert opiate-like effects by affecting the nerve system and gastrointestinal functions. Peptides from exogenous sources are denominated exorphins. The stability and lower side effects are the main advantages of food derived opioid peptides when compared to endogenous and synthetic opioid peptides. Such peptides are usually characterized by a tyrosine residue at the amino terminal end and an aromatic residue located in the third or fourth position. Exorphins have been reported in hydrolyzates from milk casein, wheat gluten and blood hemoglobin.

## Antioxidant Peptides

Depending on the chemical reactions involved, antioxidant activity of peptides can be classified into two groups: i) those peptides able to reduce free radicals by hydrogen donation in a competitive reaction, and ii) those peptides able to transfer one electron to reduce an oxidant. The methods used in the first case are oxygen radical absorbance capacity assay (ORAC), total radical trapping antioxidant parameter (TRAP) and  $\beta$ -carotene bleaching assay, while in the second case are 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) radical scavenging assay, ferric-reducing antioxidant power, and 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity.

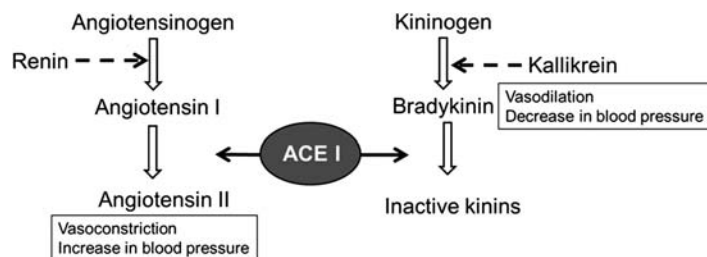

Antioxidant peptides may contribute to decrease the risk of cardiovascular disease as well as certain types of cancer. Such peptides prevent the formation of free radicals or introduce substances that compete for the existing radicals. Most of them have

Rice	Alcalase + Corolare PP	TQVY	18.2	30	−40	Li et al., 2007

**Figure 5** Antihypertensive effect of single oral administration of ACE inhibitory peptides PTPVP, RPR and KAPVA. Each point indicates the mean of systolic blood pressure of 8 SHRs, and the vertical bars represent the standard error. Treatment in each case was control (distilled water) and (a) peptide PTPVP; (b) peptide RPR; (c) peptide KAPVA; dose 1 mg peptide/kg B.W, respectively. Significant difference from control at each time: \* $P < 0.05$  and \*\* $P < 0.01$ . Reproduced with permission from Escudero, E., Toldrá, F., Sentandreu, M.A., Nishimura, H., and Arihara, K. (2012) Antihypertensive activity of peptides identified in the *in vitro* gastrointestinal digest of pork meat. Meat Science, 91, 382–384.

between 4 and 16 amino acids, and the molecular mass ranges from 400 to 2000 Da. Radical-scavenging properties have been reported in peptides containing tyrosine, tryptophan and phenylalanine. If aromatic amino acids are present in peptides at the water–lipid interface, such peptides can get access to scavenge free radicals from the lipid phase.

**Table 3** Examples of antioxidant peptides generated in foods or food hydrolyzates

Food	Enzymatic generation	Assay used	Peptide sequence	References
Tomato seeds	<i>Bacillus subtilis</i>	DPPH	GQVPP	Moayedi et al., 2017, 2018
Rice	Alcalase, Flavourzyme Protamex, Pepsin, Papain, Trypsin	DPPH, ABTS, FRAP	RPNYTDA TSQLLSDQ TRTGDPPF NFHPQ	Yan et al., 2015
Pine nut	Alcalase	DPPH, Ferric reducing power. ABTS radical, cellular antioxidant activity	KWFCT QWFCT	Yang et al., 2017

Several antioxidant peptides have been reported in hydrolyzates of soybean, milk, eggs, fish and meat proteins. An example of some of the identified antioxidant peptides in a variety of foods or food hydrolyzates are shown in **Table 3**. They can be also generated by endogenous enzymes during the processing of some foods such as cured and fermented foods.

### Peptides Against Type-2 Diabetes

Type-2 diabetes affects millions of adults worldwide constituting a major health issue. Overnutrition and obesity have a clear incidence on the development of diabetes type-2. Certain bioactive peptides have been reported to enhance insulin sensitivity and activate AMP-activated protein kinase via multiple signaling pathways.

The enzymes  $\alpha$ -glucosidase and dipeptidyl dipeptidase IV (DPPIV) are somehow regulating the glucose levels in postprandial plasma. So, an effective strategy to manage diabetes type-2 would be based on the inhibition of both enzymes. Dipeptidyl peptidase IV is a serine protease able to cleave preferentially X-proline or X-alanine dipeptides from the N-terminus of different substrates and its inhibition would reduce its action on glucagon-like peptide (GLP-1) and glucose-dependent insulintropic peptide (GIP) keeping a lower degradation of GLP-1. In fact, some drugs for controlling diabetes are based on the inhibition of DPPIV although they may exert secondary effects. Encrypted peptides in canary seeds, traditionally consumed for treating diabetes and hypertension, have shown inhibitory activity against DPPIV and ACE, which are targets for diabetes and hypertension treatments.

Peptides against type-2 diabetes have been reported in hydrolyzates of fish, seafood, milk or meat, and also naturally generated by endogenous enzymes in ripened foods like dry-cured ham. An example of some of the identified peptides against type-2 diabetes in foods or food hydrolyzates are shown in **Table 4**.

### Immunomodulating Peptides

Peptides exerting its action on immune system affect both the immune system and cell proliferation responses and have good applications in clinical medicine. So, immunomodulatory peptides can regulate lymphocytes proliferation in humans, modulate certain cytokines production, as well as stimulate the macrophages activity. Most of the reported immunomodulatory peptides are released from milk proteins either by enzymatic hydrolysis or by gastrointestinal digestion after consumption even though they may be scarce in the last case for any significant effects on human body. Enzymatic hydrolysis is necessary in order to get therapeutic amounts of immunomodulatory peptides. For instance, some milk caseins hydrolyzates stimulate the immune system while other peptides generated by pancreatin or trypsin may inhibit the proliferative responses of murine splenic lymphocytes and Peyer's patch cells. Other immunomodulating peptides were reported after trypsin hydrolysis of proteins from Alaska Pollock. The amino acid sequences were Asn-Gly-Met-Thr-Tyr, Asn-Gly-Leu-Ala-Pro, and Trp-Thr, and 20  $\mu$ g/mL of the purified peptides were reported to exert lymphocyte proliferation rates of 35.9%, 32.9%, and 31.3%, respectively.

**Table 4** Examples of mineral-binding and anti type-2 diabetes peptides in foods or food hydrolyzates

Activity	Food	Enzymatic generation	Assay used	Sequence	References
Mineral binding: Calcium	wheat germ	Alcalase	Lab assay	FVDVT	Wang et al., 2018
Mineral binding: Iron	Whey proteins	Flavourzyme/Protamex	CaCo-2 cells for iron absorption	EG and GT	Ou et al., 2010
Mineral binding: Calcium, Zinc and Iron	Alaska pollock skin	Pepsin + Trypsin	CaCo-2 cells for metal absorption	GPAGPHGPPG	Chen et al., 2017
Mineral binding: Calcium	Cod Skin gelatin	Trypsin	Lab assay	GDKGESGEAGER GEKGEGGHR	Wu et al., 2017
Anti type-2 diabetes	Fish (carp)	pepsin	DPP IV inhibitory activity	IADHFL	Zhang et al., 2017
Anti type-2 diabetes	Milk proteins	Pepsin + Pancreatin	DPP IV inhibitory activity and Cellular (CaCo-2 cells) glucose transporter inhibition	LKPTPEGDL, LPYPY, IPIQY, IPI and WR	Lacroix et al., 2017
Anti type-2 diabetes	Dry-cured ham	Muscle endogenous enzymes	DPP IV inhibitory activity	KA and AAATP	Gallego et al., 2014

### Antimicrobial Peptides

Antimicrobial peptides have been mainly isolated from milk and egg and constitute a natural defense of the organism against pathogens. Antimicrobial peptides are effective against different bacteria such as *Staphylococcus aureus* and *Escherichia coli* among others, as well as against yeast. The mode of action depends on the type of peptide but its effects are by forming pores on bacterial membranes, causing thinner membranes interacting with other components in the cell or acting in a detergent-like manner.

The most studied is the fragment 17–41 of lactoferrin, known as lactoferricin. Other proteins that are good sources of antimicrobial peptides are ovotransferrin, lysozyme, alpha-lactalbumin and beta-lactoglobulin.

### Mineral-Binding Peptides

Several food protein-derived peptides generated by enzymatic hydrolysis have shown good ability to trap mineral and trace elements constituting a strategy for their improved absorption. For example, they facilitate calcium absorption being very useful for the prevention of dental caries, osteoporosis, hypertension, and anemia. Further, some peptides can also help the remineralization and the increased absorption of calcium and other minerals in the intestine. Peptides from milk and whey protein hydrolysates show good mineral-binding properties (see Table 4). For instance, casein-derived phosphopeptides can form salts with calcium through their phosphorylated serine residues. Fish protein hydrolyzates were reported to be less effective in general than those from casein hydrolyzates even though some peptides derived from hoki, cod and Alaska Pollack frame proteins exerted similar calcium-binding properties. Iron-binding peptides have been reported in whey, walnut, egg and cod skin gelatin hydrolyzates.

# Resistant Starch Preparation Methods

Amir Amini Khoozani, John Birch, and Alaa El-Din Ahmed Bekhit, Department of Food Science, University of Otago, Dunedin, New Zealand

## Glossary

**Prebiotic** A carbohydrate-based substance which acts as a metabolite for the growth of probiotics.

**Probiotic** Microorganisms living in the large intestine with capability of fermentation and producing short chain acids that exert health benefits from the gastrointestinal system.

**Resistant starch** A part of starch that is resistant to digestion in the small intestine and can be fermented by colon microbiota.

## Introduction

Due to the importance of prebiotics in prevention of certain diseases, they have increasingly attracted the attention of food technologists (Verma and Banerjee, 2010). Prebiotics are non-digestible oligosaccharides that offer many beneficial effects on the gastrointestinal system. Typical prebiotics are dietary fibers (DF) where the most well-known are inulin, oligosaccharides and resistant starch (RS) (Buttriss and Stokes, 2008). The functional features of RS, together with its potential physiological benefits, provide an opportunity to increase the level of DF in the diet through common foods. However, processing procedures, especially thermal processing, may decrease the RS content of food products, whether naturally containing RS or RS-enriched products (Sullivan et al., 2017). In this respect, researchers started to look for ways to either increase the amount of RS or making it more resistant to processing conditions. In this chapter, in addition to review the preparation methods of RS, health benefits of this unique prebiotic will also be discussed.

## Resistant Starch

Resistant starch is mainly composed of the linear part of the starch molecule (amylose) which is fermented by probiotics, including *Bifidobacterium* species in the colon. This gives rise to the production of short chain fatty acids, mainly butyric acid, which plays a significant role in prevention of colorectal cancer. The effective dosage of RS which exerts beneficial health effects was reported as 6–12 g/d, whereas the recommendation for daily intake of another DF was 38 g/d (Fuentes-Zaragoza et al., 2011; Behall et al., 2006). RS naturally occurs in starch-based seeds, cereal grains and cooled heat-treated starchy foods. The highest amount of RS can be found in raw potato with 75 g/100 g (dry basis). Also, green banana is remarkable due to its high RS percentage of about 70 g/100 g of peeled fruit (Wang et al., 2017).

There are five types of RS introduced to date. In table 1, types, sources and description of each type are summarized.

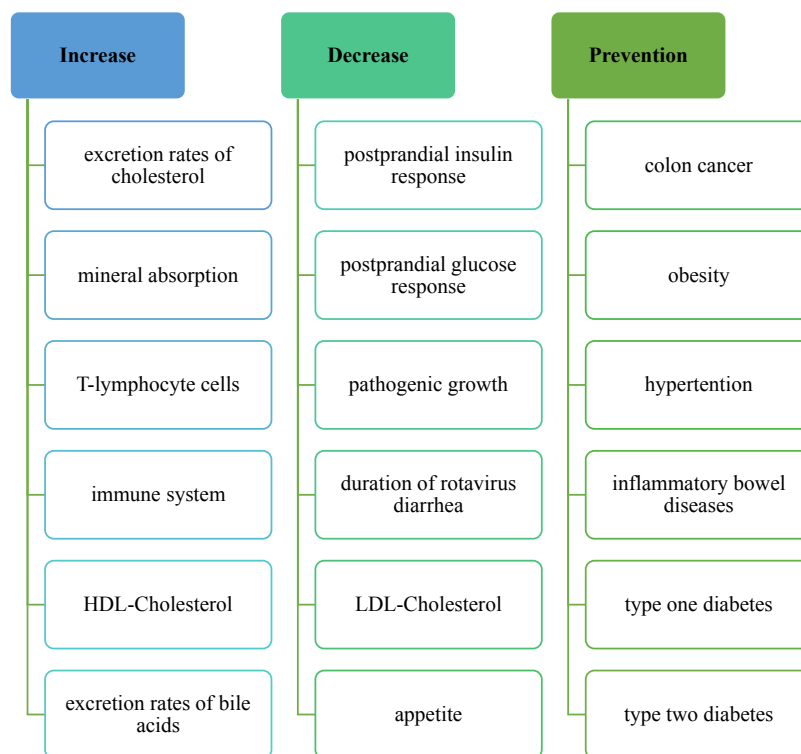

## Resistant Starch Health Benefits

Considering that several digestive diseases are triggered by inadequate or inappropriate diet, increased consumption of indigestible carbohydrates is important. Among numerous DF, RS has approximately half of the calorific value (8 kJ/g) compared with digestible starch (15 kJ/g) (Chen et al., 2017). Numerous health benefits have been shown for RS. In addition to its direct impact on the reduction of the glycemic index, most health effects have been ascribed to the prebiotic nature of RS (Boll et al., 2016).

**Table 1** Resistant starch types, description and sources (Milasinovic-Seremesic et al., 2012; Birt et al., 2013; Khalili and Amini, 2015)

Type	Description	Source
RS1	Physically inaccessible in cell walls	Grain, legumes, seeds
RS2	Granular native starch with high crystalline structure	Raw starchy foods (potato, pasta, high-amylose corn, unripe banana)
RS3	Retrograded starch	Retrograded starchy foods
RS4	Chemically modified starch	Esterified, Etherified or phosphorylated cross-linked starch
RS5	Amylose-lipid complex	Fatty acid treatment of debranched starch

**Figure 1** Health effects of resistant starch (Homayouni et al., 2014; Amini et al., 2015).

Colonic microbiota, specifically *Bifidobacterium bifidum* sp., starts to ferment RS into short chain fatty acids. Therefore, with reducing pH level of the environment by the presence of acetic, propionic and butyric acid, the proliferation of carcinomatous cells begins to be prohibited. Some studies have shown a positive effect of RS intake on prevention of colorectal cancer (Homayouni et al., 2014; Malcomson et al., 2015; Amini et al., 2015; Singh et al., 2016; Hung et al., 2016; Yuan et al., 2017; Yin and Zhao, 2017; Panebianco et al., 2017; Cray et al., 2017). As a result, the indirect effects of RS consumption are mostly due to the activity of probiotic microbiota which is illustrated in Fig. 1.

## Preparation Methods

There are three main strategies to produce resistant starch-rich powdered ingredients: physical, chemical and enzymatic processes. In the physical method, the main procedure is repeated heating–cooling cycles which lead to reorganization of linear chains of starch into a new structure which is resistant to hydrolysis by digestive enzymes (Sarawong et al., 2014). When heating is applied to a high-amylose starch dispersion, disaggregation and breaking of both amylose and amylopectin occurs and leads to formation of shorter linear chains. In the next process, cooling down of these chains brings about the formation of double helical aggregates which are denser and more resistant to be hydrolyzed. Consequently, RS produced by this method is more resistant to heat treatment and can be used as a functional ingredient for fortification of food products (Abioye et al., 2017).

Chemical methods promote modification of starch granules by lintnerization, acetylation, phosphorylation, oxidation, hydroxypropylation, esterification and combinations of these treatments (Nagahata et al., 2013). In each of these treatments, a chemical reagent prevents enzymes from binding properly to the starch. For instance, acetyl groups can be esterified to starch using free hydroxyl groups present on the glucose units with acetic anhydride commonly being used (Sha et al., 2012). In oxidation, by the utilization of reagents such as oxygen, ozone, sodium hypochlorite, periodate and hydrogen peroxide, carbonyl and carboxylic groups are produced that impedes the starch digestive enzymes (Chung et al., 2008). For hydroxypropylation treatment, propylene oxide is commonly used. Under high alkaline conditions, the esterified propylene is utilized to free hydroxy groups from the starch structure resulting in a bulky structure which cannot be digested by carbohydrase enzymes (Juansang et al., 2012). Lintnerization is the term applied to mineral acid-treated starch. By disruption of amorphous sections of starch, acid treatment (mainly by hydrochloric acid) leaves behind a higher ratio of crystalline parts which are more difficult for enzymes to access. In table 2 some of the main chemical modifications are shown.

Enzymatic treatments focus on debranching the  $\alpha$ -1-6 amylopectin bonds by pullulanase and isoamylase which results in rearranging the structure later in the retrogradation process (Reddy et al., 2013). Other enzymes such as  $\alpha$  and  $\beta$ -amylase are used to hydrolyze the starch amorphous regions and leave a tightly packed crystalline structure behind. Consequently, the aim of using debranching enzymes is to hydrolyze amylopectin branch chains and provide more linear parts (Cai and Shi, 2010). In

Phosphorylation	Pea Normal corn Canna Rice Wheat	Using sodium trimetaphosphate and sodium tripolyphosphate in alkaline conditions (around 3 h), following gelatinization at 100 °C	<ul style="list-style-type: none"> <li>• Legal limitations by FDA at excess amounts (0.4%)</li> <li>• Destructive effects on bread's rheology at high level of substitution</li> </ul>	<a href="#">Dupuis et al., 2014</a> , <a href="#">Thompson, 2001</a> , <a href="#">Yeo and Seib, 2009</a>
Carboxymethylation	Potato Rice	Addition of monochloroacetic acid in alkaline conditions with subsequent microwave treatment	<ul style="list-style-type: none"> <li>• Reducing process time by microwave heating</li> <li>• Low RS yield</li> </ul>	<a href="#">Liu et al., 2012</a> , <a href="#">Kittipongpatana and Kittipongpatana, 2013</a>
Oxidation	Normal corn Rice Pinto bean	Injection of O <sub>3</sub> , H <sub>2</sub> O <sub>2</sub> , O <sub>2</sub> in alkaline conditions for 30 min	<ul style="list-style-type: none"> <li>• Enzymatic hydrolysis by <math>\alpha</math>-amylase</li> <li>• Slightly increase in bean starch</li> </ul>	<a href="#">Chung et al., 2008</a> , <a href="#">Simsek et al., 2012</a>
Acetylation	Rice Canna Normal corn	Treatment with vinyl acetate (30 °C, 5 h)	<ul style="list-style-type: none"> <li>• Around 16% vinyl acetate led to higher amount of RS</li> </ul>	<a href="#">Sha et al., 2012</a> , <a href="#">Simsek et al., 2012</a> ; <a href="#">Juansang et al., 2012</a>
Hydroxypropylation	Canna Normal corn Waxy corn	Addition of propylene oxide in alkaline conditions Followed by gelatinization (40min)	<ul style="list-style-type: none"> <li>• Long treatment (40 h)</li> <li>• Decrease of RS compared to initial amount</li> </ul>	<a href="#">Juansang et al., 2012</a> , <a href="#">Chung et al., 2008</a> , <a href="#">Han and Bemiller, 2007</a>
Citric Acid treatment	Normal Waxy Hylon VII	12 h reaction with 0.1 or 0.01 M citric acid followed by oven heating OR Non-autoclaved method: 16 h reaction + 9 h heating at 120 °C	<ul style="list-style-type: none"> <li>• Decrease of RS2 amount</li> <li>• Long procedure time</li> <li>• Only suitable for high amylose cereals</li> </ul>	<a href="#">Sun et al., 2012</a> , <a href="#">Shin et al., 2007</a> , <a href="#">Xie and Liu, 2004</a>

**Table 3** Enzymatic treatments for the production of resistant

<i>Enzymatic method</i>	<i>Starch type</i>	<i>Main enzyme process</i>	<i>Remarks</i>	<i>Reference</i>
$\beta$ -amylase	corn Wheat	20 h of $\beta$ -amylase reaction followed by 3 autoclave cycles	<ul style="list-style-type: none"> <li>• Long preparation procedure</li> <li>• Two-fold increase in RS</li> </ul>	<a href="#">Hickman et al., 2009</a>
$\beta$ -Amylase and Pullulanase	corn starch	$\beta$ -Amylase in conjunction with Pullulanase	<ul style="list-style-type: none"> <li>• Optimum amount of enzyme concentration is of importance</li> </ul>	<a href="#">Zhang and Jin, 2011</a>
Isoamylase	Waxy corn Waxy wheat Waxy potato	1g/100 g starch dry basis Isoamylase (50 °C, 24 h) followed by retrogradation	<ul style="list-style-type: none"> <li>• Pre-cooking is needed</li> <li>• Long post-treatment (48 h)</li> <li>• Significantly increased RS3</li> </ul>	<a href="#">Cai and Shi, 2010</a>
Pullulanase	Gelatinized red kidney bean Cassava potato	Pullulanase, 40U/g, 10 h followed by heat treatment at 50 °C	<ul style="list-style-type: none"> <li>• Thermal treatment is needed</li> <li>• Long post-treatment (24h/25 °C)</li> </ul>	<a href="#">Reddy et al., 2013</a> , <a href="#">van Hung et al., 2012</a>

this regard, subsequent retrogradation will produce higher levels of RS3 with double helical structures stabilized by hydrogen bonds. However, in order to achieve maximum enzyme performance, optimal pH, temperature and time of reaction should be precisely controlled. **Table 3** shows the main enzyme processes in enzymatic treatment of starchy crops.

Regarding that a combination of mentioned methods could also increase the RS amount, most of them ended with retrogradation processes resulting in RS3 increments. The conditions and percentage of produced RS3 in the finished product are summarized in **table 4**.

**Table 4** Combination treatments for increasing resistant starch

Source	Procedure	%RS (g/100 g)	Remarks	Reference
Taro corm	autoclaving, enzymatic debranching, retrogradation and oven drying processes for two times (60 °C)	35.1 ± 1.9% (dry basis)	• A combination of methods in two cycles resulted in 16-fold increase in RS amount	Simsek and El, 2012
Maize starch	twin-screw extrusion, cooking, mild acid hydrolysis, hydrothermal treatments (110 °C)	increased from 11% to 20%	• Acid modified normal-maize starch (AMMS) produced a greater RS	Hasjim and Jane, 2009
Cassava starch	enzymatic debranching, steam cooking, drying (45 °C) and freezing (−28 °C)	19–20	• Refrigeration of cassava starch gave rise to higher RS compared to freezing storage	Abioye et al., 2017
High amylose corn starch (Hylon V and VII)	storage in 23 °C then drying at 50 °C after each extrusion cooking with high moisture feed for 3 cycles	Hylon V: from 43 to 40 Hylon VII: from 53 to 45.1	• RS3 made from Hylon VII had high emulsion stability • Repeated autoclaving-storage cycles are necessary to increase the RS3 content to the desired levels	Masatcioglu et al., 2017
High-amylose corn starch	Hydrothermal Pressure (15 MPa for 2 h) followed by retrogradation (120 °C/24h, 4 °C)	At 100 °C reached to 27%	• The hydrothermal pressure resulted in a significant increase in the total RS content if the samples were gelatinized at temperatures below 120 °C	Pu et al., 2013

## Conclusion

Resistant starch is an exceptional prebiotic with numerous additional health benefits. It also brings technological positive effects for food products as a functional ingredient. However, processing conditions, especially heat treatment, can attenuate its content. Consequently, there are ways in order to isolate and increase the amount of resistant starch with the aim of increasing its capability to be resistant during food processes.

Chemical reagents could increase the amount of resistant starch type four in starchy foods, however, long reaction times and some health concerns about the dosage of chemicals and the residue are limiting factors. Enzymatic debranching is shown to be more effective due to the high concentration of produced resistant starch type three. It also seems to be an essential step when used with other methods, such as heat and cool cycles. Though, it needs a controlled environment, effective enzyme activity and subsequent heat treatments. Although the heating-cooling cycles could increase the resistant starch type three in produced products, there are several factors that needed to be investigated including the rate of cooling/heating process, number of cycles and various temperatures. Additionally, the combination effect of fatty acid addition and other methods for producing resistant starch type five has not been considered yet.

### Overview

Mineral-protein interactions are important in milk since minerals can influence milk protein configuration and structure, and thus can play an important role in the biological and structural functions of milk (Gaucheron, 2011). Milk functionality including stability, nutritional properties, and technological/processing characteristics are all affected by the way in which proteins and minerals interact within the milk matrix (de la Fuente, 1998).

**Figure 1** Composition of milk fractions. Data sourced: Boyazoglu and Morand-Fehr (2001), Hadjipanayiotou (1995), Hernandez et al. (2014), Moreno-Montoro et al. (2015), Payandeh et al. (2015), Alves et al. (2015), Mayer and Fiechter (2012), Pavić et al. (2002), Leitner et al. (2016), Abdel-Salam and El-Sayed (2014).

Mineral and protein interactions can take a number of forms including electrostatic, ionic, and covalent (coordinate) bonding. The type of bonding that occurs is reliant on the specific protein(s) involved (Harris, 2014). Many of the interactions present are similar in nature to those present in other biological fluids such as blood (Lenton et al., 2015).

Milk proteins make up between 3% and 6% of the wet weight of milk (Fig. 1) and are involved in a wide range of functions including nutrient transport and lipid metabolism. The major proteins present in milk include the casein family (comprising  $\alpha_{s1}$ ,  $\alpha_{s2}$ ,  $\beta$  and  $\kappa$  caseins), the whey protein fraction (including  $\alpha$ -lactoglobulin,  $\beta$ -lactoglobulin, and others), and various growth factors, such as epidermal growth factor (Claeys et al., 2014). In addition there is a large number of low abundance proteins (Ha et al., 2015) involved with cell surface interactions, peptidase activity, antioxidant function, cell surface binding, and lipoprotein receptor binding (McSweeney and Fox, 2003; Ha et al., 2014).

The mineral composition of milk varies depending on species, lactation time, lactation stage and diet and is typically measured holistically as ash content (Fig. 1) (Králičková et al., 2012; Bilal et al., 2014). Although required in low concentrations, minerals play key roles in metabolic pathways and are key to maintaining cell homeostasis (Fraga, 2005; Gaucheron, 2005). Milk contains high levels of key nutritional minerals, including calcium (Ca), magnesium (Mg), iron (Fe), and zinc (Zn) (Table 1). The minerals in milk can be present in a range of forms, with the majority of minerals being present either in a soluble (ionic) form or as colloidal salts (Fox et al., 2015a). Selenium (Se) is generally found incorporated into amino acids, specifically as selenocysteine and selenomethionine (Cobo-Angel et al., 2014; Zheng et al., 2016). Likewise, phosphorus (P) within milk is present in two forms, inorganic (Pi) and organic (P). Similar to Se, the organic P is incorporated in proteins by covalent bonding (Fox et al., 2015c).

## Biological Functions Resulting From Mineral and Protein Interactions

### Facilitating Protein Function

The correct function and/or activity of a number of enzymatic proteins and non-enzymatic proteins present in milk depends on interaction with a mineral (Vegarud et al., 2000). This can occur in a number of ways. Mineral binding through chelation often stabilizes protein conformation, resulting in improved activity. Minerals can also act as part of the catalytic sites within enzymes (Vegarud et al., 2000). For example, lactoperoxidase, an enzyme present in milk with a known antibacterial function has a coordinately bound heme group containing Fe at its active site that facilitates the catalytic conversion of hydrogen peroxide to water, and thiocyanate to hypothiocyanite (Kussendrager and Van Hooijdonk, 2000). The activity of lactoperoxidase is significantly higher in the presence of  $\text{Ca}^{2+}$  ions (Kussendrager and Van Hooijdonk, 2000; Koksai et al., 2016). Lactoferrin is another protein present in milk that has been shown to have a range of functions including tumor inhibition, antibacterial activity, bacteriostatic activity, immunomodulation activity, and hemolytic function (Giansanti et al., 2016). With respect to lactoferrin bacteriostatic activity, a number of mechanisms have been suggested including one that is considered critical in the milk matrix - the sequestering of Fe ions. In this case, the binding of lactoferrin to free Fe ions restricts the access of microbes to an essential nutrient thus restricting growth (Giansanti et al., 2016; Sedykh et al., 2016).

### The Casein Micelle and Calcium Phosphate

One of the key interactions between minerals and proteins that occur in milk is the binding between colloidal calcium phosphate and the casein micelle. The casein micelle is a complex protein aggregate made up of proteins from the casein family, including  $\alpha_{s1}$ ,  $\alpha_{s2}$ ,  $\beta$  and  $\kappa$  caseins. The internal structure of the casein micelle is still an area of active scientific investigation (Ingham et al., 2015) even though the characteristics of the individual casein proteins have been extensively studied (De Kruif and Holt, 2003). The structure of the colloidal calcium phosphate casein micelle complex plays an important role in the functional properties of milk, including gel formation, emulsification, and foam formation (Fox et al., 2015a). Casein proteins contain a relatively high number of phosphates bound to serine that enable interaction with ionic Zn and Ca (Horne, 2014).

Besides ionic interactions, the casein micelle has been shown to interact with colloidal calcium phosphate present in milk. Colloidal calcium phosphate is present in equilibrium with  $\text{Ca}^{2+}$  and hydrogen phosphate ( $\text{HPO}_4^{2-}$ ) in milk. It is believed that colloidal calcium phosphate interacts with the casein micelle through associations with the phosphoserine residues present in casein proteins (Horne, 2014; Xu et al., 2016) with up to four phosphoserine residues interacting with each calcium phosphate group (Choi et al., 2011).

It is understood that colloidal calcium phosphate stabilizes the structure of the casein micelle as well as helping maintain the suspension of colloidal calcium phosphate (Fox et al., 2015a). The decalcification of the casein micelle has been shown to cause the disassociation of the micelle structure. Xu et al. (2016) decalcified milk protein concentrates by ultrafiltration and ion exchange treatment and found that the average casein micelle diameter, determined by particle size distribution, was reduced with increasing decalcification (with a z-average diameter of 179.4 and 98.6 nm at 0% and 83.6% decalcification, respectively). Inversely, when  $\text{Ca}^{2+}$  or calcium plus phosphate was added to milk an increase in the stability of the casein micelle was observed with increased resistance to gel formation by both rennet coagulation and heat (Kamal et al., 2017; Balakrishnan et al., 2018).

### Stabilization of Solubility and Ionization States of Minerals

Protein and mineral interactions in milk are able to aid maximal mineral absorption, because for minerals to be available for absorption, they must be present in the intestine in a specific form (Benito and Miller, 1998; Stahl et al., 2002). For example, inorganic iron must be present in the ferrous ( $\text{Fe}^{2+}$ ) rather than the ferric ( $\text{Fe}^{3+}$ ) form so that it can be transported through intestinal membranes by active transport proteins (Ganz, 2013; Abbaspour et al., 2014). The interactions between proteins and minerals are able to minimize changes in oxidation states and solubility during storage, processing, and digestion. This occurs through the same chelation and ionic interaction effects that help in stabilizing the structure and function of proteins (Benito and Miller, 1998; Zhao et al., 2014). Milk is considered a key source for nutritional Ca, due to high Ca concentration and the high bioavailability of the milk Ca (Heaney, 2000; Adolphi et al., 2009; Pereira and Vicente, 2017). One aspect of this increased absorption can be linked to the way in which Ca interacts with proteins in the milk matrix. The formation of amorphous calcium phosphate complexes can occur in the intestine due to the effects of pH, in addition to the native colloidal calcium phosphate discussed above (Lenton et al., 2015). These complexes are considered undesirable as they reduce the bioavailability of both Ca and P. The presence of phosphopeptide sequences within caseins in milk increases the solubility of the amorphous calcium phosphate complexes, which in turn, increases the availability of both Ca and P for absorption (Kitts et al., 1992; Cross et al., 2005; Sun et al., 2016). The absorption of Ca and P are considered critical for the correct development and maintenance of bone structures (Weaver, 2017).

### Mineral Co-dependent Interactions

One aspect of mineral metabolism that needs to be highlighted is the co-dependent and at times antagonistic nature of mineral absorption. An example is the relationship between Fe and Cu. Copper is able to support Fe absorption by facilitating oxidation and subsequently allowing Fe to bind to ferroxidase hephaestin enabling absorption from the gut into the circulatory system (Vulpe

et al., 1999; McKie et al., 2000; Datz et al., 2013). Inversely, competitive interactions can occur among Ca, Mg, Fe, and Zn in a dose-dependent manner (Bressler et al., 2007). It is believed that the competitive interactions are regulated by divalent metal transporter 1 (DMT-1) (Thompson et al., 2010). The competitive interactions between these minerals can be reduced due to the effects of milk protein and peptides. The most well studied of these are the interactions between caseinophosphopeptides (CPPs), derived from milk and Ca (Fiorilli et al., 2012). Cosentino et al. (2010) showed that the presence of CPPs resulted in an increase in the absorption of Ca in human colon adenocarcinoma cells and human epithelial colorectal adenocarcinoma cells (HT-29 and Caco-2 cells). Cell signaling, bio-modulatory effects and alternative absorption pathways were some of a range of potential mechanisms that were proposed by the authors. Furthermore, CPPs have been shown to bind other divalent cations including Fe and Zn but there is some doubt in the literature as to whether there is any beneficial effect. Garcia-Nebot et al. (2010) found that milk-derived CPPs aided in the bioavailability of Fe in Caco-2 cells when used to supplement fruit juice beverages. Subsequently, in more recent work by the same lab, also using Caco-2 cells, no effect of individual CPP fractions was demonstrated (Garcia-Nebot et al., 2015). These results indicate that further investigation is required in relation to the role of CPPs and mineral absorption.

### Milk Peptides

The proteins present in milk can be enzymatically hydrolyzed into peptide fragments. This can occur during digestion, cheese making, or due to addition of specific enzymes (Korhonen and Pihlanto, 2006). These fragments have properties that are considered independent of the proteins they are derived from (Meisel, 1998). The most commonly identified example of this is CPPs as discussed above. However, CPPs are one of a vast range of peptides formed during the digestion of milk (Mohanty et al., 2016).

The natural (gastrointestinal) digestion of milk produces a specific set of peptides. However, a wide range of peptides can be formed from milk when different hydrolysis methods (e.g. microbial fermentation or use of pure enzymes) are applied (Saavedra et al., 2013). Bacterial fermentation (using *Lactococcus lactis*, and *Lactobacillus helveticus*), and isolated proteases from bacteria and or fungi (including protease from *Aspergillus sojae*, *Aspergillus oryzae* and *Bacillus licheniformis*) are two examples of methods shown to produce novel peptides from milk proteins (Saavedra et al., 2013; Morais et al., 2014). Peptides produced using these systems have been shown to have a vast range of functions including antibacterial activity, antioxidant activity, angiotensin converting enzyme inhibition, haemolytic activity and to direct mineral binding functions (López-Expósito et al., 2006; Corrêa et al., 2011, 2014; Meira et al., 2012). Peptides derived from whey protein concentrate hydrolyzed with alcalase have been shown to bind Fe resulting in a significant increase in Fe solubility (Kim et al., 2007). Likewise, whey proteins hydrolyzed with flavorzyme and protamex has been shown to produce Ca binding peptides with binding characteristics independent of those of CPPs (Zhao et al., 2014). Other milk proteins including  $\beta$ -casein,  $\alpha$ -Lactalbumin, and  $\beta$ -lactoglobulin have also been identified as targets for the production of peptides (Saavedra et al., 2013).

*In silico* methods have been used for the identification of bioactive peptides from a range of protein sources including milk (Saavedra et al., 2013). Even so, the application of *in silico* methods allows for rapid identification of peptide targets, the application of these methods is limited because for a natural food product the technology just provides potential peptide sequences. Once a potential peptide sequence is identified the process of hydrolysis, isolation, characterization and the measurement of activity is still required (Carrasco-Castilla et al., 2012).

### Factors Affecting Mineral and Milk Protein Interactions

Milk is typically processed using one or more steps before it is sold for consumption, including pasteurization (thermal processing), cheese making (concentration, fermentation), drying (thermal processing), and freezing (cold processing) (de la Fuente et al., 1997; Huppertz, 2016). The mineral composition of milk can alter the processing parameters of the milk and the processing technology can affect the interactions between the mineral fraction of the milk and milk proteins. These interactions are collectively confounded by the differences between milks of different species (Fig. 1) (Park and Haenlein, 2013). As an example of the impact of minerals on the protein functionality, sheep milk has a larger native micelle structure and lower colloidal calcium level compared to cow milk. This means that processing (including both thermal and cold processing) may result in smaller changes of physical and functional properties of sheep milk than observed with cow milk. This is particularly true with respect to common cheese-making properties of rennet coagulation time and curd firmness (Raynal and Remeuf, 1998; Raynal-Ljutovac et al., 2007).

### Heat Processing

The safety of any food product is extremely important to ensure the wellbeing of consumers and to maintain consumer trust. The most common food preservation method used in dairy processing is pasteurization by heat treatment. Pasteurization not only minimizes potential detrimental bacterial effects (both pathogenic and spoilage) on milk products but also inactivates enzymes that can cause quality changes and shorten shelf life (Raynal-Ljutovac et al., 2007; Huppertz, 2016). The main mechanism of pasteurization is protein denaturation, which is carried out to inactivate the biological function of bacteria. Because the interactions between minerals and proteins are closely associated with protein functionality and structure, it is only logical that the interactions between minerals and proteins will also be affected (Fox et al., 2015b). The inactivation of enzymes such as lactoperoxidase, for

example, reduces the sequestering of Fe within milk and consequently this will affect the bactericidal capability of lactoperoxidase (Giansanti et al., 2016; Sedykh et al., 2016).

The solubility of minerals can also be altered by temperature changes. While an increase in temperature is normally expected to increase the solubility of a given salt, calcium phosphate, however, has reduced solubility in milk with increasing temperature (Kamal et al., 2017). Although this process is mostly reversible, exposure to high temperatures or long heating times can result in an insoluble deposition (or colloidal form) of calcium phosphate (Fox et al., 2015b). Extended heat treatments can also affect the structure of the casein micelle, due to the close relationship between calcium phosphate and the casein micelle (O'Connell and Fox, 2000). As a secondary effect of changes in the solubility of calcium phosphates, the pH of milk changes during heating. The formation of insoluble calcium phosphates occurs within an equilibrium as summarized by Eq. (1). As the pH change is related to the calcium phosphate solubility this change in pH is reversed upon cooling (Chandrapala et al., 2010; Fox et al., 2015a).

Calcium phosphate equilibrium in relation to heating (Fox et al., 2015b)

## Freezing

It is not typical for cow milk to be frozen prior to further processing and the use of any sub-zero processing is typically the final processing step, such as in the production of ice-cream (Huppertz, 2016). However, goat and sheep milk are commonly frozen (de la Fuente, 1998), as the result of the highly seasonal lactation periods that are associated with small ruminates (de la Fuente, 1998). Similar to pasteurization, freezing of milk alters the mineral distribution within its matrix. Pazzola et al. (2013) identified that freezing fresh sheep milk at  $-20^\circ\text{C}$  for up to five months resulted in negative changes in its renneting characteristics that may be due to an alteration in the ratio of soluble Ca to soluble P (de la Fuente et al., 1997). With respect to goat milk, Kljajevic et al. (2016) found no significant changes in milk coagulation properties after a frozen storage period of 60 days at  $-27^\circ\text{C}$ . It must be noted that neither of these works assessed the direct interactions between proteins and minerals.

With respect to cow milk ice cream, the interactions between minerals and proteins have not been extensively investigated. Jonkman et al. (1999) identified that the conversion of cow milk into ice cream did not result in the alteration of the casein micelle structure, although an increase in the association between minerals and the casein micelle was observed when assessed by ultrafiltration. It is understood that the addition of calcium chloride ( $\text{CaCl}_2$ ) reduces the emulsification capacity of milk proteins during the ice cream making process. This, in turn, results in an increase in the size of ice crystals and an increase in fat partial coalescence, both of which are considered undesirable characteristics for ice cream (Costa et al., 2008).

## Cheese Making

The way in which calcium in milk interacts and associates with micellar structures is a key factor in determining the renneting properties of milk and therefore the initial efficiency of the cheese making process (Park et al., 2007). In cow milk, the large association of calcium with the casein micelle results in a protective effect that slows the coagulation process (Hickey et al., 2015). Variation in the cheese making characteristics between different milk types has been associated with differences in casein micelle mineralization (calcium phosphate associations). This is exemplified by comparing sheep milk and cow milk. Even though there is a higher total calcium concentration in sheep milk, this is predominantly in the ionic form rather than being associated with the colloidal structure of the casein micelles, which results in a faster coagulation time during the renneting step (Storry et al., 1983; Ramos and Juarez, 2002). In addition, the high curd strength found in sheep milk cheeses increases the whey drainage time and reduces the cheese yield (Riddell-Lawrence and Hicks, 1989; Catarino et al., 2013; Hickey et al., 2015).

## Quantification of Mineral and Protein Interactions

As protein and mineral interactions within milk are an important characteristic, consideration of the methods available for the measurement of the interactions is of interest. The quantification of total mineral content within milk is standard practice, using methods such as inductively coupled plasma mass spectrometry (ICP-MS), atomic absorption spectroscopy (AAS) or atomic emission spectroscopy (AES), which accurately and constantly determine the elemental composition and concentration of minerals in milk (Ataro et al., 2008; Pereira et al., 2016). When more expedient measurements are required, a range of methods including mid-infrared spectroscopy have been applied (Toffanin et al., 2015). Likewise, the determination of milk protein content by total nitrogen determination is commonplace within both industry and scientific investigations (Chang and Zhang, 2017). However, the determination of mineral and protein interactions in milk is complex. This is because the interactions between proteins and minerals are in many cases extremely sensitive to pH, temperature, and ionic strength. Most of the common methods for the isolation of proteins use the manipulation of at least one of these factors (Gaucheron, 2005).

One method of analysis proposed by [de La Fuente et al. \(1996\)](#) to determine protein and mineral interactions is to use high-speed centrifugation ( $980665 \text{ m s}^{-2}$  for 1 hour). The main criticism of this method is the potential for low molecular weight peptide fractions to remain in the supernatant resulting in an underestimation of the bound mineral content ([de la Fuente et al., 2002](#)). Therefore, this method should be referred to as the determination of non-sedimentable minerals ([Gaucheron, 2005](#)). Ultrafiltration is another method that can be applied to aid in the separation of free and bound minerals. The use of low molecular weight cut off membranes (cut off less than 10–15 kDa) is able to separate out the majority of the protein phase allowing for the analysis of bound minerals ([Malacarne et al., 2015](#)). However, similar criticisms can be applied to this method as with high-speed centrifugation ([Gaucheron, 2005](#)). It must be noted that one of the benefits of ultrafiltration is the ability to carry out testing the separation of the various phases at elevated temperatures. For example, [On-Nom et al. \(2010\)](#) carried out separation at temperatures up to  $80^\circ\text{C}$ .

The determination of interactions is possible with individual proteins and peptides derived from milk. This can be carried out using isotopic measurements, protein characterization, and mineral specific assays ([Kitts and Yuan, 1992](#); [Guo et al., 2014](#); [Sun et al., 2016](#)) and has been carried out on a number of milk-derived proteins and peptides ([Zhao et al., 2014](#)). The examination of mineral binding on an individual protein or peptide is useful to understand the functionality of novel proteins and peptides derived from milk ([Korhonen, 2009](#)). However, as milk is a complex biological fluid the isolation of novel proteins and peptides can be a challenging exercise ([Guerrier et al., 2008](#); [Pa'Ée et al., 2015](#)).

## Conclusions

The interactions between the proteins and minerals present in milk are critical to the functions of milk, and the nutritional benefits that milk provides to the consumer. Minerals act to stabilize protein structure and act to facilitate enzymatic catalysis. However, the role that proteins play in increasing mineral bioavailability is just as important. This is because milk is seen as a key source of nutrients, especially during growth and development. Bioactive peptides derived from milk have also been an area of intensive research due to their applications as nutraceutical and medicinal agents. The development of *in silico* methods has resulted in the identification of a vast range of novel peptides in milk. The activity of many of these peptides is dependent on or associated with ionic minerals, particularly Fe and Ca. However, further work on the isolation and characterization of these peptides is still required. During processing, a number of changes occur within the milk matrix. Differences between the composition of milk from different species, specifically related to the casein micelle composition (and structure) can result in differences in the processing of milk, as is particularly notable in the cheese making process. Finally, the quantification of mineral and protein associations is difficult because of the complexities of separating out the bound and non-bound phases without inducing changes. The use of centrifugation and ultrafiltration are common within literature but these methods are limited and do not provide a true snapshot of milk mineral and protein interactions in their native state. Likewise, though the analysis of individual protein and or peptide fractions is well established, these methods provided a limited insight into the nature of the milk matrix at a system level. An understanding of the native protein and mineral interactions within milk, as well as how these interactions change due to processing is important to maximize the nutritional benefits of both unprocessed and processed dairy products.

## Protein-Stabilised Emulsions

Chia Chun Loi, Graham T Eyres, and E John Birch, Department of Food Science, University of Otago, Dunedin, New Zealand

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Creaming** is the upward movement of droplets in an emulsion due to lower density droplets moving upwards in the continuous phase.

**Emulsion** is a thermodynamically unstable mixture of two or more immiscible liquids.

**Emulsion stability** is the ability of the emulsion to resist changes in its physicochemical properties over time.

**Interface** is the point where immiscible phases such as oil and water are in contact.

### Introduction

Many proteins, in particular milk proteins, are surface active molecules that consist of both hydrophilic and hydrophobic functional groups (Dickinson, 1997; Wilde et al., 2004). Proteins have been used extensively as emulsifiers in foods (Rodríguez Niño et al., 2001; Sliwinski et al., 2003; Sünder et al., 2001) to form stable oil-in-water (o/w) emulsions such as milk, cream, ice-cream, mayonnaise, salad dressing and gravies (Tornberg and Hermansson, 1977). An oil-in-water emulsion consists of dispersed oil droplets in a continuous water phase. Milk proteins such as casein and whey proteins adsorb to the surface of oil droplets, reduce the surface tension between oil and water, and form a protective film surrounding the oil droplet to stabilise it (Walstra, 2002). Low molecular weight emulsifiers such as mono- and diglycerides are commonly added to improve emulsion stability (Krog, 2011; Novales et al., 2005; Sagalowicz et al., 2006). The biphasic nature of an emulsion means that it can only keep droplets dispersed for a limited time, thus affecting shelf life. Emulsions undergo destabilisation over time according to a number of different mechanisms. In this chapter, destabilisation mechanisms, extrinsic and intrinsic factors affecting emulsion stability, and the effect of mono- and diglycerides on emulsion properties are discussed.

### Protein-Stabilised Emulsions

Proteins such as casein and whey proteins from milk have a globular structure and adsorb onto most surfaces (Walstra, 2002). During the formation of emulsions, globular proteins rearrange their configuration to expose the hydrophobic amino acid groups and adsorb to the oil-water interface. The adsorption of protein to the interface will lower the surface tension and upon disruption will lead to the formation of smaller oil droplets. The adsorbed proteins form a protective layer around the oil droplets. These proteins at the interface provide repulsive forces such as steric and electrostatic forces, which stabilise the droplets for long term stability (Bos and van Vliet, 2001; Tcholakova et al., 2006; Wilde et al., 2004). Extrinsic factors (homogenisation, thermal treatment) and intrinsic factors (pH, ionic strength, biopolymers, emulsifiers) affecting emulsion stability will be discussed later in Sections [Extrinsic Factors Affecting Emulsion Stability](#) and [Intrinsic Factors Affecting Emulsion Stability](#) of this chapter.

### Emulsion Destabilisation Mechanisms

Emulsion stability is the ability of the emulsion to remain unchanged in its physical properties over time (McClements, 2007). A protein-stabilised emulsion is a thermodynamically unstable mixture that can undergo destabilisation mechanisms such as flocculation, creaming, sedimentation and coalescence. [Fig. 1](#) shows the common destabilisation mechanisms that occur in food emulsions.

#### Flocculation

Flocculation happens when neighbouring droplets come closer to each other and form colonies in the continuous phase. The aggregation is often not clearly visible and may serve as a precursor to creaming and coalescence. Flocculation could also take place during or after creaming. It may be reversible or not depending on the strength of the intermolecular bond between droplets. However, flocculation may be a desired physical property in some food products such as whipping cream. The occurrence of flocculation could derive from the chemical nature of the emulsifier, phase volume ratio and concentration of electrolytes. The following steps could prevent flocculation from happening.

- 1) To make a uniform droplet size using an appropriate size reduction process.

**Figure 1** Physical changes to the oil droplets in a protein-stabilised emulsion.

- 2) To modify the charge surrounding the droplet so that it will exert repulsive forces with neighbouring droplets.
- 3) To increase the viscosity of the continuous phase and make the globules relatively immobile.

Flocculation is common with protein-stabilised emulsions. One classic example is the feathering of cream in hot coffee. The protein-stabilised oil globules, when exposed to the hot and acidic pH in the coffee, will undergo conformation changes at the interface, thus causing the oil globules to become more attracted to each other (Krog, 2011).

### Creaming

Creaming is an upward movement of dispersed globules in a continuous phase due to the density difference between the two phases. Creaming usually happens in an o/w emulsion due to the upward movement of the relatively lower density oil globules in an aqueous phase. Sometimes the movement of different globule sizes may result in a different colour shade of the emulsion layers. Creaming is a reversible process as the globule does not merge with another globule and the micelle structure created by the emulsifier remains intact. In some instances, a little agitation such as shaking may revert the mixture to a good emulsion. Creaming is different from flocculation as there are no attractive and repulsive forces among the globules.

The creaming rate of an emulsion globule in a dilute o/w emulsion system follows Stoke's law. It describes the movement of a small spherical globule during the creaming process that freely moves without collision and has no physical or chemical attraction. According to Stoke's law, the creaming rate is given by the equation below.

$$v = \frac{d^2(\rho_o - \rho_c) g}{18 \eta}$$

where  $v$  is the creaming rate,  $d$  is the diameter of droplet,  $\rho_o$  is the density of droplet,  $\rho_c$  is the density of continuous phase,  $g$  is the acceleration of gravity, and  $\eta$  is the viscosity of the continuous phase.

From the equation, the three main factors that affect creaming are droplet size, viscosity of continuous phase and the difference in the densities between emulsion droplets and continuous phase. Theoretically, creaming can be reduced by the following actions:

- 1) Reduce the particle size by homogenisation. For example, reducing the diameter of the globule by half will increase creaming stability by a factor of four.
- 2) Increase the viscosity of the continuous phase by adding thickening agents such as xanthan gum or starch.
- 3) Reduce the difference in the densities between the dispersed phase and continuous phase.

### Sedimentation

Sedimentation is the opposite phenomenon of creaming and normally observed in water-in-oil emulsions. Sedimentation happens when the dispersed phase is denser than the continuous phase and the gravitational forces pull the denser globules towards the bottom of the emulsion. Similar to creaming, sedimentation follows Stoke's law.

## Coalescence

Coalescence is a process where the globules merge with each other to form a larger globule. In this irreversible process, the globules come close to each other and cause breakage of the emulsifier film in order to merge. This will normally result in an increased droplet size and reduce the number of globules. Eventually, coalescence will lead to 'breaking' where all of the emulsion film is destroyed and a complete separation of oil and water phases occurs. A similar phenomenon is Ostwald ripening, where large droplets grow at the expense of the small droplets due to mass transport of dispersed phase through the continuous phase. However, it is considered to be negligible in o/w emulsions due to the low solubility of triglycerides in the continuous phase (McClements, 2007). Some of the common factors for coalescence to occur include insufficient amount of emulsifying agent, large globules, and weak repulsion between globules. One preventative action to reinforce the mechanical strength of the interfacial film involves the selection of the right emulsifying agent and the right choice of mixing process, such as high-shear dispersion and high-pressure homogenisation.

## Extrinsic Factors Affecting Emulsion Stability

### Homogenisation

Homogenisation is a process to mix two immiscible liquids so that they can be in the same phase. This will turn one of the liquids into small globules that disperse uniformly in the other liquid. In the milk processing industry, homogenisation is used to reduce oil globules to about 1  $\mu\text{m}$  in diameter and to lower the tendency of creaming and coalescence (Bylund, 2015). Small oil globules are created when milk is forced through a narrow gap at high velocity. Two events happened at that time where oil globule membranes are partially disrupted and milk proteins adsorb at the interface (Lopez, 2005). Atarés et al. (2012) reported that homogenisation reduces the droplet size and size range distribution of o/w emulsions containing sunflower oil and whey proteins. High-pressure homogenisation is more effective in producing smaller droplets compared to mechanical homogenisation (Perrier-Cornet et al., 2005). The type of homogenisation process will determine the droplet size and emulsion stability.

### Heat Treatment

Various heat treatments have been utilized in the dairy industry to destroy any pathogenic microorganisms while retaining the nutritional benefits of protein-stabilised emulsions. The types of milk proteins (casein and whey proteins) in the emulsion experience different effects during heat treatment. Casein is very stable at high temperature (Fox et al., 2015), where there is relatively little aggregation upon heating. Casein-stabilised emulsions do not aggregate at 120–130 °C (Guo et al., 1989), and it has been demonstrated that heated casein has better adsorption at the interface (Liang et al., 2017). In contrast, whey proteins undergo conformational changes such as unfolding, denaturation and aggregation when heated above 65 °C (Croguennec et al., 2004; Jang and Swaisgood, 1990). These conformational changes affect whey protein functionality as emulsifiers. Heat treatment of whey protein-stabilised emulsions resulted in aggregation of oil droplets (Euston et al., 2000), increased viscosity and increased the droplet size (Sliwinski et al., 2003). Whey protein-stabilised emulsions are reported to be highly sensitive to heat treatment (Liang et al., 2013).

## Intrinsic Factors Affecting Emulsion Stability

### pH

In a protein-stabilised emulsion, the proteins adsorb to the interface and form a thin protective membrane around the oil. The emulsions are stable against flocculation due to the strong electrostatic repulsion between the charged droplets (Dickinson, 1997; McClements, 2004; Tangsuphoom and Coupland, 2008). The protein-stabilised emulsions are sensitive to the pH of the emulsion. For example, casein in milk aggregates and flocculates as a non-soluble component near to its isoelectric point around pH 4.6. Flocculation has been observed in emulsions near to their isoelectric point when there is no net interface charge (Rampon et al., 2004; Tangsuphoom and Coupland, 2008). The change in pH leads to the folding and unfolding of proteins, which occurs via an intermediate stage called the molten globule (Matsumura et al., 1994). The molten globule state is the intermediate stage between the native and the completely unfolded state, and characterised by the retained secondary structure and unfolded tertiary structure (Nylander et al., 2008). Some proteins at the molten globule state adsorb at a greater degree to the interface than the native state. For example, the adsorption of  $\alpha$ -lactalbumin to the interface increased with the lowering of pH, where the protein is in the molten globule state (Nylander et al., 2008).

### Ionic Strength

The presence of ions such as  $\text{Na}^+$ ,  $\text{Fe}^{2+}$  and  $\text{Ca}^{2+}$  in the protein-stabilised emulsion can interact with the charged droplets and affect emulsion stability. These ions can bind to the oppositely charged droplets and subsequently reduce the electrostatic repulsion between charged droplets. The ionic strength of the emulsion has a significant effect on flocculation (Das and Kinsella, 1990;

Dickinson, 1997; Tangsuphoom and Coupland, 2008; Tcholakova et al., 2006). Flocculation becomes rapid when ionic strength exceeds a certain limit.

### Biopolymers

Protein-stabilised emulsions usually contain one or more biopolymers (McClements, 2004). Biopolymers are naturally occurring polymers found in living organisms, such as proteins and polysaccharides. Both proteins and polysaccharides are usually used together in the food industry. Polysaccharides interact with protein-stabilised emulsions and influence functional properties such as thickening, gelling and emulsifying (McClements, 2004; Ye, 2008). Biopolymers may interact with the adsorbed protein to behave differently at the same emulsion conditions or during manufacturing processes (Dickinson, 2003). For example, polysaccharides have been shown to reduce droplet aggregation in emulsions with high salt concentrations (Harnsilawat et al., 2006).

### Emulsifiers

Low molecular weight emulsifiers or surfactants interact with proteins at the interface that can alter emulsion stability. Emulsifiers can be categorised according to their ability to dissolve in water or oil. Examples of common oil-soluble emulsifiers are lecithin and mono- and diglycerides, while polysorbates are water-soluble emulsifiers. Alternatively, emulsifiers can be grouped according to their head group, either non-ionic (no charge) or ionic (anionic or cationic). For examples, mono- and diglycerides have no charge while sodium stearyl lactylate has a charged head.

Emulsifiers can quickly adsorb to the interface and lower the interfacial tension to a greater extent than proteins (Bos and van Vliet, 2001). It is well known that emulsifiers compete with proteins at the interface and can displace protein from the interface, which may cause emulsion destabilisation (Dickinson, 1997). One aspect of protein displacement is the ability of ionic emulsifiers to bind with protein, which alter heat stability of proteins and adsorption strength to the interface (Nylander et al., 2008). Dodecyl trimethyl ammonium bromide, being a cationic emulsifier, binds to the proteins to promote protein unfolding and aggregation, which results in emulsion destabilisation (Kelley and McClements, 2003b). Anionic emulsifiers such as sodium dodecyl sulfate improve thermal stability of emulsions by enhancing the electrostatic repulsion between droplets and increasing the denaturation temperature of the adsorbed protein (Kelley and McClements, 2003a). Anionic emulsifiers can act synergistically with protein to improve emulsion stability, particularly creaming (Dickinson and Ritzoulis, 2000).

Another factor affecting protein displacement is the solubility of emulsifiers in water or oil and their concentrations in the emulsion (Nylander et al., 2008). Water-soluble polysorbates displace protein to a greater extent than oil-soluble mono- and diglycerides (Euston et al., 1995). Oil-soluble emulsifiers such as mono- and diglycerides and sorbitan esters at low concentration do not displace protein (Dickinson and Hong, 1994), thus enhance the robustness of emulsion droplets against destabilisation. The knowledge on protein displacement is important to food technologists in order to select the right types of emulsifiers when formulating emulsions.

### Effects of Mono- and Diglycerides on Physicochemical Properties and Emulsion Stability

Mono- and diglycerides are a mixture of mono-, di- and triglycerides together with a small amount of glycerol and fatty acids. Mono- and diglycerides are oil-soluble emulsifiers derived from the hydrolysis of oils and fats and found in many food products. Mono- and diglycerides can alter the physicochemical properties and emulsion stability of a protein-stabilised emulsion (McClements, 2004).

Mono- and diglycerides are more surface active than proteins, and thus spread rapidly at the interface and lower the interfacial tension (Fredrick et al., 2013). At low concentrations of mono- and diglycerides, protein adsorbed at the interface is high (Dickinson and Hong, 1994; Euston and Hirst, 2000). At this stage, mono- and diglycerides fill between the small gaps at the interface without displacing protein (Euston and Hirst, 2000; Munk et al., 2014). However, a higher protein displacement is seen when increasing the shear or lowering the temperature of the emulsions containing mono- and diglycerides (Carrera Sánchez and Rodríguez Patino, 2004; Davies et al., 2001; Dickinson and Tanai, 1992).

Creaming is the most common emulsion destabilisation mechanism amongst dairy-based emulsions. According to Stoke's Law, large droplets have a faster rate of creaming compared to smaller ones and are more likely to separate due to gravity (McClements, 2007). Mono- and diglycerides can effectively reduce droplet size and size range distribution of protein-stabilised emulsions (Dickinson and Hong, 1994; Krog, 2011; Liang et al., 2016; Matsumiya et al., 2010). Thus, reducing the number of large globules should delay the occurrence of creaming. Recent studies of protein-stabilised emulsions by our group found that unsaturated mono- and diglycerides reduce droplet size range distribution and enhance creaming stability to a greater extent than saturated mono- and diglycerides (Loi et al., 2018).

## Conclusions

The separation of oil and water phases in the emulsions over time have been observed in many foods and the common mechanisms of emulsion destabilisation are flocculation, creaming, sedimentation and coalescence. Simple model emulsions have been used to understand destabilisation mechanisms and the factors affecting destabilisation. Intrinsic and extrinsic factors can influence the physicochemical and emulsion stability of model emulsions. However, the complex interactions in food emulsions often makes it difficult to predict physicochemical properties and stability of emulsions. Studies on the complex interaction between biopolymers and emulsifiers will advance our understanding on stability and shelf life of food emulsions.

OLL Oleoyl-dilinoleoyl-glycerol

LnLP linolenoyl-linoleoyl-palmitoylglycerol.

## Introduction

Due to the economic importance of edible oils, it is imperative to develop and improve methods to verify authenticity, detect adulteration and define the composition and purity of blends (Ashurst and Dennis, 1996). Edible seed oils are predominantly made up of triacylglycerols (TAG) that usually follow a typical pattern in the glycerol molecule but have unique characteristics in each of the different oilseeds. The advantage of analysing the fatty acid positional profile in TAGs, compared to just the fatty acid profiles alone, is that the distribution of fatty acids on the glycerol backbone is stereo-specific. This fatty acid distribution is genetically modulated and consequently determination of the fatty acid positional profile in TAGs is of value (Aparicio and Aparicio-Ruiz, 2000).

The TAG compositional data is a valuable indicator that provides the quantitative assessment of the quality and purity of seed oils. The high specificity and precision of the TAG compositional information that can be obtained for different kinds of oils have enabled the food industry and researchers to more precisely confirm authenticity and adulteration of oils. Several techniques have been developed to analyse the TAG compositions in seed oils. This chapter briefly reviews the use of HPLC in the determination of intact TAGs and quality assessment in edible seed oil, with particular emphasis on oil products extracted by means of cold pressing.

## Cold Pressed Seed Oils

Cold pressed oils are obtained from fruit or seeds either by mechanical processes such as traditional grinding using granite mill-stones or by pressing using modern stainless-steel presses commonly found in large commercial operations. Pressing and grinding processes produce heat through friction and for oil extraction the temperature must not rise above 120°F (49 °C) for any oil to be considered cold pressed. The main advantage of cold pressed oils is that the low processing temperature during oil extraction retains the bioactivity of phenolics and essential fatty acids naturally present in the extracted oil (Teh and Birch, 2013). In addition, cold pressing retains more of the flavour, aroma and nutritional value in the extracted oil, producing a product that has minimal chemical contamination and modification (Parker et al., 2003) since no solvents are used in the extraction process. Whilst such an oil extraction process has desirable features, the main disadvantage is that the oil extraction yield from the seed is lower compared to other extraction processes that use organic solvents. Studies were carried out on cold pressing lemon seed resulted in a lower oil yield (36.84%) compared to 71.29% for solvent extraction (Yilmaz and Güneşer, 2017).

## Importance of Analysing and Characterising Intact Triacylglycerols in Seed Oils

Edible cold pressed seed oils have attracted a lot of interest due to the health benefits associated with retained bioactive compounds in the oil. The retention of essential fatty acids such as  $\alpha$ -linolenic acid (18:3n-3), vitamin E and other important oil characteristics including improved oxidative stability, has created an awareness in the industry of the value of characterising and profiling the positional fatty acid profile in the TAG components of the cold pressed seed oils (Parry et al., 2005). Most of the recent research has focused on determination of the lipid composition of cold pressed seed oils with an emphasis on quality assurance to address purported adulteration of cold pressed oils. As consumers are willing to pay a premium for quality assured cold pressed seed

oil, validation is imperative. Many of the reported studies have focused on examining the triacylglycerol profiles of closely related oils to obtain detailed compositional information. This can provide information on the raw materials used, the processing conditions, and can provide a means of quality control of purity and whether the oils have been blended (Jakab et al., 2002). The characterization of several seed oils has been reported, including oil extracts from grape (Bail et al., 2008), canola, hemp and flax seeds (Mungure and Birch, 2014).

As the distribution of TAG composition affects the physicochemical and oxidative stability of oils, this information is useful to enable development of appropriate handling and processing methods to ensure oil quality is retained. Nederal et al. (2012) showed that TAGs comprised mainly of linoleic acid at all three glycerol esterification positions (LLL) in pumpkin seed oil had less oxidative stability compared to the TAGs comprised of a mixture of trioleic acid (OOO), and those with some TGAs substituted with other fatty acids (SOO and LOO) are easier to abstract a hydrogen atom from and to initiate oxidative processes due to the linoleic acid being more unsaturated.

Validation of the origin of seed oil is increasingly a priority due to the possibility of substitution of oils obtained from alternative sources. Amaranth seed has been reported to be an ethical and healthy alternative source of edible seed oil that also contains squalene (2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene), an expensive terpenoid compound. Amaranth seed oil is now increasingly used as an ethical source instead of oils containing squalene that have been more traditionally sourced from whale (*Physeter microcephalus*), shark liver (*Cantrophorus squamosus*) and fish skin (Jahaniaval et al., 2000). The composition of TAGs has also been analysed to determine the differences in similar species grown in different geographic and climatic conditions. A study by Jahaniaval et al. (2000) showed that various Amaranth accessions displayed genetic variation and showed sizeable differences in the fatty acid profiles of TAGs.

A variety of techniques have been applied to analyse TAGs in oil samples, including MALDI-TOF MS/MS (Zollner et al., 1997; Bail et al., 2008), LC-MS/MS, thin layer chromatography (TLC), high temperature gas-liquid chromatography (HT-GLC) and silver ion-reversed phase HPLC (Ag-RP-HPLC) (Carelli and Cert, 1993). The following section reviews different HPLC techniques that have been used to characterise triacylglycerol fatty acid compositions in selected seed oils.

## Methods of Analysing Triacylglycerols Using Reversed Phase-HPLC

Many of the methods have been developed as a result of the need to achieve quality assurance in the virgin olive oil processing industry. Typically, TAGs have been analysed by HPLC using a reversed phase C-18 column, with acetone/acetonitrile as the mobile phase. HPLC triacylglycerol determination methods have been applied in analysing seed oils. The European commission has adopted an official method for the determination of TAG compositions (Butinar et al., 2010; de la Mata-Espinosa et al., 2011). This method involves a stereospecific analysis of TAGs and is commonly known as  $\Delta$ ECN42. The ECN number is the number of carbon atoms (excluding the carbons on the glycerol) less the doubled sum of the number of double bonds in a TAG (Jabeur et al., 2014). This is summarised in Eq. (1) below:

$$\text{ECN} = \text{CN} - 2n \quad (1)$$

where CN is the carbon number and n is the number of double bonds per TAG present in the attached 3 fatty acids, but not including the carbons in the glycerol (Piravi-Vanak et al., 2009). Several different detection systems have been used in HPLC separation of TAGs. Although ultra-violet/visible spectroscopy and refractive index (RID) have been the most commonly used detection systems, evaporative light scattering display (ELSD) and more recently charged aerosol detector (CAD) systems have been used (de la Mata-Espinosa et al., 2011). The different analytical techniques are discussed in detail below.

### HPLC-ELSD

The principle of ELSD is to nebulize or spray the mobile phase effluent in a stream of nitrogen gas forming a dispersion of droplets. The mobile phase is evaporated leaving a fine mist of dried particles, and the light scattered by the particles is recorded and an electrical signal is generated. Nederal et al. (2012) used HPLC-ELSD to analyse/compare the TAG composition and the oxidative stability of pumpkin seed oils extracted following roasting or by cold pressing the seed. The TAGs in these oil extracts were identified using known TAG standards and unknowns were determined using the ECN number system explained above, and up to 13 TAGs were identified. The results obtained showed that cold pressing de-husked pumpkin seed produced higher yields of TAG with OLL fatty acid profile compared with cold pressing the complete seeds. The saturated fatty acids namely stearic and palmitic were shown to have a preference of *sn*-1, -3 positions compared to the unsaturated fatty acids taking *sn*-2 position (Nederal et al., 2012).

### HPLC-CAD

HPLC-CAD has been reported to provide significant advantages of increased sensitivity and shorter analysis time compared with current protocols officially adopted by the European Commission for TAG identification in virgin olive oil (de la Mata-Espinosa et al., 2011).

With HPLC-CAD, TAG identification is commonly done using known standards. [de la Mata-Espinosa et al. \(2011\)](#) applied two different approaches with the first one adding the TAG standards into a test sample solution and secondly by comparing the retention times for the TAG from a standard solution with the sample solution. After the identification, the chromatograms were verified by comparison to official results published by the International Olive Council (IOC). HPLC-CAD provided the same results with 13 major TAGs identified as reported with the IOC protocol. HPLC-CAD offered better sensitivity and detection of lower abundance TAGs.

### HPLC-ESI-MS

[Mungure and Birch \(2014\)](#) used HPLC coupled with ESI-MS to characterise cold pressed canola, flax, and hemp seed oil. TAGs were separated by HPLC and the detection was carried out using a diode array detector at wavelengths of 215 nm (flax and canola) and 205 nm (hemp). Collected intact TAGs were introduced by direct infusion onto the electrospray ionisation (ESI) source of a mass spectrometer set to positive ion mode with a high collision energy of up to 10 eV. Eight TAGs were detected for cold pressed hemp at wavelength  $\lambda = 215$  nm. Seven TAGs were detected at  $\lambda = 205$  nm in cold pressed flax and canola oils. The TAG fractions obtained from HPLC were subjected to ESI-MS. The results obtained are summarised in [Table 1](#), in terms of elution order characterised according to partition number/ECN number, and TAG abundances. It is interesting to note that all three cold pressed seed oils had the highest TAG abundance with highest fatty acid content. For instance, flax was reported to have linolenic acid as the most abundant fatty acid (Ln = 58.8%) and the TAG with the highest abundance was LnLnLn. The results reported for flax by [Mungure and Birch \(2014\)](#) were in agreement with that reported by [Choo et al. \(2009\)](#). A representative chromatogram of cold pressed hemp seed oil is presented in [Fig. 1](#), for which HPLC fractions of the TAGs were collected prior to ESI-MS.

Cold pressed canola oils presented a different pattern compared to the other two oils, with the most abundant TAG being OOLn, with LLL and LnLP co-eluting and the two constituted up to a fifth in total abundance.

### HPLC-RID

This method involves detection by refractive index and is one of the most widely used detection methods. It has been used for assessing genuineness of selected Slovenian cold pressed pumpkin seed oils ([Butinar et al., 2010](#)). The pumpkin seed oil was subjected to RP-HPLC using propionitrile as the mobile phase eluant and fractions containing TAGs were collected and then identified using TAG standards derived from olive oil reference TAGs. The use of propionitrile and column temperature control were reported to provide more accurate and repeatable data with improved baseline stability ([Butinar et al., 2010](#)). A total of 29 TAGs were identified in this study which is considerably greater than that reported in previous investigations by [Jakab et al. \(2002\)](#) and ([Andrikopoulos et al., 2001](#)) who identified only 12 TAGs. This method demonstrated that coupling stereospecific analyses with other chemical determinations (i.e. fatty acid profiles using GC) could be useful in evaluating the authenticity of the cold pressed seed oils.

## Conclusion

Most of the current work on the evaluation of edible cold pressed oil adulteration is based on high-performance liquid chromatography analysis. Improvements in the detection of TAGs eluted from HPLC such as using CAD, have provided increased precision and have achieved excellent recoveries of compounds compared to earlier HPLC configurations. In some cases, a combination of HPLC and chemometrics has enhanced the correlation of obtained compositional data with accredited reference quality parameters in the cold pressed oil product. By comparing the relative proportions of TAGs, in addition to the positional identification of fatty acids on individual TAGs, is collectively becoming an important measure of characterisation and quality assessment.

**Table 1** Summary of the most abundant TAGs present in various cold pressed seed oils

Cold pressed seed oil	Detection system	Number of TAGs identified	Most abundant TAG	References
Canola	ESI-MS	7	OOLn	<a href="#">Mungure and Birch, 2014</a>
Flax	ESI-MS	7	LnLnLn	<a href="#">Mungure and Birch, 2014</a>
Hemp	ESI-MS	8	LLL	<a href="#">Mungure and Birch, 2014</a>
Pumpkin seed oil Northern Slovenia (Stajersko prekmursho bučno olje)	RID*	29	OLL	<a href="#">Butinar et al., 2010</a>

## Glossary

OSs Oligosaccharides

XOSs Xylooligosaccharides

GOSs Galactooligosaccharides

IMOSs Isomaltooligosaccharides

## Introduction

Oligosaccharides (OSs) are carbohydrates with low molecular weight showing considerable variety in terms of sugar composition and degree of polymerization (DP). These compounds are naturally found in foods, in mixtures containing the parental polysaccharides, as well as monosaccharides. Due to the biological activities presented by the different OSs, there is a growing demand for the industrial production of these compounds. Some non-digestible OSs, such as fructooligosaccharides, galactooligosaccharides and xylooligosaccharides, are considered efficient functional foods because they can selectively stimulate the growth and/or activity of benefic bacteria. Such effects are involved with many positive aspects in relation to human health, including lower risks of intestinal infections and prevention of some types of cancer (Rastall, 2010; Rajendran et al., 2017).

The contemporary demand of green technologies has increased the use of enzymatic process at industrial level. The use of enzyme as biocatalysts offers benefits such as mild reaction conditions, biodegradability and specificity. In this context, OSs production, specially through the enzymatic route, has received major attention; and examples of target enzymes are fructosyltransferases, xylanases and  $\beta$ -galactosidases, among others, as presented in Chapter XX. The severe conditions of industrial processes however can result in enzyme destabilization, shortening their industrial lifespan. Immobilization, in turn, is an effective alternative to circumvent these concerns by enhancing enzyme properties, simplifying downstream processing and improving operational stability of biocatalysts (Mohamad et al., 2015). Due to the advantages of using immobilized enzymes, we included this chapter reviewing recent data dealing with different techniques used for the immobilization of different microbial enzymes involved in OSs production.

## Immobilization of Xylanolytic Enzymes for Xylooligosaccharides Production

Xylooligosaccharides (XOSs) are the only nutraceutical that can be obtained from lignocellulosic biomass which can be generally considered a low-cost and abundantly available raw material. Immobilization of enzymes acting on the components of plant cell walls, remarkably xylanases, which are responsible for hemicellulose degradation has been previously reviewed (Terrasan et al., 2015). From 2015, new studies dealing with immobilization of microbial xylanases for XOSs production have arisen and their respective data are summarized in Table 1. Most of them deals with xylanolytic enzymes of bacterial origin, such as those from mesophilic *Bacillus subtilis* (Milessi et al., 2016), *Paenibacillus* sp (Young Kyu Hwang, 2015) or from extremophilic strains such as *Selenomonas ruminantium* (Terrasan et al., 2016), and *Geobacillus thermodenitrificans* JK1 (Kieraitė et al., 2015). Yet, some other studies deal with fungal xylanases or microbial enzymes present in commercial mixtures/cocktails (Bagewadi et al., 2016; de Oliveira et al., 2018a; de Oliveira et al., 2018b; Zhang et al., 2016).

Among these several studies evaluating different techniques for xylanase immobilization on diverse supports, a high stabilization degree was achieved by covalently immobilizing the xylanase (XynA) produced by *Bacillus subtilis*. This enzyme was 75- and 8600-fold thermo-stabilized after immobilization on glyoxal-chitosan and glyoxal-agarose supports, respectively. Furthermore, it was observed that when applied for substrate hydrolysis, the agarose-glyoxal derivative released xylobiose, xylotriose and xylotetraose from both soluble and conventional birchwood xylan, in a process that reached 20% of substrate conversion up to ten cycles of substrate hydrolysis (Milessi et al., 2016). In another study, a bifunctional enzyme with xylanase and cellulase activity was constructed and successfully immobilized by covalent bonds on carbon-coated chitosan nanoparticles. Immobilization improved thermal and storage stability, and the derivative was able to release XOSs from purified oat spelt, birchwood and beechwood xylans, as well as from wheat bran insoluble xylan and wheat bran. Xylooligosaccharides with chain-length in the range 2–6 were the main products released from wheat hydrolysis (Liu et al., 2015). Purohit et al. (2017) developed a magnetic cross-linked enzyme aggregate (CLEA) using a xylanase isolated from the bacterium *Acinetobacter pittii* MASK 25. After optimizing conditions for enzyme-glutaraldehyde crosslinking with magnetic nanoparticles, the aggregate was applied for hydrolysis of physically pretreated rice straw and corn cobs. Similar to the

DP: degree of polymerization, CLEA: crosslinked enzyme aggregate; X2: xylobiose; X3: xylotriase.

verified with the crude xylanase, the magnetic aggregate predominantly produced xylopentaose and xylohexaose from both biomasses, nevertheless, the aggregate-mediated hydrolysis presented 15%-higher xylan conversion of both biomass into XOSs.

In addition,  $\beta$ -xylosidases such as that from *Talaromyces thermophilus* covalently immobilized on chitosan, when catalyzing reverse hydrolysis reaction, synthesized xylooligosaccharides with DP from 2 to 4 in the presence of high xylose concentration (40%, w/v), a reaction which was not performed by the free enzyme. This characteristic was attributed to the immobilization process wherein a hydrophobic microenvironment was created at the active site, favoring synthesis activity (Guerfali et al., 2009).

### Immobilization of $\beta$ -galactosidases for Galacto-Oligosaccharides Production

Most of immobilized  $\beta$ -galactosidase for galactooligosaccharides (GOSs) synthesis were from fungal origin specially from filamentous *Aspergillus* spp. or yeasts *Kluyveromyces* spp (Table 2). Among many different approaches evaluated for  $\beta$ -galactosidase immobilization, the  $\beta$ -galactosidase gene (bgaL3) from *Lactobacillus bulgaricus* L3 was fused with a cellulose binding domain (CBD) and expressed in *Escherichia coli*. The fusion protein could be directly adsorbed onto microcrystalline cellulose with 61% immobilization efficiency. The enzymatic and transglycosylation characteristics of the immobilized enzyme were similar to those from the free form. By using the immobilized catalyst, the yield of galactooligosaccharides (GOSs) reached 49% (w/w) from 400 g/L initial lactose at pH 7.6, 45 °C for 75 min, with productivity of 156.8 g/L/h. A reusability assay demonstrated the immobilized derivative retained over 85% of activity after 20 batches with GOSs yield above 40% (Lu et al., 2012).

In addition, the use of lactulose (4-O- $\beta$ -D-galactopyranosyl-D-fructose) instead of lactose as precursor of novel GOSs was evaluated (Cardelle-Cobas et al., 2016) due to the well-recognized prebiotic properties of lactulose (Olano and Corzo, 2009), and therefore GOSs produced from transglycosylation of lactulose might have higher added value when compared to conventional GOSs. On this regard, the  $\beta$ -galactosidase from *Aspergillus oryzae* was successfully immobilized on glutaraldehyde-agarose. After process optimization, it was verified that immobilization increased thermal stability, allowed the enzyme reuse by many operational cycles and, hence, the yield of OsLu (oligosaccharides from lactulose). Furthermore, it was observed that some reaction conditions, specially in relation to pH conditions, affected the selectivity of the enzyme (Cardelle-Cobas et al., 2016).

### Isomaltooligosaccharides (IMOSs) Production

IMOSs consist of  $\alpha$ -D-glucose residues that are linked by  $\alpha$ -(1–6) glycosidic bonds with a DP from 2 to 6 and can be obtained through three main enzymatic processes: a) transfer of glucosyl residue from sucrose to acceptors such as glucose, fructose, maltose and isomaltose catalyzed by dextranucrase, b) digestion of highly linear dextran with dextranase, or c) conversion of sucrose involving both dextranucrase and dextranase (Kubik et al., 2004; Wu et al., 2017). Individual and/or concomitant immobilization/application of these enzymes present some peculiarities, as presented below and in Table 3.

#### Immobilization of dextran(glucan)sucrase

Dextranucleases (EC 2.4.1.5) traditionally obtained from Gram-positive bacteria *Leuconostoc* spp. are enzymes that perform the transfer of the glucosyl moiety of sucrose forming dextran and that can also catalyze acceptor reactions by transferring glucosyl residues from sucrose to other carbohydrate acceptors, producing oligosaccharides with  $\alpha$ -(1–6)-glucosyl linkages. Studies dealing with dextranucrase immobilization, however, have not been successful with respect to yield and stability. The reasons are that the dextran associated with the enzyme can mask the reactive groups of the enzyme or the presence of residues such as lysine, cysteine, aspartic and glutamic acids at the active site, which can react with aldehyde and epoxy groups leading to enzyme inactivation, in the case of covalent immobilization (Ölçer and Tanrıseven, 2010; Parlak et al., 2013).

Despite its disadvantages such as physical instability and undesired influence of several anions, encapsulation of dextranucleases in alginate is the most common immobilization method since it usually renders high process yields. In this respect, the *Leuconostoc* sp dextranucrase in the native form and after crosslinking with glutaraldehyde was entrapped in alginate beads and then coated with a film of chitosan. The immobilization process presented similar yield when different concentrations of glutaraldehyde were evaluated and in presence or absence of a chitosan coating. The preparations of native dextranucrase entrapped in alginate beads were less stable and rendered a lower degree of sucrose conversion what was attributed to enzyme leakage from the support. High operational stability was observed for all preparations which contained the crosslinked enzyme and the best results were achieved with 10% glutaraldehyde crosslinking. In the first cycle of sucrose conversion it was obtained 90% yield, and it dropped to 60%–70% from the sixth batch. The final products mixtures contained 55%–60% isomaltose, 20% glucose, as well as isomaltotriose and tetraose at 10%–15% (Kubik et al., 2004). By using a bio-engineering approach, Parlak et al. (2013) designed a novel dextranucrase that could be successfully immobilized by covalent linkages on Eupergit C 250L, with 100% immobilization and 83.3% activity yields. The problems commonly associated to covalent immobilization of dextranucleases were solved by eliminating of the enzyme and by fusing a glutathione S-transferase to the dextranucrase, what allowed reaction with epoxy groups from the support. Optimal activity conditions were not affected and thermal stability was increased by immobilization. Immobilized enzyme was quite active performing dextran biosynthesis and acceptor reactions effectively. In fact, the novel enzyme formed more acceptor products than the native enzyme. Furthermore, the

DP - degree of polymerization; IMOSs - isomaltooligosaccharides.

immobilized enzyme showed no decrease in activity over 15 batch reactions and retained its initial activity for 35 days at 4 °C storage.

### Immobilization of Dextranases

Dextranases (EC 3.2.1.11), usually obtained from filamentous *Penicillium* spp. belong to a group of hydrolytic enzymes that specifically hydrolyze (1–6) linkages in dextrans producing IMOSs. These enzymes have been immobilized using different methods including physical adsorption, covalent binding, ionic binding and entrapment (Table 3). Recently, the dextranase from *Penicillium lilacinum* was covalently immobilized on Eupergit C, and the derivative presented much higher stability both at low and high pH, and also under high temperatures. Furthermore, no decrease in activity was verified even after 20 batch reactions for IMOSs production (Aslan and Tanriseven, 2007). Immobilization of the dextranase from *Aspergillus penicillioides* NRC 39 was evaluated by using different carriers and various techniques rendering an immobilization process with high yield when using covalent binding using 2% glutaraldehyde and prawn shell as support (El-Shamy and Atalla, 2014). In another case, a commercial dextranase from *Penicillium* sp (Sigma) was covalently immobilized on epoxy-activated macroporous monolithic support and applied to continuous operation reactor producing IMOSs with DP 8–10 from dextran. The IMOSs were generated all over the hydrolysis process and a residual enzymatic activity about 78% was verified after 5400 vol column (Bertrand et al., 2014).

### Co-immobilization of Dextranase and Dextran(glucan)sucrase

Considering dextran is a product of sucrose conversion, the hydrolysis of this polysaccharide by dextranases generates about 20% of unwanted branched oligomers. Therefore, for enzymatic synthesis, in addition to dextranase, the presence of a soluble or immobilized dextranase for the conversion of sucrose to dextran would be ideal (Table 3). In this case, dextranase and dextranase can be easily combined to produce these oligosaccharides from sucrose, mainly because of their similar optimum pH (Erhardt et al., 2008). Furthermore, from kinetic and economic points of view, it is more advantageous the use co-immobilized derivatives allowing simultaneous activity of dextranase and dextranase. In addition, co-immobilized derivatives can be applied not only to reduce reaction time, but also as an efficient approach to achieve higher product yields. In this sense, some studies have evaluated the co-immobilization of these enzymes and the application for IMOSs production.

In order to obtain a more sustainable process, sucrose instead of dextran has been used in a process which combines the use of dextranase for the conversion of sucrose into dextran and dextranases for the dextran decomposition. In this regard (Erhardt et al., 2008), created a biocatalyst from the co-immobilization of commercial dextranase pre-adsorbed onto bentonite and soluble dextranase which rendered high yields during IMOSs production. The dextranase from *Leuconostoc mesenteroides* and the dextranase from *P. lilacinum* were co-immobilized by encapsulating the dextranase and covalently attaching the dextranase to Eupergit C in alginate in presence of soluble starch, resulting in high immobilization yield and activity retention during 20 batch reactions producing isomaltooligosaccharides from sucrose and one month storage at 4 °C. In addition, the amount of produced oligosaccharides was increased after sucrose addition due to the co-immobilized dextranase (Ölçer and Tanriseven, 2010).

### Immobilization of $\beta$ -glucosidases for Glucooligosaccharides (GLOs) Production

GLOs can be produced by vegetable  $\beta$ -glucosidases which are usually extracted from almond (*Prunus dulcis* var. *amara*) and perform reverse hydrolysis and transglycosylation reactions. In this respect, a  $\beta$ -glucosidase from almond was immobilized on polyamine microspheres by cross-linking with glutaraldehyde for synthesis of octyl glucoside (OG) from glucose and octanol through reverse hydrolysis. Immobilization increased enzyme activity at pH 6.0–7.0 and optimal temperature was identical for both enzyme forms; however, both thermal stability and solvent tolerance were increased after immobilization. In a co-solvent system using *t*-butyl alcohol and water, the OG yield was increased by 1.7-fold compared to that from a system without co-solvent. Besides, initial reaction velocity was increased by three-fold after immobilization and OG synthesis was inhibited by surplus glucose. When OG synthesis was performed for 336 h in a fed-batch reaction to minimize inhibition by substrate, OG yield and glucose conversion rate reached 134 mM and 59.6%, respectively. Finally, when compared to the batch operation, fed-bath increased OG yield and glucose conversion rate by 340% and 381%, respectively (Wang et al., 2017).

### Other Oligosaccharides

#### Fructooligosaccharides (FOSs)

FOSs can be produced by the action of enzymes with transfructosylating activity either fructosyltransferase (EC 2.4.1.9) or  $\beta$ -fructofuranosidase (EC 3.2.1.26) derived from plants or microorganisms, mostly filamentous fungi such as *Aspergillus* sp. *Aureobasidium* sp. *Penicillium* sp. and *Fusarium* sp (Ganaie et al., 2014a). FOS production can be evaluated by using commercial fructofuranosidase and fructosyltransferase covalently immobilized on chitosan using glutaraldehyde (Lorenzoni et al., 2015), but it is more usually

performed by using immobilized cell systems which avoids laborious enzyme extraction and purification techniques. To accomplish cell immobilization system, entrapment of cells within porous matrices such as calcium alginate or chitosan gel beads are commonly evaluated approaches (Huang et al., 2016; Ganaie et al., 2014b). (Lorenzoni et al., 2015) operating two packed bed reactors (PBR) and two fluidized bed reactors (FBR) found FOS production achieved a 59% yield in the PBR and 54% in the FBR. They also observed that varying the flow rate it was possible to modulate the FOS composition and the operational stability in the PBR was evaluated for 40 days with no reductions in yields.

### Inulo-Oligosaccharides (IOSs)

The commercial *endo*-inulinase (EC 3.2.1.7) from *Aspergillus niger* (Megazyme) was covalently immobilized on glutaraldehyde-activated chitosan and the immobilized preparation was more stable at high temperature than the free enzyme, allowing continuous operation at 60 °C for prolonged periods. The biocatalyst presented prolonged storage stability at 4 °C and successfully produced IOSs from inulin and Jerusalem artichoke juice with DP 7–4 and the system produced higher IOSs content (from 35% to 65%) when operating continuously (Nguyen et al., 2011).

### Chitosan-Oligosaccharides

The chitosanase (EC 3.2.1.132) from *Bacillus pumilus* BN-262 an *endo*-type enzyme which produces dimeric and trimeric oligosaccharides from chitosan was immobilized by entrapment on agar-coated disks giving rise to a reactor with agar gel-coated multidisc impeller. The reactor was applied for repeated hydrolysis of chitosan using the immobilized enzyme, and the target products were obtained at high concentrations without activity loss of the immobilized biocatalyst (Ming et al., 2006).

### Mano-Oligosaccharides

The mannanase (EC 3.2.1.78) from *Penicillium occitanis* Pol6 was immobilized on chitin by cross-linking with glutaraldehyde. The immobilized enzyme exhibited improved thermal and pH stability in relation to its free counterpart. The immobilized biocatalyst also exhibited long-term storage stability retaining 70% of activity after 120 days. The main hydrolysis products yielded from locust bean gum were mannotriose and mannotetraose, which could be used as nutrient for lactic bacteria (Blibech et al., 2011).

### Future Perspectives

In this chapter, we reviewed recent data regarding immobilization of enzymes associated to the production of oligosaccharides with special focus on xylo-, galacto-, isomalto- and gluco-oligosaccharides production. Immobilization not only turn soluble enzymes into heterogeneous catalysts, instead it can also improve enzyme properties such as activity, specificity and stability under different conditions. Advances in immobilization science include developments of new matrices and the establishment of new and practical protocols, that can also take in consideration the absence of a support, the case of crosslinked aggregates (CLEAs). However, there is a gap in relation to studies evaluating the application of immobilized biocatalysts at larger scale. In addition, molecular biology tools to modify or create enzyme properties can improve or even allow the immobilization of a protein in certain support, as demonstrated in this chapter for the  $\beta$ -galactosidase harboring a cellulose binding domain for immobilization on cellulose; or the dextranucrase truncated at glucan binding regions to remove associated dextran and also containing amino acids that interact with reactive groups from the support, thus allowing immobilization of these enzymes; yet, even new catalytic activities can be added to an enzyme, as demonstrated with chimeric bifunctional enzyme with xylanase and cellulase activities.

### Glossary

**Complex coacervation** when oppositely charged macromolecules in solution are mixed, liquid–liquid phase separation can occur. The macromolecular complexes are concentrated in one liquid phase while the other liquid phase is depleted of the macromolecular complexes

**$\beta$ Lg**  $\beta$ -lactoglobulin

**DM** degree of methyl esterification (of pectins). The percentage of carboxylic acids that are esterified

**DP** degree of polymerisation

**ITC** isothermal titration calorimetry (the stepwise measurement of the heat of reaction produced by the interaction of molecules)

**SANS** small angle neutron scattering (used to study the size and shape of macromolecular complexes). Labelling a macromolecule with deuterium (e.g. protein) allows you to “see” it in a complex with unlabelled macromolecule (e.g. a polysaccharide)

**SAXS** small angle x-ray scattering (used to determine the size and shape of small particles)

**Self-assembly** a process by which individual molecules form defined molecular assemblies such as aggregates or clusters

**Self-organisation** a process by which the self-assembled aggregates or clusters create higher-ordered structures or networks

### Introduction

Why are people interested in the interaction of  $\beta$ -lactoglobulin and pectins? Because it is a good model for studying the protein-polysaccharide interactions found in a soft matter such as food (Schmitt and Turgeon, 2011; Aryee and Nickerson, 2014). Protein-polysaccharide interactions have been widely investigated in food emulsions (Augustin and Hemar, 2009; Damianou and Kiosseoglou, 2006), encapsulation of bioactives (Ron et al., 2010; Hosseini et al., 2015; Chen et al., 2016), gels (Laneville et al., 2006), foams (Ganzevles et al., 2006; Ganzevles et al., 2007) and as scaffolds for delivery of nutraceuticals and drugs (Xu et al., 2017b). An understanding of how such interactions occur can lead to better control of structure and texture of manufactured foods and more effective delivery of bioactive compounds to the target region of the human gut.

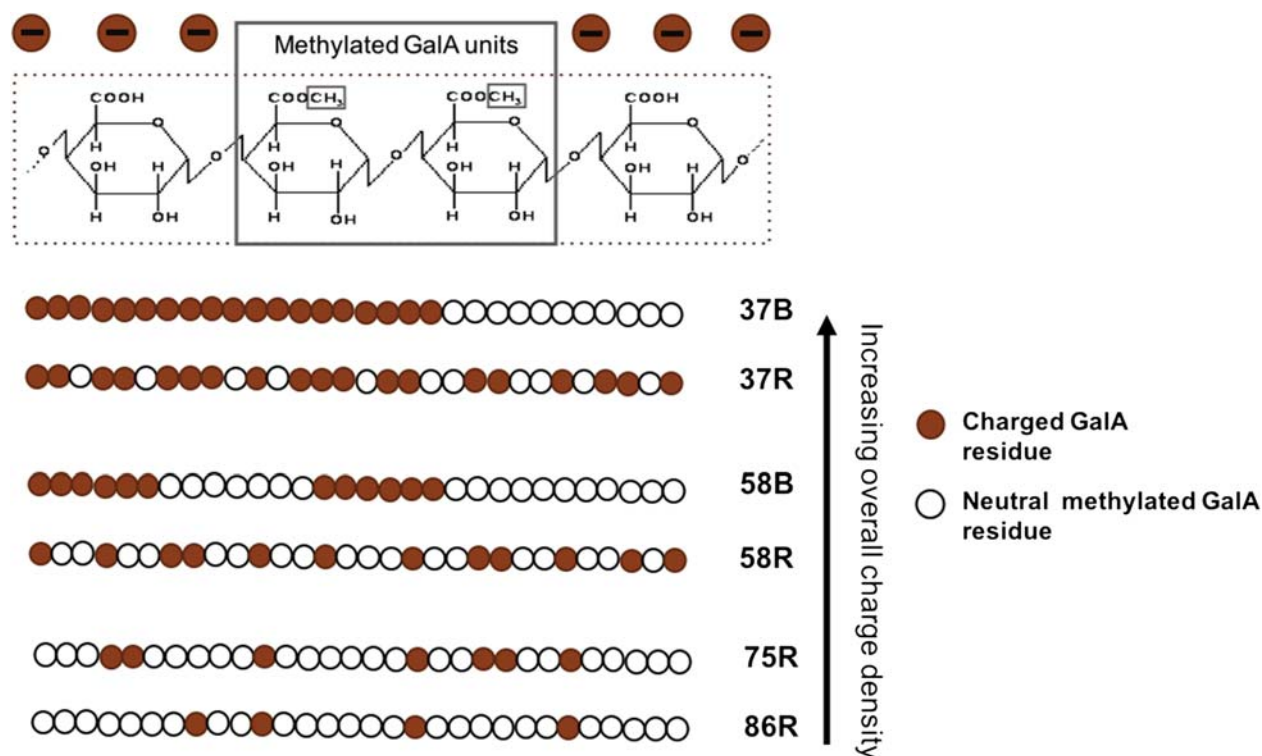

$\beta$ -Lactoglobulin ( $\beta$ Lg) is found in the milk of almost all mammals; humans being an exception. It is the most abundant protein in the whey from cow's milk from which it is isolated. It is a small globe-shaped protein comprising 162 amino acids with a mass of 18.4 kDa and an isoelectric point of pH 5.4 (Edwards et al., 2009). At the isoelectric point the overall charge is zero, while at pH less than 5.4 it will be positively charged and at pH greater than 5.4 it will be negatively charged. It is very robust, for example it passes through the stomach largely unchanged.

$\beta$ -Lactoglobulin exists as a dimer (Fig. 1) at pH 2.5 to 7.5 as long as salts are present, which means in all foods and almost all manufacturing conditions (Mercadante et al., 2012). It should be noted that the dimer is in equilibrium with a small amount of the monomer (Fig. 1) and so it is conceivable, although unlikely, that it could interact with other food components as the monomer.

The second thing to note is pectin comes in a variety of forms. Here we are concerned with commercial pectins and not the far more complex pectins that occur in plant cell walls (dietary fibre). The basic structure is a polymer made up of  $\alpha$ -D-galacturonic acid

**Figure 1** (A) The structure of the  $\beta$ -lactoglobulin dimer (B) monomers of  $\beta$ -lactoglobulin,  $\alpha$ -helices are red and  $\beta$ -strands are green. From Mercadante, D., et al., 2012. Biophysical J. 103, 303–312. Reproduced with permission The Biophysical Society.

**Numbers** = Degree of Methylesterification, determines overall charge density

**'R' or 'B'** = Random or Block-wise distribution of charged groups, determines local charge density

**Figure 2** Pectins samples used in this research. The molecular structure of pectin backbone: 1,4-linked  $\alpha$ -D-galacturonic acid (GalA) is in the top panel. When the solution pH is sufficiently high, the GalA units are negatively charged while the methyl-esterified GalA units are neutral. The pectin samples are named based on the degree and distribution of methyl-esterified groups: the numbers indicate the degree of methyl-esterification in percentage, and the letters 'R' and 'B' indicate random and blockwise distribution patterns of the uncharged methyl-ester groups respectively. Xu, A.Y., Melton, L.D., Ryan, T.M., Mata, J.P., Rekas, A., Williams, M.A.K., McGillivray, D.J. 2018. Effects of polysaccharide charge pattern on the microstructures of  $\beta$ -lactoglobulin-pectin complex coacervates, studied by SAXS and SANS. *Food Hydrocolloids* 77, 952–963. <https://doi.org/10.1016/j.foodhyd.2017.11.045>, plus supplementary data. Reproduced with permission from Elsevier.

units (Fig. 2). Hence it will have a negative charge. Not only the length of the polymer can vary but also the carboxylic acids in the galacturonic acids can be esterified by methyl groups so they have no charge. Not only does the degree of methyl esterification varies (typically from 80% to 40%) but also the arrangement of the methyl esters which occur in blocks or at random (Fig. 2). As you will see whether blocky or random can have a considerable influence on how the pectin interacts.

We chose to work at pH 4, so the positively charged  $\beta$ -lactoglobulin ( $\beta$ Lg) will interact electrostatically with negatively charged pectins. Isothermal titration calorimetry (ITC) showed they do indeed interact (Fig. 3) but it is complex interaction which varies according to the type of pectin (Xu et al., 2015). There are two stages of interaction between  $\beta$ -lactoglobulin and pectins which have an adequate amount of charge distribution (e.g. pectins with DM between 37 and 75) (Fig. 4). Starting at about  $-14$  Kcal and finishing at  $-8$  Kcal the interaction sites are quickly exhausted. Then in the second stage the same interaction is recurring because the amount of heat produced remains constant at  $-8$  Kcal until the  $\beta$ Lg to pectin molar ratio is 16 when the interaction quickly ends with the amount of heat given off declining to zero. This is explained in Fig. 5. The sites on the pectin for binding  $\beta$ Lg are rapidly used up in the first step then the  $\beta$ Lg molecules interact with  $\beta$ Lg molecules that are already bound to the pectin. In this way protein rich domains are formed, which serve as crosslinks to bring individual pectin chains together to form a compact structure. Circular dichroism showed the  $\beta$ Lg loses  $\alpha$ -helix structure and increases  $\beta$ -strands when it interacts with pectin or itself (Xu et al., 2015). In other words, the change in the secondary structure may be the same in the protein-pectin interaction as in the protein-protein interaction.

To understand what is the minimum block length required for interaction with a single  $\beta$ Lg to occur, we adopted another approach (Xu et al., 2017a). We studied how oligosaccharides composed of galacturonic acids interacted with a  $\beta$ Lg. They ranged in size from a trisaccharide to decasaccharide. In other words the degree of polymerisation was DP3 to DP10. All of the galacturonic acids in each oligosaccharide are negatively charged; none being methyl esterified. Isothermal titration calorimetry showed the trisaccharide (DP3) and hexasaccharide (DP6) did not interact with  $\beta$ Lg but dramatically the heptasaccharide (DP7) did. One

**Figure 3** Typical ITC thermogram of the titration of  $\beta$ -lactoglobulin and pectin 37B showing a two stage interaction. From Xu, A.Y., et al., 2015. *Soft Matter* 11, 6790–6799. Reproduced by permission of the Royal Society of Chemistry.

**Figure 4** ITC integrated binding isotherms for  $\beta$ -lactoglobulin and various pectins:  $\beta$ -lactoglobulin to 37R titration (red), 37B (orange), 58R (green), 58B (blue), 75R (purple). From Xu, A.Y., et al., 2015. *Soft Matter* 11, 6790–6799. Reproduced by permission of the Royal Society of Chemistry.

more galacturonic acid makes a huge difference. As one might expect the deca-saccharide (DP10) also interacted (Fig. 6). Circular dichroism showed that the  $\alpha$ -helix content decreased and the  $\beta$ -strand content increased when  $\beta$ Lg interacted with the heptasaccharide and deca-saccharide but there was no change with the tri- or hexa-saccharide as one would expect if there was no interaction. SAXS and SANS confirmed the interaction with DP7 and DP10 oligo-galacturonic acids and determined the size of the protein clusters to be about 8 nm in cross-section and the primary particles about 80 nm. This allowed us to generate a new model of the interaction (Fig. 7). Clearly a minimum of 7 adjacent galacturonic acids are need for an interaction with a  $\beta$ Lg. However, it does not follow that all 7 negative charges are needed; it may be the length of the oligosaccharide is essential to reach positively charged

**Figure 5** Model of the two-step interaction of  $\beta$ Lg and pectin. In the first step “seeding proteins” interact with negatively charged sites on the pectin. In the second step the seeding proteins trigger interaction with other proteins leading to the formation of local  $\beta$ Lg rich domains. Native  $\beta$ Lg is shown as orange circles and the changed conformation of  $\beta$ Lg is shown as ellipses. From Xu, A.Y., et al., 2015. *Soft Matter* 11, 6790–6799. **Figure 6** ITC integrated binding isotherms for  $\beta$ Lg titration with galacturonic acid oligosaccharides: DP3 (orange), DP6 (red), DP7 (green) and DP10 (blue). Xu, A.Y., et al., 2017. *Soft Matter* 13, 2698–2707. Reproduced by permission of the Royal Society of Chemistry.

binding sites on the  $\beta$ Lg. Initially when there is an excess of DP7 or DP10 relative to  $\beta$ Lg the reaction products are soluble. However, when  $\beta$ Lg is in excess the samples are turbid. We believe the  $\beta$ Lg -oligosaccharide complexes interact with each other to form primary particles (Fig. 7) that further aggregate into larger branched fractal structures. The primary particles act as precursors for the formation of the larger structure.

**Figure 7** Two systems during  $\beta$ Lg titration into OGAs (DP greater than 6). In the first system (left), observed when OGA is in excess,  $\beta$ Lg binds to OGAs forming soluble complexes. In the second stage when  $\beta$ Lg is in excess, the  $\beta$ Lg-OGA complexes form primary particles which aggregate, resulting in a turbid sample. Xu, A.Y., et al., 2017. *Soft Matter*. 13, 2698–2707. Reproduced by permission of the Royal Society of Chemistry.

**Figure 8** SANS of  $\beta$ -lactoglobulin-pectin complexes in  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$ . Formation of primary particles during  $\beta$ Lg to pectin titration. Deuterated proteins are brown circles while pectins are green lines. Dotted circles show the primary particles.  $\text{H}_2\text{O}$  is light brown and  $\text{D}_2\text{O}$  is brown. Xu, A.Y., et al. 2018. *Food Hydrocoll.* 77, 952–963. Reproduced with permission from Elsevier.

The final stage in understanding the interaction of  $\beta$ Lg with pectins is to apply the knowledge gained from the oligosaccharide interactions to interpret the interactions of the larger pectic polymers when they form complex coacervates. SAXS and SANS were used to study the complexes formed by  $\beta$ Lg and the pectins with different degrees of methylation and blockiness (Xu et al., 2018). This showed the coacervates consist of compact primary particles which are composed of adjacent pectin chains cross-linked by

**Figure 9** Models showing the size of the structural components that make up the  $\beta$ -lactoglobulin-pectin complex coacervates based on SAXS and SANS measurements. Xu, A.Y., Melton, L.D., Ryan, T.M., Mata, J.P., Rekas, A., Williams, M.A.K., McGillivray, D.J. 2018. Effects of polysaccharide charge pattern on the microstructures of  $\beta$ -lactoglobulin-pectin complex coacervates, studied by SAXS and SANS. *Food Hydrocolloids* 77, 952–963. <https://doi.org/10.1016/j.foodhyd.2017.11.045>, plus supplementary data. Reproduced with permission from Elsevier.

clusters of  $\beta$ Lg molecules (see Fig. 8). The overall and local charge densities of pectin influence the size and distribution of  $\beta$ Lg domains within the primary particles. The results confirmed that the greater the charge density of the pectin the smaller the  $\beta$ Lg-rich domains in the primary particles. When the primary particles are arranged in an open fractal network structure a complex coacervate results (Fig. 9). However, if the primary particles associate extensively the result is a precipitate.

## Conclusion

Overall we have shown the amount and arrangement of charges on the pectin influences the structure of the protein-polysaccharide complexes. This knowledge can be applied to improve the structure and texture of food products and delivery systems.

## Introduction

Proteins and polysaccharides are commonly used as ingredients in food formulations. These biopolymers confer vital functionality, such as thickening, stabilizing, gelling, and emulsifying properties, to food products. The functional properties of individual biopolymers (either used naturally or added as ingredients) add to the complexity of the multi-component food system. The overall stability and the microstructure of the food system depend on the individual functionalities of the proteins and polysaccharides and also on the nature and the strength of interactions between them. Milk proteins, namely caseins and whey proteins, have different characteristics depending on the type of system in which they are present. Casein exists in different states, ranging from small dissolved macromolecules to stable colloidal particles. It exists mostly in the colloidal state in commercial dairy products, whereas whey proteins are present as dissolved polymers of low molecular weight unless temperature/high pressure treatments are induced, which lead to unfolding and aggregation. Aggregates of whey proteins that are formed by thermal and high pressure processing have their own versatile functional properties. The interaction of polysaccharides with milk proteins leads to the formation of a ternary 'milk protein–polysaccharide–water' polyelectrolyte solution. An understanding of the basic concepts of the mixing behavior of biopolymer solutions and the factors contributing to their formation and their various functionalities is important in the elucidation of this rather complicated system.

## Theoretical Concepts on Mixing Behavior of Biopolymers

When aqueous solutions containing proteins and polysaccharides are mixed, one of four phenomena can occur: (1) co-solubility, i.e., the components mix well and the solution is stable; (2) thermodynamic incompatibility, i.e., the polymers repel each other and two phases appear, one abundant in polysaccharide and the other abundant in protein; (3) depletion interaction, which occurs in colloidal dispersions in the presence of non-interacting polymers (e.g., polysaccharides in an emulsion, or polysaccharides and colloidal casein micelles); (4) complex coacervation, i.e., electrostatic interaction occurs, giving rise to a concentrated protein–polysaccharide phase and a dilute phase.

It is important to consider the influence of the biopolymer concentration on the enthalpic interactions occurring in the system. For mixed polymer systems at high dilutions, the system becomes homogeneous regardless of whether thermodynamic incompatibility or coacervation occurs. However, coacervation can occur in dilute solutions whereas thermodynamic incompatibility cannot.

Some terms associated with mixed biopolymer systems are listed below.

### Co-solubility

This phenomenon is based on the thermodynamic principle that the Gibbs free energy of mixing ( $\Delta G_{\text{mixing}}$ ) is negative when the entropy of mixing favorably exceeds the enthalpy term. The highest entropy is achieved when different kinds of molecules are randomly distributed throughout the system. The expression for the Gibbs free energy accompanying mixing under standard conditions is given by

$$\Delta G_{\text{mixing}} = \Delta H_{\text{mixing}} - T\Delta S_{\text{mixing}}$$

where  $\Delta G_{\text{mixing}}$ ,  $\Delta H_{\text{mixing}}$ , and  $T\Delta S_{\text{mixing}}$  are the free energy, enthalpy (interaction energy), and entropy changes, respectively, between the mixed and unmixed states.

The interaction of smaller molecules (monomers, hydrophilic amino acids) on mixing results in a co-soluble system. As the entropy of a mixed biopolymer system is much lower than that for smaller molecules, the system tends to become less co-soluble because of thermodynamic incompatibility. Also, given the polymeric nature of proteins and polysaccharides and the presence of various functional groups in their macromolecules, co-solubility is the least typical situation.

### Thermodynamic Incompatibility

This occurs when two dissimilar noninteracting macromolecular species separate into two different phases because the enthalpy of mixing exceeds the entropy difference. Such phenomena are also observed when the two biopolymers have different affinities towards the solvent. For mixed systems, molecular and structural differences between the same biopolymers also give rise to thermodynamic incompatibility (polysaccharides with different structures, proteins of different classes, e.g., proteins of different solubilities, native and denatured forms of the protein, and aggregated and nonaggregated forms of the same protein).

### Depletion Interaction

Depletion interaction occurs in systems containing depletants such as nonadsorbing polysaccharides. It occurs by entropically driven exclusion of the depletant by an osmotic pressure gradient, ultimately leading to flocculation of the system. This type of flocculation is considered to be weak or reversible as the flocs are easily broken down on remixing. However, in most food systems, this weak flocculation leads to extensive aggregation, resulting in creaming and instability of the system.

### Complex Coacervation

This phenomenon occurs because of the formation of electrostatic complexes between the protein molecules and the polysaccharide molecules, resulting in a two-phase system. One phase is rich in both of the biopolymers that represent the complex, whereas the other phase contains the excluded solvent and is depleted in biopolymers. This is observed when two oppositely charged biopolymers interact. These reactions are highly dependent on the ionic nature of the system. Coacervates are formed when proteins interact with polysaccharides that have a low charge density and/or a very elastic backbone, e.g., gum arabic, gelatin, dextran, pectin etc.

## Mixing Behavior of Milk Proteins and Polysaccharides

### Casein–Polysaccharide Systems

Casein micelles are assembled in large supramolecular entities that may be considered to be spherical particles. The surface of casein micelles is covered by  $\kappa$ -casein, which helps in suspension stabilization by means of steric and electrostatic repulsions. Its hairy surface restricts the adsorption of neutral polymers on to the micelles. Inherent problems of casein micelles include association over a wide pH range, especially in the presence of calcium ions, and insolubility at the isoelectric point (pI). When casein micelles are added in a mixed food system, in which excessive pH adjustments are not made and the environmental ionic changes are minimal, the behavior of the system can be assessed in terms of the adsorption or nonadsorption of polysaccharides on to the colloidal casein micelles.

Dairy products are abundant in surface-active colloidal particles on to which polysaccharides can be adsorbed or nonadsorbed. Both adsorbing and nonadsorbing polysaccharides are capable of increasing or decreasing the stability of the mixed system, depending on their concentrations and the ratio of protein to polysaccharide. For pectin–casein systems, it has been observed that the pectin does not adsorb on to the micelles at neutral pH (Maroziene and de Kruif, 2000). Nonadsorbing pectin causes a segregative phase separation. Adsorption leads to bridging flocculation in casein–pectin systems; for example, by lowering the pH, pectin and casein micelle complexes are formed. A casein–polysaccharide mixture results in depletion flocculation because of the difference in osmotic pressure between the bulk solvent containing the polysaccharide and the solvent entrapped between the casein micelles, from which the polysaccharide is excluded because of steric hindrance. This leads to the casein micelles being pushed together and finally aggregating. Polysaccharides with a lower intrinsic viscosity or hydrodynamic molecular volume tend to occupy lesser volumes, leading to a lesser extent of their exclusion. This leads to a reduction in the phase separation because the aggregation of casein is slowed. Phase separation in dairy systems results in visual separation of a clear serum (wheying off) and loss of the desired quality in the product. Hence, the type of polysaccharide added to a casein-containing system can be tailored depending on the desired functionality of the system.

### Whey Protein–Polysaccharide Systems

Whey proteins in their native state behave like low molecular weight dissolved polymers (mainly in the form of  $\beta$ -lactoglobulin present as pH-dependent oligomers). Processing factors such as heat and high pressure lead to the unfolding of whey proteins and their aggregation. Generally, when whey proteins are mixed with polysaccharides, thermodynamic incompatibility occurs. If one of these polymers is highly viscous or forms a gel, phase separation is retarded. That is, the rate and the extent of phase separation may be severely retarded when one phase gels and the other remains dispersed in the gel. The addition of xanthan gum to whey protein with 200 mM sodium chloride (salt) resulted in the formation of a protein gel network in which xanthan-gum-rich regions were embedded. However, without the addition of salt, the system formed two separate phases (Bryant and McClements, 2000). Mixtures of whey protein isolate (WPI)/pectin and WPI/guar gum showed phase separation, but a mixture of WPI/iota-carrageenan showed no visual separation because of the high gelling capacity of iota-carrageenan (Erçelebi and İbanoğlu, 2007). In some cases, when the polysaccharide concentration is low, phase inversion causes dispersed whey protein gel particles in a dilute polysaccharide solution to form whey protein gels with polysaccharide-rich regions (Syrbe et al., 1998). Electrostatic interactions between whey proteins and polysaccharides at a pH slightly above their pI, lead to the formation of soluble complexes. This mechanism enhances the interfacial properties of whey protein emulsions, because a thicker homogeneous layer is formed around the oil droplets or air bubbles (Benichou et al., 2002), and also helps in modifying the heat-induced gelation of the whey protein. For complexation, the ratio of protein to polysaccharide and the pH should be regulated because a high concentration of polysaccharide causes the complexes to re-solubilize, whereas a lower concentration leads to un-complexed protein remaining in the solution. On mixing with whey protein, nonionic polymers can show thermodynamic incompatibility.

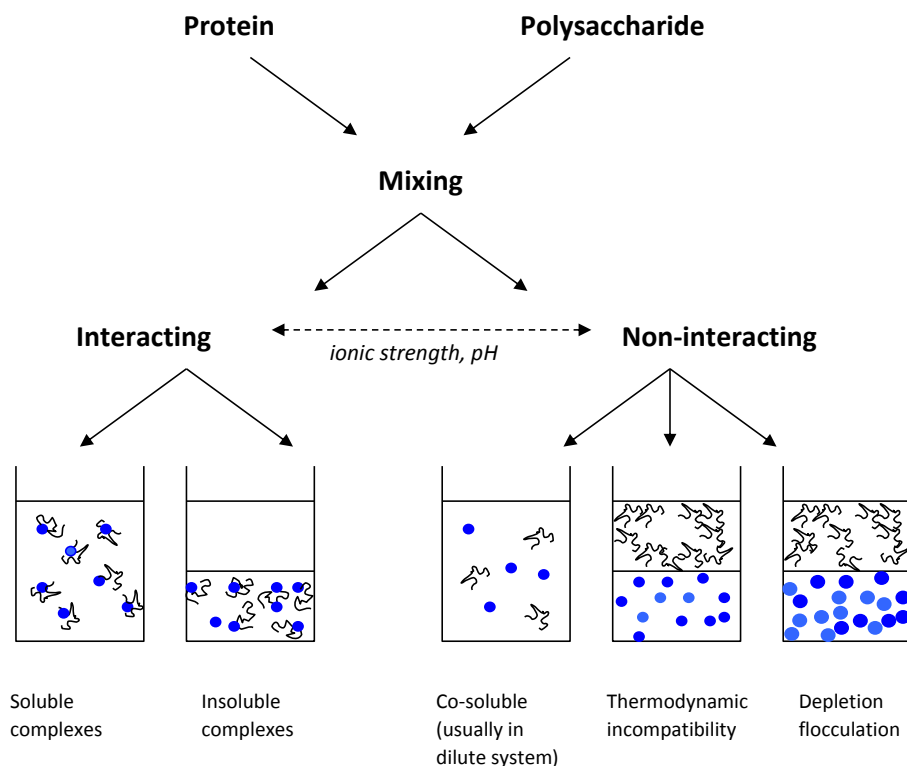

## Phase Diagram

The mixing together of aqueous solutions of proteins and polysaccharides results in either a one-phase system or a two-phase system, depending on the composition of the solution and the environmental conditions, as depicted in Fig. 1. In one-phase systems, the biopolymers exist as individual molecules or as soluble complexes that are uniformly dispersed throughout the entire system. However, if the molecular weight and the concentration of the biopolymers are increased, the system starts to become less co-soluble and this results in the formation of two distinct phases, in which each phase has different biopolymer concentrations. A typical phase diagram demonstrating the segregating biopolymer system that is caused by thermodynamic incompatibility is shown in Fig. 2A and a phase diagram of a milk protein–polysaccharide system is given in Fig. 2B. Phase diagrams aid in determining the effective concentrations of the biopolymers in the two phases and the concentration at which maximal co-solubility of the biopolymers is achieved.

## Interactions Involved in Protein–Polysaccharide Complex Formation

Tolstoguzov (1997) classified the macromolecular interactions required for complex formation into three types: interactions between charged biopolymers, interactions between oppositely charged functional groups, and interactions between other available side groups of poly-ions, i.e., charged regions on polymers called 'patches'. Repulsive interactions exist transiently and are considered to be weak (unless the molecules exist at very close range or at low ionic strengths). They are considered to be nonspecific and to arise because of electrostatic interactions and/or excluded volume effects. Attractive interactions may be weak or strong and specific or nonspecific. Whereas electrostatic forces are commonly involved in complex formation, non-Columbic interactions contribute to nonspecific net attractive protein–polysaccharide interactions. Non-electrostatic interactions are usually less sensitive to pH and ionic strength changes and the formation and the stabilization of complexes occur by hydrogen bonds, hydrophobic interactions, and van der Waals' forces. These forces generally depend on the physico-chemical properties of the biopolymers and the system. The overall interaction that occurs between proteins and polysaccharides is the average of the multitude of intermolecular forces that occur between the biopolymers.

Depletion flocculation and thermodynamic incompatibility in whey protein stabilised O/W emulsions. *Food Hydrocolloids* 14, 521–530.

### Factors that Influence Protein–Polysaccharide Interactions

Factors that affect the nature of protein–polysaccharide interactions and the corresponding structures formed on the basis of these interactions can be classified as extrinsic, intrinsic, and processing factors. These factors can be varied to obtain desired functionalities for tailored applications (Table 1).

Syrbe et al. (1998) laid down some basic rules for understanding the combined effect of pH and ionic strength on the mixing behavior of protein–polysaccharide systems. For protein–nonionic polysaccharide systems, pH and ionic strength affect only

**Table 1** Factors that influence milk protein–polysaccharide interactions

	Factor	Observations
Extrinsic	Mixing ratio ( $r$ )	Affects structure of complexes or coacervates formed. Lower $r$ results in the formation of coacervates that coalesce quickly, whereas higher $r$ results in more stable coacervates.
	Molecular concentration	Coacervation can occur in very dilute solutions, whereas thermodynamic incompatibility is favored in more concentrated systems.
	pH	At a pH > the isoelectric point (pI) of the protein, there is repulsion between the protein and the polysaccharide. Near the pI, soluble complexes are formed, whereas a further reduction in the pH results in the formation of coacervates.
	Ionic strength	At high salt concentration, micro-ions cause a decrease in electrostatic interaction, whereas, at low ionic strength, interference to the formation of the protein–polysaccharide complex is minimal.
	Charge density	Coacervation does not occur at low charge densities, whereas precipitation of the inter-polymeric complexes occurs at very high charge densities. The nature of the charge group (carbonyl versus sulfated) influences the interaction strength.
Intrinsic	Molecular conformation	Increased chain flexibility and increased charge mobility result in stronger binding.
	Charge distribution	Evenly charged chains form large homogeneous phases, whereas an uneven charge distribution leads to the formation of a meso-phase with a micellar structure.
	Molecular weight	The internal structure and the final size of the complexes/coacervates can be controlled by adjusting the molecular weight of the polyelectrolyte.
Processing	Shear	Shear either can cause restructuring of the complexes formed or can stabilize coacervates against flocculation.
	Pressure	Pressure causes partial denaturation of the protein, which strengthens the interaction during complex formation.
	Temperature	Heat denaturation increases the molecular flexibility, which leads to stronger electrostatic interactions, yielding more stable complexes.
	Acidification	The type of acidification method used, e.g., hydrochloric acid or glucono-delta-lactone, influences the structure of the complexes formed.

protein self-association. Incompatibility is directly correlated with protein self-association, which is highest at the pI of the protein and decreases towards acidic and alkaline pHs. In mixed systems, incompatibility in the pH range close to the pI is linked to low ionic strengths, where both biopolymers are uncharged, the difference in charge densities is zero, and the presence of salt suppresses protein self-association. The presence of charged carboxylated or sulfated groups causes ionic polysaccharides to have an anionic nature in the pH ranges that are relevant to food, where complexation occurs with the positively charged protein.

### Effect of Protein–Polysaccharide Interactions on the Interfacial Behavior of Food Systems

The interfacial property of emulsions and foams is attributed mainly to the proteins that adsorb at the air–water and oil–water interfaces and enable stabilization of these systems. Although not all food proteins are surface active, all are amphiphilic and most contain similar amounts of polar and nonpolar amino acid residues. The surface activity of a protein depends on its chain flexibility, its thermodynamic stability, its charge, its molecular size, and the presence of polar and nonpolar domains. Milk proteins are highly surface active in both their soluble form and their dispersed form. Extensive literature on milk-protein-based emulsions is available. Flexible caseins have no tertiary structure whereas compact globular whey proteins possess a tertiary structure and preserve their globular shape even after adsorption on to an interface. As most high molecular weight polysaccharides are hydrophilic, they are not considered to be surface active. These include polysaccharides such as xanthan gum, pectin, and their derivatives. Surface-active polysaccharides include gum arabic, gum tragacanth, cellulose-derivative polysaccharides such as methylcellulose, carboxymethylcellulose, and hydroxypropyl methylcellulose, and propylene glycol esters of alginic acid. However, in the literature, their surface activity is attributed to the presence of protein impurities.

The stability of protein foams during storage can be improved by complexation with polysaccharides. The stability increases because of the thick interfacial layers of protein–polysaccharide complexes that stabilize the bubbles and prevent coalescence. These interfacial networks also tend to show a ‘jamming effect’, which reduces foam drainage and maintains the structural integrity of the system. The main factors governing the surface pressure, dilatational, and surface shear rheological behavior of protein–polysaccharide interfacial films under associative (i.e., net attractive) conditions depend on the electrostatic charge of the complexes in the bulk solution and the order of adsorption of the biopolymers to the interface (simultaneous or sequential). Under conditions of limited thermodynamic compatibility, the polysaccharides adsorb to the interface by competing with the protein or by complexing with the adsorbed protein. This leads to excluded volume effects that cause the protein at the interface to perform as a more concentrated film, leading to an increase in the surface pressure.

### Effects of Milk Protein–Polysaccharide Interactions on Rheological Properties

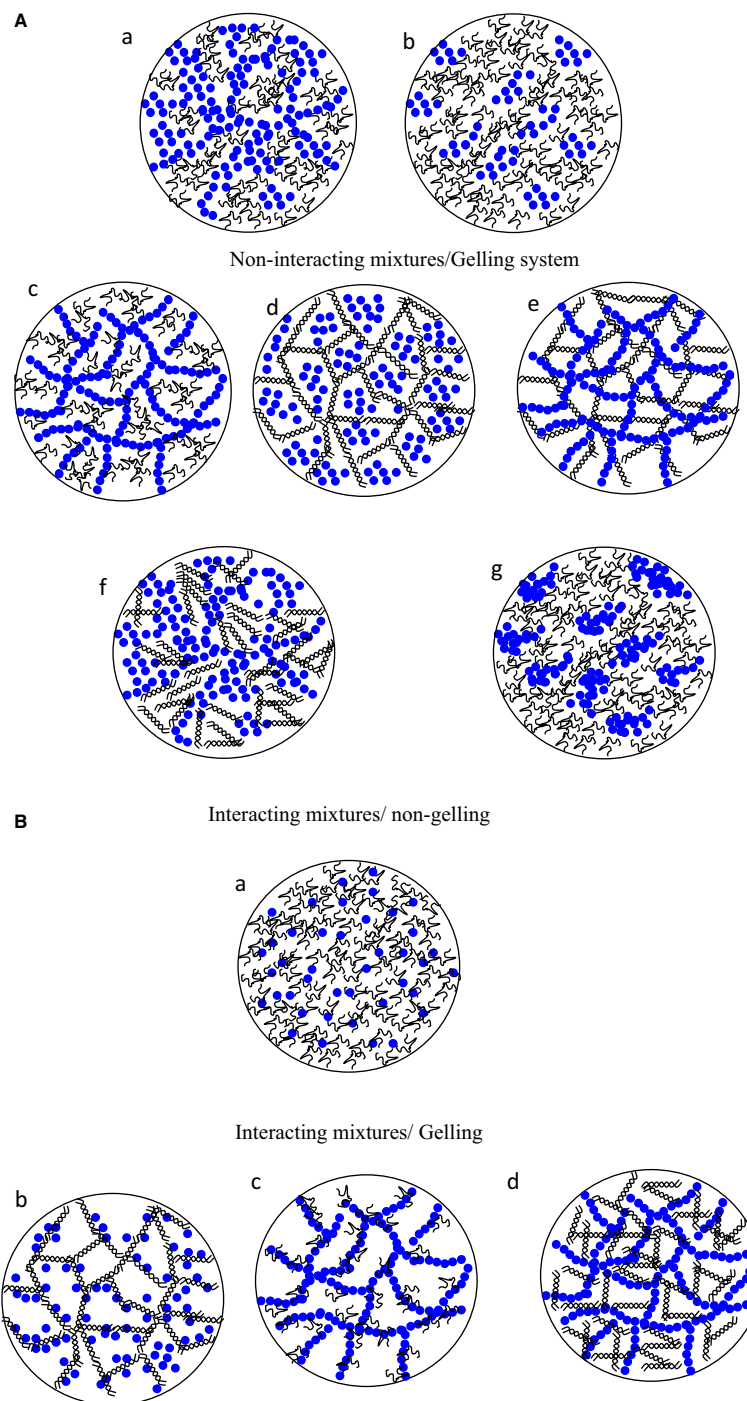

The rheology of a substance is defined as the behavior of a solid or liquid under shear. For mixed systems, the rheology of the bulk system is similar to those occurring at the interface. The functional properties of biopolymer mixtures that confer stability and texture-modifying effects generally include aggregation and gelation of the biopolymers. Aggregation is a generic term for a process in which two or more colloidal particles associate under the influence of attractive colloidal interactions. Gelation is a multistage reaction that gives rise to an extended three-dimensional network that entraps a large amount of solvent molecules. Changing the processing conditions that induce aggregation and gelation by denaturing the structure of the biopolymers helps to create novel microstructures with versatile functionalities.

Goh et al. (2008) classified milk protein–polysaccharide systems into two broad categories, i.e., interacting mixtures and noninteracting mixtures Fig. 3A and B. These categories can be further classified according to the ability of these mixtures to form gels, i.e. gelling or nongelling. Mechanisms resulting in the formation of these microstructures are listed below.

- For interacting mixtures, complexes are formed if electrostatic attraction occurs between the biopolymers. If one of the biopolymers in the interacting mixture is gelling, the other phase directly interacts with the gelled network. If both biopolymers form gels, then a coupled gel network is formed.
- Phase-separated networks are formed when de-mixing of the system occurs prior to gelation. Phase separation comes to a halt when gelation occurs. The final structure of the system depends on the relative rates of phase separation and gelation. Subsequent gelation of the other phase (i.e., if the phase is made up of a gelling polymer) will result in a second gel phase. If the first network is weak, enthalpic advantage results in the second network forming a stronger gel and becoming the continuous phase, with the first network being broken down into dispersed particles.
- Some polysaccharides do not interact with the protein but instead modify the viscosity of a gelling system by limiting the fluidity of the gel. When mixed with proteins, neutral hydrocolloids such as guar gum impart a bulking effect to the gelling system and are not affected by the ionic strength or pH of the system.

### Applications of Milk Protein–Polysaccharide Systems in the Food Industry

Protein–polysaccharide interactions can give rise to a multitude of functional colloids that can have numerous applications in the food industry. The functional properties of protein–polysaccharide complexes and the rationale behind their application are listed

**Figure 3** (A) Schematic diagrams of some possible microstructures formed between noninteracting protein–polysaccharide mixtures. Circle (●) represents protein; coil structure represents polysaccharide molecules. (a) Flocculated protein network formed with polysaccharide filling the space in the network; (b) polysaccharide molecules overlap and form a continuous 'network' with protein filling the space; (c) particulate protein gel network formed with polysaccharide filling the space; (d) polysaccharide gel network formed with protein filling the space; (e) bi-continuous network formed from protein and polysaccharide; (f) polysaccharide gels dispersed among weakly flocculated protein network; (g) protein gels dispersed among entangled polysaccharide molecules. Reproduced with permission from Elsevier, from Goh, K.K.T., Sarkar, A., Singh, H., 2014. Milk protein–polysaccharide interactions. In: Boland, M., Singh, H., Thompson, A. (Eds.), *Milk Proteins: From Expression to Food*, second ed. Academic Press, London, pp. 387–419.

**Table 2** Functional properties of protein–polysaccharide complexes and rationale behind use of protein–polysaccharide complexes

Functionality	Molecular interactions involved
Fat substitutes/Prevention of excess protein aggregation	Thermal aggregation of proteins leads to gritty textures, which can be prevented by the addition of polysaccharides, which minimize excessive protein aggregation by minimizing protein–protein interactions. Their hydrophilic characters confer plasticity, lubricity, and creaminess, which improves the mouthfeel of the complexes, making them excellent fat mimetics.
Meat analogs	Thermal treatment is carried out to destabilize regions of a protein–polysaccharide complex, which stabilizes the interaction of divalent metal ions and the polysaccharides, resulting in a thermostable polysaccharide gel that entraps proteins and resemble minced meat.
Improvement in protein solubility	The complexation of a polysaccharide with a protein increases the solubility of the protein at its isoelectric point (pI). Insoluble complexes that are formed are solubilized by acid titration. The main principle is to modify conditions such as pH and ionic strength to obtain maximum complex coacervation for maximum efficiency.
Encapsulation	Complexes can be utilized to encapsulate bioactive compounds against processing and storage conditions. The complexes can be tailored for controlled release to specific target sites. Release can be controlled by modifying the pH or changing the enzymatic conditions.
Emulsification and foam stabilization	Complexes can be formed by electrostatic interaction or Maillard reaction to stabilize oil-in-water emulsions. Polysaccharides can be added to a protein-stabilized emulsion so that complexation can take place at the interface and stability is achieved by the formation of a stronger steric-stabilizing layer. Smaller droplet sizes are obtained when emulsions are homogenized with the polysaccharides and, as long as no bridging flocculation occurs, the rate of creaming may be reduced.
Biodegradable film formation	The formation of a protein–polysaccharide complex improves the emulsifying and solubility properties of the biopolymers, which results in better mechanical and moisture sorption properties of the composite film formed.
Stability in dairy products	Dairy products contain dispersed particles in the form of emulsions and other dairy ingredients (e.g., cocoa) coated with caseins. Polysaccharides can act as adsorbing polymers and can incorporate these dispersed particles as fillers in their network, thus stabilizing the system. Further gelation of this system will result in additional stability.
Protection of probiotic bacteria in the gastrointestinal tract	Complexes act as good protective matrices to protect probiotic bacteria from various stresses encountered during processing, storage, and passage through the gastrointestinal tract, preventing loss of viability of the bacteria.

**Table 3** Some applications of milk proteins with commonly used polysaccharides in the food industry

Milk protein	Polysaccharide	Mechanism	Application
Casein	$\kappa$ -Carrageenan	Electrostatic interaction OR suspension of casein micelles in a weak $\kappa$ -carrageenan gel.	Stabilization of milk gels, dairy emulsions, and suspensions. Also acts as a secondary stabilizer in ice cream mixes.
	Carboxymethylcellulose (CMC)	Electrostatic interaction OR, when added in excess, depletion flocculation of the system by excess CMC.	Prevents milk protein flocculation in acidified milk drinks and stabilizes oil-in-water emulsions.
	High methoxyl pectin	Prevents settling out of casein aggregates (whey off) in acid milk drinks by electrostatic complexation.	Stabilization of low pH milk drinks, preventing protein aggregation at low pH, and stabilizing emulsions.
	Dextran	Complexation by Maillard reaction.	To improve casein solubility at acidic pH.
	Chitosan	Induces destabilization and coagulation of casein micelles without changes in the milk pH or the stability of whey proteins OR thermodynamic incompatibility OR depletion flocculation.	Casein micelle precipitation, biodegradable packing materials, and stabilizing emulsions.
Whey protein	Xanthan gum	Coacervation.	Used to produce fibrous complexes that are used as meat mimetics.
	Gum arabic	Coacervation.	Encapsulation.
	Exopolysaccharides	Electrostatic complexes are formed under acidic conditions whereas segregative interactions are observed at neutral pH.	Stabilize the texture of dairy food products.
	Dextran	Conjugation by Maillard reaction.	Improved emulsification properties.
	Maltodextrin	Conjugation by Maillard reaction.	Improved emulsification properties.
	Pectin	Conjugation by electro-synthesis.	Film formation.

in Table 2. Milk protein–polysaccharide systems can have innumerable applications as many variables can be exploited to create colloids with specific functionalities. Some common applications of milk proteins with food-grade polysaccharides are given in Table 3.

## Conclusions

Over the last few decades, extensive work has been carried out on the rather complicated protein–polysaccharide system to deduce the fundamental molecular interactions that occur. As numerous factors are involved in determining the formation and the stability of the system, it becomes difficult to develop colloids with specific functionalities. Also, for many food applications, the digestive fate of these systems is unknown, which creates a huge gap in the successful application of the system. Bridging this gap will help to create food systems and ingredients that are of high value to the food industry.

## Introduction

Semi-solid food, i.e. amorphous solid food, is a viscous rather than solid-like substance which possesses both solid and liquid characters (Laverne et al., 2015). Different from conventional crystalline solids, the microscopic structures of semi-solid foods are disordered (i.e. lacks long range ordered arrangement of atoms, molecules, or ions within the structure). For semi-solid food, structure, texture and stability are important and fundamental attributes which depend on the rational design of food structure and complex assembly of various food ingredients such as polysaccharides, proteins, lipids, water and others (Ai et al., 2015). Among the food components, the nature of biopolymers and their interactions (e.g. those between polysaccharides and proteins) are essential to the structuration and stabilization of semi-solid food systems owing to their influences on gel-forming, thickening, hydration and surface/interface stabilizing properties (Cgde and Tuinier, 2001). A number of recent reviews and research publications (Jain et al., 2015; Li et al., 2016b; Timilsena et al., 2016) describe thermodynamic considerations and dominant molecular properties underlying the interactions of biopolymers, and emphasize the importance of polysaccharide-protein interactions in developing food products with desired structure, texture and stability.

## Overview of Polysaccharide-Protein Interaction

Interestingly, the simultaneous addition of protein and polysaccharides may induce intermolecular interactions that modify or generate functional properties more desirable than those derived from proteins or polysaccharides alone (Souza and Garcia-Rojas, 2016). The overall polysaccharide-protein interaction, depending mainly on the functional groups and environmental conditions, is made up from an average over the large number of different intermolecular forces arising between the various segments and side-chains on the two macromolecules including electrostatic forces, excluded volume effects, hydrogen bonding, hydrophobic interactions, ion-bridging, and Van der Waals interactions (Dickinson, 1998). Under the influence of the aqueous environmental conditions (e.g. pH, charge density, solvent quality, biopolymer ratios, ionic type and strength, etc.) and the distribution of various functional groups for molecular bonding (charged, hydrophobic, hydrogen bonding, etc.), protein/polysaccharide mixtures in an aqueous dispersion is often accompanied by either segregative/associative phase separation (Fig. 1) through thermodynamic incompatibility or compatibility (Le et al., 2016).

**Figure 1** Mixed biopolymer solutions may encounter phase separation under conditions where either attractive or repulsive interactions take place between the biopolymer molecules. Adapted from McClements, D.J., 2006. Non-covalent interactions between proteins and polysaccharides. *Biotechnol. Adv.* 24 (6), 621–625.

The strength and specificity of attractive interactions (including covalent and non-covalent bonding) vary widely (Benichou et al., 2002). Covalent bonding can be considered as the simplest extreme case of thermodynamic compatibility with “highly specific” and very “strong” characteristics. Non-covalent bonding is often derived from specific and non-specific ionic or non-ionic interactions, resulting in weak (reversible) or strong (difficult to reverse) protein-polysaccharide attraction. The aqueous environmental conditions (solvent quality, pH, ionic content, etc.) and macromolecular structure characteristics (net charge, shape, size, length, flexibility) (Dong et al., 2013; Sabliov et al., 2015) all influence the nature of non-covalent bonding. Complexation can take place when the overall net attraction exists between the oppositely charged protein and polysaccharide macromolecular chains. Most proteins (e.g. acidic and basic species) can form complexation with anionic polysaccharides in the region of pH ( $pK_{a\text{polysaccharide}} < \text{pH} < pI_{\text{protein}}$ ).

At low concentrations, biopolymers with the same type of charge can co-exist in a solvent solution (i.e. co-solubility) (Khalesi et al., 2016), whereas, at higher concentrations, phase separation into two phases, protein phase and polysaccharide phase, is possible. Thermodynamic incompatibility is the driving force of the phase separation between proteins and polysaccharides under repulsive conditions ( $\text{pH} < pI_{\text{protein}}, pK_{a\text{polysaccharide}}$ ).

## Polysaccharide-Protein Interaction in Semi-Solid Food Systems

Polysaccharides and proteins are conducive to the textural and structural features of semi-solid food owing to their aggregation and gelation behaviors. In comparison with the polysaccharide-protein interactions in solutions and at the interfaces (which have been studied extensively), the interactions in food colloids still are less examined and remain challenging topics (Semenova, 2017). Accordingly, this article is focused on the polysaccharide-protein interactions in semi-solid foods, two typical systems, hydrogels and wheat doughs.

### Hydrogels

Interactions between polysaccharides and proteins allow efficient approaches to construct food structures and improve the stability and textural properties of semi-solid food colloids (such as viscoelastic emulsions, gels and their mixtures) (Le et al., 2016; Semenova, 2017) through their water-holding capacity, interfacial properties and gelation behavior (Ghosh and Bandyopadhyay, 2012). Mixed polysaccharide-protein hydrogels are ideal model for the studies on the influence of microstructure on the textural and other properties (Stieger and Velde, 2013).

The network of the mixed hydrogels can be classified into three types: interpenetrating, phase-separated and coupled networks (Turgeon and Beaulieu, 2001). Donato et al. (2005) observed an interpenetrated network of BSA (4 and 8 wt%) and low-methoxyl pectin (0.21 wt%) gels in the presence of  $\text{CaCl}_2$  after a heat treatment (80 °C, 30 min) using Confocal Laser Scanning Microscope (Bastien et al., 2007). reported an interpenetrated structure i.e. gelatin helices (at a low gelation concentration like 1.5%) elongated inside a pre-existing calcium-alginate network.

Phase-separated networks are obtained under segregative conditions in aqueous mixed protein-polysaccharide systems. During the formation of the gel network using gelling molecules, phase segregation in an aqueous medium may be trapped to generate a two-phase co-gel containing continuous and dispersed phases. Spotti et al. (2012) reported higher gel strength and solid character in phase-separated networks of proteins and polysaccharides. Coupled networks are formed under associative conditions when proteins and polysaccharides are linked together through electrostatic attraction (Le et al., 2016). To date, there are only a few reports on the formation of coupled network gels between proteins and polysaccharides. Laneuville et al. (2006) firstly reported a coupled gel formed between oppositely charged proteins (native  $\beta$ -lactoglobulin) and polysaccharides (xanthan gum) at an extremely low concentration (0.1 wt %). Through tailoring the composition and hydrophilic-hydrophobic balance of the internal and surface structure, the polysaccharide-protein hydrogels can be used as encapsulants for bioactives, fat mimetics, and oil–water or air–water interfacial stabilizers (Dickinson, 2015; Mao et al., 2015). The roles of polysaccharide-protein hydrogels as fat mimetics and interfacial stabilizers are described as follows.

### Polysaccharide-Protein Electrostatic Hydrogels as Stabilizers of Emulsions and Foams

Polysaccharide-protein complexes and coacervates play important roles in the preparation of emulsions/foams and control of product shelf-life, e.g. in soft drinks and a large number of semi-solid foods such as ice-cream, sauces and dressings etc. Owing to their abilities to facilitate the formation and stabilization of oil droplets or air bubbles during and after emulsification, polysaccharides and proteins can be used as stabilizers and emulsifiers at oil–water and air–water interfaces (Dickinson, 2009; Wagoner et al., 2016). In the past decade, there have been increasing investigations on the adsorption behaviors, rheological properties and stability of polysaccharide-protein at the oil–water and air–water interfaces (Table 1).

Monitoring influencing factors such as pH, ionic strength, solvent quality and experimental procedure can facilitate delicate dynamic balance of competitive and cooperative (associative) processes (Dickinson, 2008; Hernández-Marín et al., 2013) between proteins and polysaccharides at the oil–water or air–water interface. Pre-formed protein-polysaccharide complex may adsorb together on the interface to form a single complex layer (Fig. 2A). Alternatively, a protein monolayer formed first, with protein-polysaccharide complex underneath after subsequent addition of polysaccharide (Fig. 2B).

**Table 1** Physicochemical factors studied for polysaccharide-protein interaction at the oil (air)-water interface

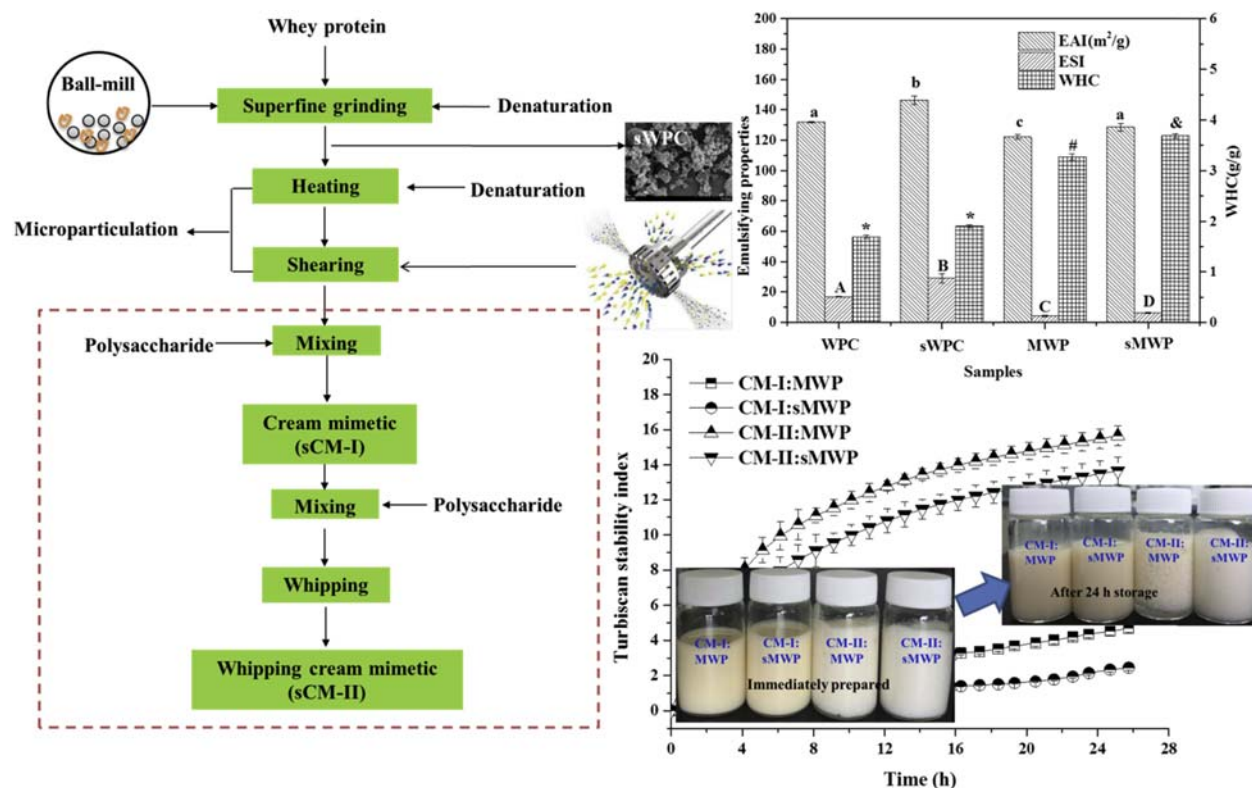

Protein(s)	Polysaccharide(s)	Parameters under consideration	References
Egg white protein	Gum arabic	pH 3.5–7.5 Protein concentration 0.05–0.50 wt%	Padala et al. (2009)
Whey protein	Carboxymethylcellulose	pH 3.3–4.3 Protein: polysaccharide 2:1–1:6 Experimental procedure (layer-by-layer or pre-formed complex)	Hernández-Marín et al. (2013)
	Gum arabic	pH 2.0–8.0 Salt concentrations 100–500 mM Temperature 30–90 °C	Ozturk et al. (2015)
	Pure gum	pH (3.0–7.0)	Li et al. (2016b)
Lentil legumin-like protein	Gum arabic	Polysaccharide concentration 0–12 wt%	Jarpa et al. (2016)
	Guar gum	pH 3.0–7.0	
	Xanthan gum		
Egg white protein	Pectin		Asghari et al. (2016)
	Rice starch	Protein concentration 0.5, 1 wt % Polysaccharide concentration 0.5–5 wt %	
Pea protein isolate	Xanthan	pH 5.4–6.4	Hanazawa and Murray (2014)
Sodium caseinate		Calcium ion concentration 1–64 mM	
Wheat protein	Pectin	pH 3.5–7.0	Qiu et al. (2015)
	Xanthan gum	Polysaccharide concentration 0–0.3 wt%	
Crayfish protein	Xanthan gum	Protein concentration 0.5–5.0 wt%	Felix et al. (2017)
	Xanthan gum	pH 3.0–8.0

### Biopolymer-Based Hydrogel Particles as Fat Mimetics

Small spheroidal protein particles (0.1–10 µm in diameter) as fat mimetics have similar textural, rheological and sensory properties to those of fats (Liu et al., 2016). Polysaccharides act as fat replacements mainly through stabilizing a large quantity of water in the gel-like matrix to generate creamy and flow attributes in a way similar to that of fat (Tiwari et al., 2015). Single carbohydrate-based and protein-based fat mimetics suffer from several sensory and functional limitations such as poor stability and undesirable mouth-feel. Thus, gelled polysaccharide-protein based particles as fat mimetics have attracted growing attention (Lee and Chin, 2017; Toto-saus and Rojas-Nery, 2017). For example, microparticulated whey protein (MWP) in combination with either modified starch or locust bean gum (LBG), with or without fat droplets (5%), could be used as fat mimetics to modulate the texture, appearance and stability of emulsion-based food products with reduced calorie such as sauces, mayonnaise, dressings and dips (Chung et al., 2014).

In recent years, our research team has done a lot of investigations on the interaction between polysaccharides and proteins at the interface and the rational design of food colloidal structures using various food ingredients such as polysaccharides, proteins, fat and water etc. Our studies reveal that protein molecular configuration, protein aggregation and protein particle size as well as

**Figure 3** The regulatory roles of protein molecular configuration and particle size in the interactions between polysaccharides and proteins and associated application in the design of a composite fat mimetic. Adapted from Sun, C., Wu, T., Liu, R., Liang, B., Tian, Z., Zhang, E., Zhang, M., 2015. Effects of superfine grinding and microparticulation on the surface hydrophobicity of whey protein concentrate and its relation to emulsions stability. *Food Hydrocolloids* 51, 512–518 and Sun, C., Liu, R., Wu, T., Liang, B., Shi, C., Cong, X., Hou, T., Zhang, M., 2016. Combined superfine grinding and heat-shearing treatment for the microparticulation of whey proteins. *Food Bioprocess Technol.* 9 (2), 1–9.

the aqueous environmental conditions could modulated macromolecular structure characteristics, balance between phase separation and gelation and heating/cooling kinetics of polysaccharide-protein systems.

Compared with microparticulated whey protein (MWP), superfine and microparticulated whey protein (sMWP) exhibited more stable liquid behaviors (Sun et al., 2015) and could maintain creamy mouth-feel better due to high dispersion stability of sMWP-pectin-xanthan gum gel mixtures (Sun et al., 2016). Accordingly, a composite fat mimetic (microparticulated whey protein-pectin-xanthan gum gel complex system) (Fig. 3) and a texture-controllable fat mimetic can be designed and applied in semi-solid emulsion-based food systems such as mayonnaise, ice cream and Chinese sausage.

Our most recent focus is on the regulation of protein molecular conformation to allow oil–water interfacial compatibility of protein-polysaccharide electrostatic complexes, and the characterization of the emulsions in terms of the stability, lipid oxidation and in vitro digestibility.

## Dough

Bread, steamed bread, biscuits and other wheat flour products are popular consumer foods worldwide. Therefore, the properties of wheat dough including rheological, textural and nutritional attributes have attracted considerable attention. Effects of various hydrophilic gums on the properties of dough and gluten proteins have been widely investigated (Burešová et al., 2017).

Among the hydrophilic gums, soluble dietary fiber (SDF) represents a valuable constituent for health-promoting foods (Garrett, 2015). SDF participates in the regulation of cholesterol in blood and offers prevention from cardiovascular disorders such as atherosclerosis. Further, SDF acts as prebiotics in the gastrointestinal tract. SDF can exert more significant physiological functions due to its hydrophilic characteristics and availability to beneficial microorganisms (Chawla, 2010). Thus, consumption of foods with a high SDF content would promote human health.

Wheat is a global staple food thus wheat flour-based consumer foods provide ideal matrices for SDF delivery. The processing adaptability of wheat dough during mixing, kneading and rising is largely dependent on the complex interactions among natural constituents in flour and other added ingredients or additives in dough. Many studies have been carried out and both positive and negative effects of SDF addition on the properties of dough were found (Flander et al., 2008; Saeed et al., 2011). These contradictory findings are usually governed by the molecular characteristics of SDF such as composition, molecular weight distribution,

**Figure 4** The scanning electron micrographs of doughs fortified with different SDF samples. SDF refers to water-soluble dietary fiber. NI, NII and NIII are SDF fractions from the natural wheat bran precipitated with <40%, 40%–60%, and 60%–80% ethanol. FI, FII and FIII are SDF fractions from the fermented wheat bran precipitated with <35%, 35%–65%, and 65%–80% ethanol.

substitution degree and substitution position, etc. (Scheller and Ulvskov, 2010). For instance, the arabinofuranose (Araf) and other substituents can cause steric hindrance and prevent the aggregation of xylan backbone structure of the molecular chains, leading to the formation of an extended polysaccharide molecular structure and changes in corresponding functions. Thus, besides the structural characteristics of SDF, complicated interactions between SDF and individual constituents or whole matrix of wheat dough may play significant roles in dough quality.

The addition of SDF can not only improve the nutritional value of flour-based products, but also alter the rheological properties of wheat dough because of the influence of SDF on dough microstructure (Izydorczyk et al., 2001) e.g. addition of arabinoxylans or  $\beta$ -glucans to wheat flour. The interactions between SDF molecules and gluten may lead to desirable outcomes such as increased SDF addition and improved processing adaptability or dietary function.

It is of high interest to study the structural features and physico-chemical properties of SDF preparations that have been sub-fractionated via stepwise ethanol precipitation from natural and fermented SDF materials (Li et al., 2016a). The relationship between the structural features and physicochemical properties of isolated and purified SDF fractions were also investigated. Analysis of the distribution of SDF fractions (major components: Arabinoxylans (AXs)) from natural and fermented wheat bran in the wheat dough network by confocal laser scanning microscopy (CLSM) allows the examination on the effects of SDF addition on the microstructure and morphology (as shown by scanning electron microscope (SEM), Fig. 4), texture, extension property, and thermodynamic stability of wheat dough (Li et al., 2017). The relationship between the self-aggregation of SDF molecules and the interactions of SDF fractions with gluten network is shown in Fig. 5. To our best knowledge, the use of double staining for protein and polysaccharide fractions in the dough system has not been published previously. The following parameters, such as average size ( $\Phi_A$ ) and fractal dimension (FD) parameters of SDFs and the protein, are useful for elucidating the correlation between the structural factors affecting SDF molecular entanglement and the distribution of SDF in the dough found by CLSM. The correlations among the physicochemical properties of SDF, and the results of CLSM, texture analysis, tensile tests and differential scanning calorimetry (DSC) analysis can also be determined for displaying the effects of SDF addition on the properties of wheat dough. The interactions of SDF fractions with wheat gluten network can be demonstrated by CLSM with the dynamic and minimally invasive observation of dough microstructure, and the collected CLSM images can be converted into statistical data (Jekle and

**Figure 5** The self-aggregation of SDF molecules and the interaction between SDF fractions and gluten network. SDF, NI, NII, U-Xylp and 2, 3-Xylp refer to water-soluble dietary fiber, natural SDF fractions precipitated with <40%, 40%–60% ethanol, un-substituted and di-substituted at O-3 and O-2 xylose residues.

Becker, 2011). This technique does not require complicated sample preparations for microscopy (e.g. the fixing and dehydrating steps in SEM), and provides images of dough's native structure in an original environment (Jekle and Becker, 2015). Based on the theory of the wormlike model of tangled macromolecule chains (a very large molecule, such as polysaccharide, protein) in a soft condensed state, the different molecular weights and stiffness of the molecular chains affect the morphology and dynamics of the molecules (Egorov et al., 2003; Wei et al., 2016). Therefore, it is possible to estimate interactions between SDF fractions and wheat gluten network based on  $\Phi A$  and FD of SDFs and corresponding protein CLSM images, as a functions of  $M_w$  and the  $\rho$  parameter (which estimates the rigidity of dough) of SDFs using the SPSS software (Li et al., 2017).

## Conclusions

As interactive polysaccharide-protein polymers can be assembled into functional particles or gels, designed polysaccharide-protein interactions are used to control the structure, texture and shelf-life of semi-solid foods. The emphasis in this article has been on segregative or associative phase separation of polysaccharide-protein mixtures in two semi-solid food systems, such as hydrogel and dough, through thermodynamic incompatibility or compatibility. Modulation of polysaccharide-protein hydrogels structure and functionality can be controlled through fabrication conditions (biopolymer type, concentration, pH, biopolymer ratios, ionic type and strength). These polysaccharide-protein hydrogels have the potential to act as emulsion/foam stabilizer and fat mimetics. Thus, more investigations are needed to better understand the structure and processing characteristics of such polysaccharide-protein complexes in real multicomponent semisolid foods during their processing, storage, and digestion.

## Introduction

Grains are the edible seeds of specific grasses belonging to the *Poaceae* family, which includes wheat and its types (farro, freekeh, emmer and spelt), oats, rice, corn, barley, sorghum, rye and millet (Grains & Legumes Nutrition Council, 2017). Pulses comprise the dried seeds of the legume family, which includes pea, lentil, bean and chickpea. In the western civilization, cereal grains have been a major food source for centuries but more recently, pulses are also drawing a lot of attention due to their higher protein, fibre and mineral contents. Cereal grains and pulses together could theoretically make up for daily human intake of all essential nutrients, i.e. carbohydrates, protein, lipids, vitamins and minerals. Determining the chemical composition and knowing the microstructure of cereal grains and pulse crops allow the understanding of desirable traits in their derived products. Various interactions occur within the food systems on a molecular level to bring about changes in food properties. The interactions among the chemical constituents (such as water, starch, protein, etc.) and their functional properties within grains are critical to several ongoing chemical and biological reactions. This chapter primarily focuses on the interactions between protein and starch, their relevance to the functional properties of foods, processes that cause alteration in the protein-starch matrix, and the chemical imaging methods typically used to understand these interactions.

## Functional Attributes of Cereal Grains and Pulses

Cereal grains and pulses comprise starch, protein, lipids, carbohydrates, fibre, ash, etc. Starch is primarily composed of amylose and amylopectin whereas proteins are categorized into albumins, globulins, gliadins and glutenins, based on their solubility (Kiosseoglou and Paraskevopoulou, 2011; Lásztity, 1996). Starch granules of cereal grains vary in size (2–35  $\mu\text{m}$ ), size distribution (normal, bi-modal or tri-modal), gelatinization onset temperature, and amylose content (0%–70%) (Wrigley, 2010). Similarly, pulse starch granules vary in shape (disk, elliptical, irregular, oval, round and spherical) and size (0.4–103  $\mu\text{m}$  depending on the botanical source) (Singh, 2011). Difference in starch granule size affects the physico-chemical properties such as swelling power, light transmittance and water-binding capacity (Singh, 2011). Moreover, the functional properties of individual starch granules and protein bodies such as swelling, solubility, digestibility, water-holding and fat-holding capacities affect the overall protein-starch matrix in food products.

Swelling of starch granules happens as a result of molecular disruption caused by heating in excess water. This change in structure is generally characterized by parameters such as swelling power or swelling factor (Singh, 2011). Swelling power is a measure of inter- and intra-granular water (Leach et al., 1959), whereas swelling factor only measures the former (Tester and Morrison, 1990). As a function of temperature, the swelling power of pulse starches have been found to increase considerably above 70 °C with no change observed below 60 °C (Hoover et al., 2010). Li and Yeh (2001) found that the swelling power of starches from cereals (corn and rice) and legumes (peas and mung bean) increased with temperature beyond 55 °C, but starch granular size, amylose content and heat of gelatinization were not statistically correlated with the swelling power of starches. However, Sasaki and Matsuki (1998) demonstrated that the swelling power of wheat starch was positively interrelated with the structure, gelatinization temperature and enthalpy whilst negatively related to the starch-amylose content. Cereal starches show higher swelling power and amylose leaching than pulses due to lower amylose content and higher bound lipid content (Hoover et al., 2010).

Protein solubility reflects the balance between protein-solvent (hydrophilic) and protein-protein (hydrophobic) interactions (Schwenke, 2001), and it depends on the method of extraction, stirring and configuration conditions, and pH (Kiosseoglou and Paraskevopoulou, 2011; Tiwari and Singh, 2012). High solubility of legume proteins is typically found at low acidic (pH 4–6) and high alkaline (pH 8–9) conditions (Boye et al., 2010). For instance, higher solubility values (61%–96%) have been found for certain legume protein isolates obtained via isoelectric precipitation compared to those via salt extraction (38%–96%) (Karaca et al., 2011). Starch solubility is associated with the swelling power as it increases with elevated granular swelling depending on the amylose content. Starch solubility (leaching of soluble species) also depends on the starch-lipid content and formation of amylose-lipid complexes (Singh, 2011). Higher amylose compacts the starch granules thus restricting their overflow, which causes lower solubility (Wani et al., 2012).

Water- and oil-absorption capacities (WAC, OAC) are defined as the amount of water or oil absorbed per gram of the respective protein material. WAC and OAC values for pulse proteins were reported in the ranges of 0.6 to 4.9 and 1.0 to 3.96 g/g, respectively. These functional properties are dependent on pulse type, variety and method of extraction (Kiosseoglou and Paraskevopoulou, 2011). Water binding capacity (WBC, similar to WAC) of several cereal and tuberous starches decreases with an increase in amylose content (Wootton and Bamunuarachchi, 1978). Therefore, pulse starches that are known for its low amylose content would likely have lower WBC values than cereal grains. However, high WBC values are also possible for pulse starches e.g. 73%–84% for starches of black gram varieties (Kaur et al., 2004).

Interactions between the foods can be binary and ternary (more complex) comprising main food components (starch, proteins and lipids). The interactions between starch and biopolymer mixtures within food systems have been studied extensively (Yang et al., 2004). Tang and Copeland (2007) provide a comprehensive review of the binary starch-lipid interactions in wheat. Efforts have also been made to explore the ternary interactions of protein-starch-lipids (Zhang et al., 2003; Zhang and Hamaker, 2003). It is worth noting that information on protein-starch interactions in foods is scattered throughout the literature and it is only studied with respect to the effect of certain functional (viz. swelling, OAC, WAC, thermal, and rheological) and physico-chemical properties in food systems.

## Protein-Starch Matrix

Study of protein-starch matrix is very important for understanding the various biochemical interactions that occur in foods. Eliasson and Larsson (1993) discussed two possible interactions: proteins interacting with amylose/amylopectin in solution or proteins interacting with the solid starch granule. The latter type of interaction is described elsewhere (Eliasson and Tjerneld, 1990). In this section, we will discuss the protein-starch interaction at a broader level.

Protein-starch interaction is purely electrostatic in nature given the facts that protein bodies are negatively charged and starch granules are positively charged. Takeuchi (1969), Dahle (1971), and Dahle et al. (1975) conducted extensive experiments to unravel the protein-starch interaction in foods. It was found that the protein-starch interaction is pH dependent, with the degree of wheat protein-starch interaction being the highest at pH 6.5 (corresponding to the lowest absorption). Additionally, the interaction of gelatinized wheat starch and protein was much greater at low and neutral pH; heat denaturation and an alkaline pH could further reduce the degree of interaction (Dahle, 1971). The author further reported that sustaining the native structure of proteins is essential for the formation of protein-starch complexes (Dahle et al., 1975). This interaction plays a major role in food products typically obtained via grain processing. For instance, the interaction of starch with gluten proteins determines bread baking performance while staling of bread is also influenced by the degree of protein-starch interaction (Martin et al., 1991; Martin and Hoseney, 1991). The effect of protein-starch interaction on the thermal and rheological properties of food systems has been summarized by Jamilah et al. (2009).

Protein-starch interactions change with the amount of moisture and processing temperature in the initial grain pre-processing. For instance, protein-starch interactions may stimulate an increase in viscosity upon surpassing the starch gelatinization temperature in wheat and maize (Madeka and Kokini, 1992), which was also shown upon protein addition to corn starches by Chedid and Kokini (1992). An inverse relationship was found between the moisture content and the threshold temperature (temperature at which the viscosity increases) as a result of the protein-starch interactions (Madeka and Kokini, 1992). Furthermore, the interaction of amylopectin with gliadin (wheat protein) could lead to a lower threshold temperature than the interaction with zein (maize protein).

Dry and mature endosperm of grain cereals have a matrix of protein bodies fused around the starch granules that also engulf other cellular structures (Shewry and Halford, 2002). The gluten proteins form the same continuous protein matrix, which allows the flour to form a dough and enhances visco-elastic properties to enable the incorporation into fermented, baked, or pasta-based products (Shewry and Halford, 2002). Weaker cross-links between starch and gluten produce less firm bread while greater amylose-protein interactions would enhance the staling process (Martin et al., 1991). The shape and size of starch granules play major roles in bread quality (Kang et al., 2015; Sahlström et al., 1998). Further, the protein-starch interaction may present nutritional advantages. Protein-starch interaction in bread made from white flour has been demonstrated responsible for a decrease in glycemic rate and digestion rate as compared to gluten-free bread or gluten-free bread with gluten added later (Jenkins et al., 1987).

Texture (hardness or softness) of the wheat kernel has been attributed as either the degree (Barlow et al., 1973; Simmonds et al., 1973) or strength (Stenvert and Kingswood, 1977) of adhesion between starch granules and the protein matrix. Positive relationship between the grain hardness and the presence/adsorption of certain proteins on starch granules has been established (Eliasson, 2016). In hard wheats, greater adhesion may also be due to the large amount of water-soluble material of uniform composition among the starch granules surrounded by the protein matrix (Simmonds et al., 1973), which was later revealed to be the presence of protein (fibrillin) on the surface of starch granules (Greenwell and Schofield, 1986).

The functional properties of cereals and pulses depend on the interaction of starch and protein. For instance, tight adhesion of proteins (obtained from the flour of the outer portion of rice kernels) to starch granules inhibits the crystalline and pasting properties of rice, and starch swelling is restricted as a result of the interactions between starch and the protein matrix (Yang and Chang, 1999). Using scanning electron microscopy (SEM), Saleh (2017) found that the rigidity of the closely-bound protein-starch matrix could be attributed to the higher pasting viscosity of rice flour. The behavior of starch changes from linear viscoelastic to nonlinear due to its introduction into gluten protein (Smith et al., 1970).

## Alteration in Protein-Starch Matrix

Processing operations (viz. baking, cooking, dough formation, drying, fermentation, extrusion, milling, thermal processing, etc.) to create food products from pulses and cereal grains affect the protein-starch network. The resultant alteration of protein-starch matrix then changes food properties such as texture, flavor and aroma.

The microstructural changes during dough development and baking processes are highly dependent on the interactions between starch and protein, and to a lesser extent, between other carbohydrates and protein. The interactions between gluten protein and starch lead to phase separation that makes uniform alignment of starch granules in the continuous gluten phase crucial for the closely-packed structure of dough (Eliasson and Larsson, 1993). Dough microstructure is described as a bicontinuous protein-starch system (Eliasson and Larsson, 1993). Regarding the effects of processing steps such as mixing, proofing and reshaping during dough development, Kieffer and Stein (1997) showed how protein and starch segregate during dough reshaping after a rest period. Sadowska et al. (2003) reported the progressive changes (swelling of the starch granule and increased protein content) resulting from the significantly higher protein to starch ratio in pea-flour supplemented dough. The pasta made from soft wheat was found to have a "less extensive protein framework with more diffuse starch particles" (Resmini and Pagani, 1983).

Milling of grain into flour decreases the particle size while increasing the surface area thereby causing microstructural changes. More importantly, as starch damage occurs due to extensive milling of cereal grains and pulses, the effect of milling on the protein-starch matrix is inevitable. Micrography has revealed compactly packed elliptical starch granules within the protein matrix of coarse-ground green gram flour whilst higher starch damage and disentangled aggregates of protein matrix with single, unaggregated starch granules were found in finely-ground flour (Sakhare et al., 2014). Moreover, red gram, green gram, and black gram have elliptical starch granules ingrained in the protein matrix, similar to other well-known legumes except for the shape and size differences of starch granules between legumes (Joseph et al., 1993). During dry milling of barley and likely other cereals and pulses, endosperm cells could be drawn out where starch was embedded within the protein matrix (McAllister et al., 1993). In comparison, wet milling may detach the starch granules from the matrix.

Thermal processing of raw food materials is essential to introduce desirable organoleptic and textural qualities in end-products (e.g. gelatinization of starch caused by thermal treatment can lead to mechanical changes in extrudes). Gelatinization of starch is attributed to water interrupting crystallinity, swelling of granules, amylose leaching from starch granule with intact amylopectin, and eventually the formation of an amylose-matrix gel with disintegrated granule (Remsen and Clark, 1978). During cooking, the protein matrix offers rigidity to the starch granules resulting in enhanced visco-elastic properties (Derycke et al., 2005). Cooking quality of pasta is dependent on the formation of continuous gluten protein network rather than the physio-chemical properties of gelatinized starch (Sung and Stone, 2005). Cooking of rice at 120 °C for a short duration (e.g. 20 minutes) led to starch granules still attached to the protein matrix and adjacent protein areas (Srikaeo et al., 2006). Further cooking caused starch gelatinization and fusing of the molten granules. Disintegration of the surface layers, cells and granules via cooking evokes the change in the interactions between protein bodies and starch granules (Chrastil, 1990). Likewise, the degree of binding of rice protein (oryzenin) to starch proportionally increases the stickiness of rice (as a result of cooking and cooling) (Chrastil, 1990).

Roasting, micronization, hydrothermal treatment and high-temperature drying are commonly used thermal operations, which can induce changes in the microstructure of starch and protein. Roasting of barley resulted in a reduced bulk density due to the potential loss of structural integrity between starch-starch and protein-starch matrices and void (pore) creation in the endosperm (Chandrasekhar and Chattopadhyay, 1990; Sharma and Gujral, 2011). Micronization (infrared heat processing) of barley (hulless and pearled) kernels caused more expansion due to starch gelatinization as shown in the micrographs of hulless barley (Fasina et al., 1999). McAllister and Sultana (2011) also showed that micronization of three wheat varieties (Kansas, Laura, and Sceptre) modified the protein matrix and slowed the *in situ* starch digestion. Micronization-induced changes in the mechanical properties of different types of barley were attributed to starch gelatinization, and alterations in protein-starch and starch-lipid interactions (McAllister and Sultana, 2011). SEM analysis revealed that hydrothermal treatment (parboiling) of rice grain caused the formation of a peripheral thin layer due to the stronger insoluble protein matrix escaping the starch granules (Chandrasekhar and Chattopadhyay, 1990). High temperature-low moisture (HT-LM) drying treatment of raw pasta resulted in a continuous protein network while improving pasta quality (Resmini and Pagani, 1983). This cooking treatment stimulates protein-starch interactions in the outer part and linear or branched fibrils in the central area by creating a coagulated protein network and restricting starch swelling. However, high temperature-high moisture (HT-HM) treatment of raw pasta (made from soft wheat flour) led to expanded volume and restricted protein coagulation and network formation. This resulting pasta was of poor quality with no protein-starch interaction observed.

Extrusion is another common process for grains that utilizes high moisture and high temperature to allow product expansion or puffiness by which breakfast cereals, pasta products and snacks, etc. are produced. Extrusion modifies the structural configuration of food products by which these foods can be enriched with resistant starch through controlled swelling and boiling during cooking (Vaz Patto et al., 2015). A review by Moraru and Kokini (2003) on extrusion of cereal foods revealed the influence of starch in product expansion; protein matrix also affects water distribution and promotes extensive framework formation because of covalent and non-bonding interaction in the extruded product. Protein-starch interactions also prevent molecular starch from degradation as a result of the formation of amylose-protein complex (Matthey and Hanna, 1997). Alkali addition during extrusion promotes higher degrees of protein-protein and protein-starch interactions leading to a cohesive extrudate product (Allen et al., 2007).

## Chemical Imaging

Visual characterization allows illustration of how the presence, and more importantly distribution, of chemical components within grain kernels influence food properties. Additionally, it can illustrate the spatial and structural alteration of the chemical constituents during various processes. With the advances in imaging and microscopy technology, real-time and accurate analyses of the distribution of food components are conceivable. Numerous imaging techniques, such as scanning probe microscopy e.g.

atomic force microscopy (ATF), SEM, scanning tunneling microscopy (STM), and optical/spectral imaging e.g. light microscopy (LM), near-infrared (NIR) spectroscopy, Fourier Transform Infrared (FTIR) spectro-microscopy, hyperspectral imaging (HSI), and X-ray microcomputed tomography ( $\mu$ -CT), have been utilized to study the chemical changes and microstructure of food products. Herein, we focus on the imaging techniques such as SEM, FTIR and NIR spectroscopy, HSI, and X-ray  $\mu$ -CT that have been utilized to understand the allocation and distribution of the protein-starch matrix during processing.

SEM involves a focused beam of electrons to produce images encompassing the topographical and compositional information of the scanned material. This technique allows us to study the microstructure of food products in a way that was previously impossible. For example, a SEM study could show a higher degree of protein-starch interaction and protein matrix continuity in the hard kernels than in soft kernels of barley (Nair et al., 2011). By which, the authors explained why milling of hard barley kernels produced coarse particles compared to soft kernels that produced fine particles (Nair et al., 2011). The strong protein-starch interaction and continuous endosperm protein matrix in hard kernels would require much more energy during milling to release the strongly bound starch particles. In addition, SEM also showed starch granules not connected to the disorganized protein matrix in mature soft wheat kernels as opposed to the mature hard wheat kernels (in which a uniform matrix and stronger adhesion of starch and protein bodies were found) (Turnbull and Rahman, 2002).

Difference in wheat cultivars corresponding to the degree of adhesion between starch and protein matrix has already been reported (Moss et al., 1980). A more homogenous and less porous structure along with a disorganized matrix composed of partially "fused" starch granules and proteins was found in SEM images of puffed wheat, emmer wheat, and barley as compared to rice (Mariotti et al., 2006). Further magnification of SEM images of puffed wheat and barley revealed a non-homogeneous structure with compact matrix in some areas and large cavities elsewhere. In a different study, SEM analysis was able to demonstrate more starch agglomeration in pearl millet flour than finger millet suggesting a greater protein-starch interaction, whereas, FTIR analysis failed to reveal significant differences as similar stretching and bending vibrations were detected for both flours (Gull et al., 2016).

SEM has also been used to explore the structural changes that take place during various unit operations involved in the production of processed food products. Matsuo et al. (1978) used SEM to image each step during the development of spaghetti. Preliminary mixing of the semolina and water resulted in visible starch granules held within the protein matrix. With the dough entering the extrusion auger, protein particles were clearly visible with different shapes (platelets and jagged edges rather than sheet and fibril-form). The pasta exiting the auger still had irregular protein matrix; however, starch particles were aligned along the direction of flow. SEM of freshly extruded spaghetti exhibited starch granules embedded deep within the protein matrix. High-absorption doughs tended to have fibrillar network with smooth protein matrix, whilst low-absorption doughs had jagged network with the outer surface containing pores with starch granules loosely held within a discontinuous protein matrix.

FTIR spectroscopy can show the presence or absence of a functional group in a sample by measuring the absorption of light at different wavelengths. The wavelengths are typically measured in wavenumbers ( $1/\lambda$ , expressed in  $\text{cm}^{-1}$ ) over the range from 4000 to  $400\text{ cm}^{-1}$ . The absorption of the infrared radiation produces a fingerprint region for a particular functional group. FTIR defines the natural chemical variability of *in situ* structures (to elucidate their differences) (Wellner, 2013). The technique is readily utilized to characterize the chemical composition of materials (cereal grains, gels, and vegetables), and the wavenumbers corresponding to the functional groups and their bonding of certain plant components such as starch, protein, fibre, etc. are well understood and documented (Barron and Rouau, 2008; Starr and Paliwal, 2012; Vlădoiu et al., 2017). The presence or dominance of functional groups associated with constitutional components is gleaned by manipulating the spectral data. For example, the distribution or component ratio (such as protein-starch or protein-carbohydrate ratio) within a sample can be obtained by dividing the area (or height) under a functional group band by the area (or height) under another functional group (Yu, 2007; Yu et al., 2004a). Accordingly, the protein to starch ratio for cereal grain (i.e. barley) could be obtained by utilizing the protein (amide I at  $1650\text{ cm}^{-1}$ ) and starch (at  $1025\text{ cm}^{-1}$ ) peaks, which indicates the adhesion between starch and protein matrix (Yu et al., 2004a). Following this method, extensive differences in the absorbance intensities of starch and protein were found between two barley varieties ("Valier" and "Harrington"). A lower ratio of protein absorbance intensity for "Valier" variety suggested a closer association of starch granules with the protein than "Harrington" variety (Yu et al., 2004b).

NIR spectroscopy is a non-invasive method that predicts the chemical composition of a sample through indirect measurements of its optical characteristics based on light absorption in the wavelength range of 750–2500 nm (Jayas et al., 2016). NIR spectra of wheat flour indicated a decrease in free water corresponding to the reduced absorbance of the O–H stretch at 1160 nm (Wesley and Blankeney, 2001). Further explanation of the differences in the interactions of gluten components (glutenin and gliadin) with starch is provided but only with respect to the changes in bound water with temperature.

HSI provides direct identification of different components and their distribution in a sample using a 2-D spatial array of vectors representing the spectrum at each pixel location (ElMasry and Sun, 2010; Erkinbaev et al., 2017). HSI has been utilized for estimating moisture, kernel hardness, pre-germination status, etc. in grains and legumes (Fox and Manley, 2014). HSI of wheat kernels showed clear spectral differences around 1450–1550 nm for starch and protein; relocation of these peaks would demonstrate differences in starch/protein mixture (Arngren et al., 2011). The authors proposed a Bayesian method for spectral analysis of wheat kernel (back and front) to reveal differences in protein-starch matrix, and believed this method was similar or better than other volume constrained methods based on a projected gradient non-negative matrix factorization framework. In another study, NIR-HSI of whole yellow maize showed positive peaks at 1220, 1405, 1690 and 1870 nm resulting from the differences in starch composition for vitreous endosperm signifying tight adhesion (or density) of starch granules and the protein matrix (Manley et al., 2009). Different peaks and thus different interactions occurred in floury endosperm.

X-ray  $\mu$ -CT is a non-destructive and non-invasive technique that takes 3-D sectional images of a cross-section with micrometer pixel sizes based on the differences in absorbance of X-rays by the constituents in a sample. With the advent of benchtop instrumentation,  $\mu$ -CT is becoming extensively popular for characterizing food microstructure (Schoeman et al., 2016). This technique is useful for determining various microstructure properties of starch-based extruded products (average diameter, cell wall thickness, true void fraction, cell number density, etc.) (Horvat et al., 2014; Trater et al., 2005). The effects of different processing methods (milling, parboiling, wet-processing and extrusion) have been shown via  $\mu$ -CT by examining porosity, pore size and mean pore diameters (Mohorič et al., 2009). The information about the cavities and pores allows predicting the milling characteristics (Guelpa et al., 2016). Based on the wealth of microstructural information generated using this technique, one can easily provide in-depth interpretation of the interactions between the building blocks (e.g. protein and starch) in food products.

## Conclusions

The importance of understanding protein-starch interactions in raw and processed grains and pulses has been discussed. These interactions have been studied using a variety of tools and it is established that the interactions are strongly correlated to moisture, pH, kernel hardness, processing operations (such as dough and bread making, pasta formation, etc.), and other functional properties of food products. A number of modern imaging modalities have been used to unravel the structure (and structural alterations due to changes in the aforementioned factors) and so far, SEM has been found to be the best technique to unravel the protein-starch interactions. However, implementation of other promising non-destructive and non-invasive 3-D imaging techniques, especially X-ray  $\mu$ -CT, for studying protein-starch interactions has not gained much attention primarily due to the rigorous analyses required post image acquisition. Further progress in imaging research would require publication of standards and protocols for easy quantification and analyses of 3-D images. These techniques can provide exhaustive characterization of food materials that can assist in the development and formulation of new products and processes to enhance the overall product quality.

## Glossary

**Electrostatic interaction** Electrostatic interactions are the interactions between charged species. Electrostatic interactions between unlike charges are attractive, and repulsive between like charges.

**Head group** In phospholipids, the polar moiety that is attached to the phosphate is referred to as the head group. For example, in phosphatidylcholine and phosphatidylethanolamine, the choline moiety and ethanolamine moiety, respectively are the head groups.

**Hydrophobic interaction** The tendency of nonpolar molecules in a polar solvent (usually water) to interact with one another is called the hydrophobic effect. The interactions between the nonpolar molecules are called hydrophobic interactions. Hydrophobic interactions play an important role in the clustering of amphiphilic lipid molecules such as phospholipids to form bilayers and micelles.

**Integral membrane protein** An integral membrane protein is a protein that is permanently attached to the biological membrane. All transmembrane proteins are integral membrane proteins. In addition, proteins which are permanently associated with the membrane, for example, by a lipid anchor such as glycosylphosphatidylinositol, are also considered as integral membrane proteins. Glycophorin in the erythrocyte membrane, cytochrome oxidase in the mitochondrial membrane are some of the well characterized integral membrane proteins.

**Outer hyperfine splitting ( $2A_{\max}$ )** The spectral width between the first maximum and the last minimum in the ESR spectrum of a nitroxide spin label.

**Peripheral protein** Peripheral membrane proteins are proteins that adhere only temporarily to the biological membrane with which they are associated. These proteins may attach to the membrane by electrostatic interaction with the negatively charged lipids of the membrane, or by interaction with integral membrane proteins. Some peripheral protein may exhibit partial penetration into the hydrophobic interior of the lipid bilayer. Cytochrome c, which binds to cytochrome oxidase in the mitochondrial membranes and myelin basic protein, which binds to negatively charged lipids in membranes and forms a part of the myelin sheath in the spinal cord, are well characterized peripheral proteins.

**Segmental motion** Due to the rotation around the C—C bonds in the hydrocarbon chains of lipid molecules, the chains exhibit lateral movement, which increases as one goes further away from the head group region. This is referred to as segmental motion.

**Transmembrane protein** An integral membrane protein that spans the entire thickness of the membrane at least once. Glycophorin is a classic example of a transmembrane protein that spans the membrane once. Rhodopsin, the transmembrane present in the retinal rods has 7 transmembrane segments.

## Introduction/Overview

Biological membranes are made up of lipids and proteins in nearly comparable quantities by weight. While the lipids are essentially organized in a bilayer format, membrane proteins can be associated with the lipid bilayer in different ways. Peripheral (or extrinsic) proteins are attached to the membrane surface predominantly by electrostatic interactions whereas the driving force for the association of transmembrane (or intrinsic membrane) proteins, which are embedded in the membrane and traverse its thickness, is primarily hydrophobic in nature. Their association with the lipid membrane is primarily driven by the hydrophobic effect. A third category of protein association with membranes involves initial association by either electrostatic attraction or specific recognition of the lipid head group, followed by partial insertion of protein segment(s) into the hydrophobic core of the membrane.

## Spin Labelled Lipids

Since neither membrane proteins nor membrane lipids normally possess paramagnetism, biomembranes do not give rise to an ESR spectrum. This apparent limitation, can be turned into an advantage by attaching stable nitroxide spin labels to membrane lipids or proteins at specific sites. The attached spin label then can act as a probe or reporter and give information about the dynamics of the surrounding environment. The doxyl (4,4'-dimethyl-oxazolidine-*N*-oxyl-) and proxyl (2,2,5,5-tetramethyl-1-pyrrolidinyloxy) groups are the most commonly employed spin labels, and they contain the nitroxide moiety bearing an unpaired electron. In order to probe the environment at different depths of the bilayer lipid membrane, the spin label is attached at different positions of the lipid acyl chains. A host of lipid derivatives bearing these stable free radical probes are commercially available. In addition, a number

**Figure 1** Structures of spin-labelled phospholipids used for investigating lipid-protein interactions by ESR spectroscopy. n-PCSL are phosphatidylcholines spin-labelled on the sn-2 acyl chain at various positions (C-5, C-8, C-10, C-12 and C-14). 14-XXSL are spin-labelled phospholipids bearing different head groups, but the same acyl chain structure, with the nitroxide moiety located on the 14th C-atom of the sn-2 acyl chain. Androstanol spin label (ASL) and cholestane spin label (CSL) are sterol based spin labels. In ASL the hydroxyl group of cholesterol is derivatized to introduce the spin label into the structure, resulting in a loss of the hydrogen bonding capability of the steroid. On the otherhand, in CSL, the 8 carbon tail is replaced by a hydroxy group; hence this molecule is capable of forming H-bonds, but is devoid of the 8-carbon long hydrocarbon tail present in cholesterol. Reprinted from Swamy, M.J., 2004. Interaction of bovine seminal plasma proteins with model membranes and sperm plasma membranes. *Curr. Sci.* 87, 203–211.

of small molecules bearing functional groups that can react with the amino or thiol side chains of proteins are also commercially available for labelling proteins. Structures of selected spin labelled phospholipids are given in [Fig. 1](#). Besides these, spin labelled fatty acids and gangliosides as well as spin labelled lipids bearing other head groups have been used to investigate lipid-protein interactions. For the structures of a variety of such spin labelled lipid probes used in membrane research, the reader is referred to [Marsh \(1982, 2010\)](#).

### ESR Spectrum of the Nitroxide Spin Labels

In the commonly used spin labels, such as those shown in [Fig. 1](#), the nitroxide radical is incorporated into a heterocyclic ring. In such a structure the unpaired electron is predominantly localized on the N–O bond and ESR signal arising from the unpaired electron is split into three lines since the nuclear spin,  $I$  of the nitrogen atom ( $^{14}\text{N}$ ) is unity. If the molecule bearing the nitroxide group is tumbling rapidly in solution then the spectral anisotropy is averaged and three sharp, narrowly spaced lines of nearly comparable width and intensity. However, the extent of averaging is influenced by molecular size, temperature, viscosity of the medium or other

**Figure 2** ESR spectra of 5-PCSL in DMPC membranes in the gel phase at 8 °C (1) and in the liquid crystalline phase at 28 °C (2). The spectral width is 100 G. The spacing between the first maximum and the last minimum is referred to as the outer hyperfine splitting,  $2A_{\text{max}}$ .

parameters that can affect the molecular motion. In general, as motion slows down the spectral lines become broader and appear farther apart from each other. The ESR spectrum of a phosphatidylcholine spin label, bearing the doxyl spin label on the fifth C-atom of the sn-2 acyl chain, incorporated in the gel phase of dimyristoylphosphatidylcholine (DMPC) membranes is shown in Fig. 2 (spectrum 1). The molecular motion is strongly reduced in the lipid gel phase and the spectral lines are broad, with large separation between the outer wings (first maximum and last minimum). In the liquid crystalline phase, increased rotational motion and segmental mobility result in a sharpening of the spectral lines and the spacing between the outer wings of the spectrum is decreased (see Fig. 2, spectrum 2). However, significant anisotropy is still retained in the spectrum, reflecting that although the molecular motion increases when the lipid membrane undergoes gel-liquid crystalline phase transition, the motion is still significantly anisotropic.

## Effect of Membrane Proteins on the ESR Spectra of Spin Labelled Lipids

### Intrinsic Membrane Proteins

The effect of transmembrane proteins on the motional properties of membrane lipids is investigated by ESR spectroscopy employing spin-labelled lipid probes shown in Fig. 1. Most useful information is obtained when such studies are carried out with individual purified and reconstituted proteins incorporated either in lipid extracts obtained from the native membranes or in pure synthetic lipids. An extensively characterized system is that of cytochrome oxidase, and the results obtained with this system are described below to illustrate the type of information that can be obtained in such studies.

Studies employing either 16-doxylstearic acid (Jost et al., 1973) or 14-PCSL (Knowles et al., 1979) as the spin label probe incorporated into reconstituted cytochrome oxidase membranes yielded similar results. The study of Jost et al. (1973) is a seminal work that gave the first evidence for the existence of boundary lipid around transmembrane proteins. However, the studies by Knowles et al. (1979, 1981) provided a more extensive characterization of the system and their results will be discussed below to illustrate the application of spin-label ESR spectroscopy for investigating the interaction between transmembrane proteins and membrane lipids.

Knowles et al. (1979, 1981) employed a variety of phospholipid spin labels bearing the doxyl probe on the 14th C-atom of the sn-2 acyl chain. ESR spectra of 14-PCSL incorporated into cytochrome oxidase reconstituted in dimyristoylphosphatidylcholine (DMPC) membranes of different lipid/protein ratios are shown in Fig. 3. A spectrum of the spin label in pure DMPC membranes is also shown in this figure. All the spectra recorded in lipid/protein complexes could be resolved into two components, an immobilized component and a more mobile, fluid like component. Analysis of the relative proportions of these two components revealed that a constant number of lipid molecules ( $55 \pm 5$ ) per protein are immobilized. This was attributed to a single shell of boundary lipid molecules associated with the protein, which is then surrounded by fluid bilayer. The motional correlation times from the immobilized lipid difference spectrum gave values of  $\geq 50$  ns, suggesting that the rate of exchange between bilayer and boundary lipids is probably at least 1 order of magnitude slower than the rate of lateral diffusion of unperturbed bilayer lipids in pure DMPC membranes.

The preference of transmembrane proteins to interact with different membrane lipids would be expected to be different based on the lipid structure. ESR spectroscopic studies employing spin-labelled phospholipids bearing different head groups provide a sensitive and elegant approach to investigate this. ESR spectra of various spin labelled phospholipids incorporated into DMPC membranes containing reconstituted cytochrome oxidase are shown in Fig. 4A and spectra obtained in pure DMPC membranes are shown in Fig. 4B (Knowles et al., 1981). A careful observation of these spectra reveals that the proportion of the motionally restricted and more mobile components varies with the different spin-label head groups for complexes of the same lipid/protein ratio. Similar proportions of phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylglycerol

**Figure 3** ESR spectra of 14-PCSL spin-label in cytochrome oxidase-DMPC complexes of various lipid/protein ratios at 32 °C. Spectra from all the lipid/protein complexes exhibit two-components; however, in samples with increasing lipid/protein ratio the immobilized component becomes relatively weaker. In some spectra, the immobilized component is highlighted by showing a vertically expanded segment of the outer wings. Adapted with permission from Knowles, P.F., Watts, A., Marsh, D., 1979. Spin-label studies of lipid immobilization in dimyristoylphosphatidylcholine-substituted cytochrome oxidase. *Biochemistry* 18, 4480–4487. Copyright (1979) American Chemical Society.

have been found to have restricted chain motion. On the other hand a distinct preference was seen for cardiolipin (CL) and phosphatidic acid (PA), with the greatest preference being seen for cardiolipin. From an analysis of the relative proportions of the immobilized components seen in their spectra, the selectivity for cardiolipin and phosphatidic acid was expressed as increased relative binding constant:  $K_r^{CL} \sim 5.5$  and  $K_r^{PA} \sim 2$ , respectively (Knowles et al., 1981).

### Peripheral Proteins

A well-studied example of the application of spin label ESR spectroscopy to the study of peripheral protein interaction with membrane lipids is that of cytochrome c. This association is mediated predominantly by electrostatic interaction of the protein with anionic lipids such as phosphatidylglycerol and phosphatidylserine (Görrissen et al., 1986). On the other hand, the major protein of bovine seminal plasma, PDC-109, associates with lipid membranes by a specific association with the head group of the zwitterionic phospholipid, phosphatidylcholine and sphingomyelin (Ramakrishnan et al., 2001). These two examples are discussed in the following sections with the objective of highlighting the application of ESR spectroscopy to the study of such diverse modes of protein association with lipid membranes.

### Interaction of Apocytochrome c With Lipid Membranes

ESR spectra of spin-labelled phosphatidylglycerol (n-PGSL,  $n = 5, 8, 10$  and  $14$ ) incorporated into bovine phosphatidylserine membranes in the absence and in the presence of apocytochrome c are shown in Fig. 5. For all positional isomers of the spin labelled lipid (up to  $n = 10$ ), the spectral lines are broader in the presence of the protein as compared to those obtained in lipid alone and values of the outer hyperfine splitting increase. For 12-PGSL and 14-PGSL, in which the spin label is closer to the terminal methyl group of the acyl chain, the spectra contain two components with one component that is motionally restricted, whereas the other component is more mobile and fluid-like. The two components in the spectrum of 12-PGSL could be resolved by spectral subtractions (see Fig. 6), and the resulting immobilized component had an outer hyperfine splitting ( $2A_{max}$ ) of 56 G. This value is considerably smaller than the value of ca. 60 G observed for the motionally restricted component found with typical integral

**Figure 4** (A) ESR spectra of phospholipids with different head groups spin-labelled on the 14th C-atom of the sn-2 acyl chain, introduced exogenously into separate aliquots taken from the same cytochrome oxidase-dimyristoylphosphatidylcholine complex of lipid/protein ratio 95:1, at  $T = 32^\circ\text{C}$ . Corresponding spectra of the spin labelled phospholipids in DMPC alone are shown in (B). Total scan width = 100 G. Adapted with permission from Knowles, P.F., Watts, A., Marsh, D., 1981. Spin-label studies of head-group specificity in the interaction of phospholipids with yeast cytochrome oxidase. *Biochemistry* 20, 5888–5894. Copyright (1981) American Chemical Society.

membrane proteins (Marsh and Watts, 1982). This observation is consistent with only a partial penetration of the protein segment into the hydrophobic core of the membrane. Further, at low lipid/protein ratios (that is, in the presence of excess lipid), approximately 5 lipids per protein were motionally restricted. This number compares reasonably well with the number of lipids that could be arranged around a cylinder of  $10\text{ \AA}$  diameter that penetrates only half of the bilayer. These dimensions are similar to those of an  $\alpha$ -helix and suggest that most likely a single  $\alpha$ -helical segment of the protein inserts into the lipid membrane.

### Interaction of PDC-109 With Lipid Membranes

As indicated above, association of the major bovine seminal plasma protein, PDC-109 with phospholipid membranes is mediated by a specific binding of the protein with choline phospholipids such as phosphatidylcholine and sphingomyelin. Binding of PDC-109 to sperm plasma membranes results in an efflux of choline phospholipids and cholesterol. This process, referred to as cholesterol efflux, is crucial for priming the sperm cells for fertilizing the egg (reviewed in Swamy, 2004). In view of this, the interaction of this protein with membranes made up of DMPC and DMPC/cholesterol mixtures was investigated in the absence and in the presence of cholesterol by spin-label ESR spectroscopy (Ramakrishnan et al., 2001; Swamy et al., 2002).

ESR spectra of 5-PCSL in DMPC membranes in the absence and in the presence of PDC-109 are shown in Fig. 7A. Plots of the outer hyperfine splittings ( $2A_{\text{max}}$ ) for the two samples are shown in Fig. 7B. The spectra recorded in the absence of protein (dashed lines) exhibit a sharp change in the line shapes and outer hyperfine splittings ( $2A_{\text{max}}$ ) at  $\sim 24^\circ\text{C}$ , resulting from the increase in lipid chain mobility at the chain-melting phase transition. On the other hand, spectra recorded in the presence of PDC-109 (solid lines) show more gradual changes with increase in temperature. Importantly, at all temperatures the  $2A_{\text{max}}$  values obtained in the presence of the protein are higher than those obtained with lipid alone, suggesting that binding of PDC-109 makes the membrane more rigid.

Since PDC-109 was able to induce efflux of lipids from sperm plasma membranes, it was expected that the protein most likely penetrates into the hydrophobic interior of the bilayer membrane. This was probed by employing spin labelled phosphatidylcholines (n-PCSL) and sterol probes (ASL and CSL) shown in Fig. 1. Spectra of these probes obtained at  $28^\circ\text{C}$  in the fluid phase of DMPC host membranes in the absence and in the presence of PDC-109 are shown in Fig. 8A and plots of the  $2A_{\text{max}}$  values obtained as a function of the chain position of the spin label are shown in Fig. 8B. Whereas the ESR spectra of spin-labels near the head group ( $n = 5$  and  $8$ ) are broadened by protein binding, possibly indicating the presence of overlapping components, those that are near

**Figure 5** ESR spectra of phosphatidylglycerol spin-label positional isomers n-PGSL in bovine phosphatidylserine dispersions in the presence and absence of apocytochrome c. The upper spectrum of each pair (+apo) is with a saturating amount of apocytochrome c bound (4:1 w/w added apocytochrome c), and the lower spectrum of each pair is from the lipid alone. Total scan width = 100 G;  $T = 30^\circ\text{C}$ . Adapted with permission from Görrissen, H., Marsh, D., Rietveld, A., de Kruijff, B., 1986. **Figure 9** ESR spectra of different phospholipid spin labels, 14-XXSL, bearing the spin label on the 14th C atom of the sn-2 chain, as well as the cholestane spin label (CSL) and androstanol spin label (ASL), in the fluid phase of DMPC membranes (.....) and of DMPC/PDC-109 (lipid:protein, 1:2 w/w) recombinants (—). Phospholipid spin labels are: 14-PCSL (phosphatidylcholine), 14-PGSL (phosphatidylglycerol), 14-SMSL (sphingomyelin), 14-PESL (phosphatidylethanolamine), 14-PSSL (phosphatidylserine), and 14-NAPESL (N-acyl phosphatidylethanolamine). Spectra were recorded at 28 °C. The spectral width is 100 G. Reprinted from Ramakrishnan, M., Anbazhagan, V., Pratap, T.V., Marsh, D., Swamy, M.J., 2001. Membrane insertion and lipid-protein interactions of bovine seminal plasma protein PDC-109 investigated by spin-label electron spin resonance spectroscopy. *Biophys. J.* 81, 2215–2225. the chain end ( $n = 12$  and  $14$ ) clearly consist of two components. In particular, the spectrum of 14-PCSL closely resembles the spectra obtained with integral transmembrane proteins reconstituted into lipid membranes. The plots in Fig. 8B show that the values of  $2A_{\max}$  obtained for the lipid membranes alone decrease as the spin-label position is shifted down the sn-2 chain of the lipid, reflecting the chain flexibility gradient characteristic of fluid lipid membranes, whereas values of  $2A_{\max}$  for the motionally restricted component remain approximately constant, and are consistently larger than those obtained in pure lipid membranes, throughout the chain. These observations are consistent with a penetration of the protein segments into the membrane interior and their direct interaction with the lipid chains.

ESR spectra of different spin labelled phospholipids (14-XXSL, see Fig. 1) and sterol probes (CSL and ASL) in DMPC host membranes in the absence and in the presence of PDC-109 are shown in Fig. 9. Similar to what is observed with cytochrome oxidase, all spectra obtained in the presence of the protein show two components, a motionally restricted component and a more mobile, fluid-like component. However, analysis of the relative proportions of the two components (obtained by spectral subtraction) revealed that the motionally restricted component is highest for 14-PCSL and 14-SMSL, both of which have the choline moiety in the headgroup. The overall lipid selectivity of PDC-109 was found to be in the following order: phosphatidylcholine  $\approx$  sphingomyelin  $\geq$  phosphatidic acid (pH 6.0)  $>$  phosphatidylglycerol  $\approx$  phosphatidylserine  $\approx$  androstanol  $>$  phosphatidylethanolamine  $\geq$  N-acyl phosphatidylethanolamine  $\gg$  cholestane.

## Conclusions

Spin label ESR spectroscopy is a powerful technique which provided versatile information on protein-lipid interactions in membranes. In this chapter, several examples employing lipid spin labels are discussed which show that this technique can yield valuable information from rather simple and elegant experiments. The major results obtained in the studies discussed include: i) evidence for boundary lipid in the case of transmembrane proteins and the corresponding stoichiometry (i.e. the number of lipids surrounding each protein molecule), ii) lipid selectivity of different membrane proteins (both transmembrane and peripheral), iii)

evidence for partial membrane penetration by peripheral proteins, and iv) evidence for the abolition of lipid chain-melting phase transition by protein binding in specific cases. To get more detailed information about employing spin label ESR spectroscopy for the investigating protein-lipid interactions the reader is referred to the articles listed in the end of the chapter under 'Further Reading'.
